In this paper, we adopt the following methodology for computing term similarity. Our various web crawls, described in Section 6.1, are POS-tagged using Brill's tagger (1995) and chunked using a variant of the Abney chunker (Abney 1991). Terms are NP chunks with some modifiers removed; their contexts (i.e., features) are defined as their rightmost and leftmost stemmed chunks. We weigh each context f using pointwise mutual information (Church and Hanks 1989). Let PMI*(w)* denote a pointwise mutual information vector, constructed for each term as follows: $PMI(w) = (pmi_{w1}, pmi_{w2}, \ldots, pmi_{wm})$, where pmi_{wf} is the pointwise mutual information between term w and feature f:

$$pmi_{wf} = \log \frac{c_{wf} \times N}{\sum_{i=1}^{n} c_{if} \times \sum_{j=1}^{m} c_{wj}}$$

where c_{wf} is the frequency of feature f occurring for term w, n is the number of unique terms and N is the total number of features for all terms.

Term similarities are computed by comparing these *pmi* context vectors using measures such as cosine, Jaccard, and Dice.

3.1 Large-Scale Implementation

Computing the similarity between terms on a large Web crawl is a non-trivial problem, with a worst case cubic running time – $O(n^2m)$ where n is the number of terms and m is the dimensionality of the feature space. Section 2.1 introduces several optimization techniques; below we propose an algorithm for large-scale term similarity computation which calculates *exact* scores for *all* pairs of terms, generalizes to several different metrics, and is scalable to a large crawl of the Web.

Our optimization strategy follows a generalized sparse-matrix multiplication approach (Sarawagi and Kirpal 2004), which is based on the well-known observation that a scalar product of two vectors depends only on the coordinates for which both vectors have non-zero values. Further, we observe that most commonly used similarity scores for feature vectors $\vec{x}$ and $\vec{y}$, such as *cosine* and *Dice*, can be decomposed into three values: one depending only on features of $\vec{x}$, another depending only on features of $\vec{y}$, and the third depending on the features shared both by $\vec{x}$ and $\vec{y}$. More formally, commonly used similarity scores $F(\vec{x},\vec{y})$ can be expressed as:

$$F(\vec{x},\vec{y}) = f_0\left(\sum_i f_1(x_i,y_i), f_2(\vec{x}), f_3(\vec{y})\right)$$

Table 1 defines f_0, f_1, f_2, and f_3 for some common similarity functions. For each of these scores, $f_2 = f_3$. In our work, we compute all of these scores, but report our results using only the *cosine* function.

Let A and B be two matrices of PMI feature vectors. Our task is to compute the similarity between all vectors in A and all vectors in B. In computing the similarity between all pairs of terms, $A = B$.

Figure 1 outlines our algorithm for computing the similarity between all elements of A and B. Efficient computation of the similarity matrix can be achieved by leveraging the fact that $F(\vec{x},\vec{y})$ is determined solely by the features shared by $\vec{x}$ and $\vec{y}$ (i.e., $f_1(0,x) = f_1(x,0) = 0$ for any x) and that most of

the feature vectors are very sparse (i.e., most possible contexts never occur for a given term). In this case, calculating $f_1(x, y)$ is only required when both feature vectors have a shared non-zero feature, significantly reducing the cost of computation. Determining which vectors share a non-zero feature can easily be achieved by first building an inverted index for the features. The computational cost of this algorithm is $\sum N_i^2$, where N_i is the number of vectors that have a non-zero i^{th} coordinate. Its worst case time complexity is $O(ncv)$ where n is the number of terms to be compared, c is the maximum number of non-zero coordinates of any vector, and v is the number of vectors that have a non-zero i^{th} coordinate where i is the coordinate which is non-zero for the most vectors. In other words, the algorithm is efficient only when the density of the coordinates is low. On our datasets, we observed near linear running time in the corpus size.

Bayardo et al. (2007) described a strategy that potentially reduces the cost even further by omitting the coordinates with the highest number of non-zero value. However, their algorithm gives a significant advantage only when we are interested in finding solely the similarity between highly similar terms. In our experiments, we compute the exact similarity between all pairs of terms.

Distributed Implementation

The pseudo-code in Figure 1 assumes that A can fit into memory, which for large A may be impossible. Also, as each element of B is processed independently, running parallel processes for non-intersecting subsets of B makes the processing faster. In this section, we outline our MapReduce implementation of Figure 1 deployed using Hadoop[1], the open-source software package implementing the MapReduce framework and distributed file system. Hadoop has been shown to scale to several thousands of machines, allowing users to write simple "map" and "reduce" code, and to seamlessly manage the sophisticated parallel execution of the code. A good primer on MapReduce programming is in (Dean and Ghemawat 2008).

Our implementation employs the MapReduce model by using the *Map* step to start $M \times N$ *Map* tasks in parallel, each caching $1/M$th part of A as an inverted index and streaming $1/N$th part of B through it. The actual inputs are read by the tasks directly from HDFS (Hadoop Distributed File System). Each part of A is processed N times, and each part of B is processed M times. M is determined by the amount of memory dedicated for the inverted index, and N should be determined by trading off the fact that as N increases, more parallelism can be obtained at the increased cost of building the same inverse index N times.

Input: Two matrices A and B of feature vectors.

```
## Build an inverted index for A (optimiza-
## tion for data sparseness)
AA = an empty hash-table
for i in (1..n):
   F2[i] = f2(A[i]) ## cache values of f2(x)
   for k in non-zero features of A[i]:
      if k not in AA: AA[k] = empty-set
      ## append <vector-id, feature-value>
      ## pairs to the set of non-zero
      ## values for feature k
      AA[k].append( (i,A[i,k]) )
## Process the elements of B
for b in B:
   F1 = {} ## the set of Ai that have non-
        zero similarity with b
   for k in non-zero features of b:
      for i in AA[k]:
         if i not in sim: sim[i] = 0
         F1[i] += f1( AA[k][i], b[k])
   F3 = f3(b)
   for i in sim:
      print i, b, f0( F1[i], F2[i], F3)
```

Output: A matrix containing the similarity between all elements in A and in B.

Figure 1. Similarity computation algorithm.

The similarity algorithm from Figure 1 is run in each task of the *Map* step of a MapReduce job. The *Reduce* step is used to group the output by b_i.

4 Application to Set Expansion

Creating lists of named entities is a critical problem at commercial engines such as Yahoo! and Google. The types of entities to be expanded are often not known a priori, leaving supervised classifiers undesirable. Additionally, list creators typically need the ability to expand sets of varying granularity. Semi-supervised approaches are predominantly adopted since they allow targeted expansions while requiring only small sets of seed entities. State-of-the-art techniques first compute term-term similarities for all available terms and then select candidates for set expansion from amongst the terms most similar to the seeds (Sarmento et al. 2007).

[1] Hadoop, http://lucene.apache.org/hadoop/

Formally, we define our expansion task as:

> **Task Definition**: Given a set of seed entities $S = \{s_1, s_2, ..., s_k\}$ of a class $C = \{s_1, s_2, ..., s_k, ..., s_n\}$ and an unlabeled textual corpus T, find all members of the class C.

For example, consider the class of *Bottled Water Brands*. Given the set of seeds S = {*Volvic*, *San Pellegrino*, *Gerolsteiner Brunnen, Bling* H^2O}, our task is to find all other members of this class, such as {*Agua Vida*, *Apenta, Culligan*, *Dasani*, *Ethos Water*, *Iceland Pure Spring Water*, *Imsdal*, …}

4.1 Set Expansion Algorithm

Our goal is not to propose a new set expansion algorithm, but instead to test the effect of using our Web-scale term similarity matrix (enabled by the algorithm proposed in Section 3) on a state-of-the-art distributional set expansion algorithm, namely (Sarmento et al. 2007).

We consider S as a set of prototypical examples of the underlying entity set. A representation for the meaning of S is computed by building a feature vector consisting of a weighted average of the features of its seed elements $s_1, s_2, ..., s_k$, a centroid. For example, given the seed elements {*Volvic*, *San Pellegrino*, *Gerolsteiner Brunnen, Bling* H^2O}, the resulting centroid consists of (details of the feature extraction protocol are in Section 6.1):

```
brand, mineral water, monitor,
lake, water, take over, …
```

Centroids are represented in the same space as terms allowing us to compute the similarity between centroids and all terms in our corpus. A scored and ranked set for expansion is ultimately generated by sorting all terms according to their similarity to the seed set centroid, and applying a cutoff on either the similarity score or on the total number of retrieved terms. In our reported experiments, we expanded over 22,000 seed sets using our Web similarity model from Section 3.

5 Evaluation Methodology

In this section, we describe our methodology for evaluating Web-scale set expansion.

5.1 Gold Standard Entity Sets

Estimating the quality of a set expansion algorithm requires a random sample from the universe of all entity sets that may ever be expanded, where a set represents some concept such as *Stage Actors*. An approximation of this universe can be extracted from the "*List of*" pages in Wikipedia[2].

Upon inspection of a random sample of the "*List of*" pages, we found that several lists were compositions or joins of concepts, for example "*List of World War II aces from Denmark*" and "*List of people who claimed to be God*". We addressed this issue by constructing a quasi-random sample as follows. We randomly sorted the list of every noun occurring in Wikipedia[2]. Then, for each noun we verified whether or not it existed in a Wikipedia list, and if so we extracted this list. If a noun belonged to multiple lists, the authors chose the list that seemed most appropriate. Although this does not generate a perfect random sample, diversity is ensured by the random selection of nouns and relevancy is ensured by the author adjudication.

The final gold standard consists of 50 sets, including: *classical pianists*, *Spanish provinces*, *Texas counties*, *male tennis players*, *first ladies*, *cocktails*, *bottled water brands*, and *Archbishops of Canterbury*. For each set, we then manually scraped every instance from Wikipedia keeping track also of the listed variants names.

The gold standard is available for download at:

http://www.patrickpantel.com/cgi-bin/Web/Tools/getfile.pl?type=data&id=sse-gold/wikipedia.20071218.goldsets.tgz

The 50 sets consist on average of 208 instances (with a minimum of 11 and a maximum of 1,116) for a total of 10,377 instances.

5.2 Trials

In order to analyze the corpus and seed effects on performance, we created 30 copies of each of the 50 sets and randomly sorted each copy. Then, for each of the 1500 copies, we created a trial for each of the following 23 seed sizes: 1, 2, 5, 10, 20, 30, 40, …, 200. Each trial of seed size s was created by taking the first s entries in each of the 1500 random copies. For sets that contained fewer than 200 items, we only generated trials for seed sizes

[2] In this paper, extractions from Wikipedia are taken from a snapshot of the resource in December 2008.

Table 2. Corpora used to build our expansion models.

CORPORA	UNIQUE SENTENCES (MILLIONS)	TOKENS (MILLIONS)	UNIQUE WORDS (MILLIONS)
Web100	5,201	217,940	542
Web020†	1040	43,588	108
Web004†	208	8,717	22
Wikipedia[6]	30	721	34

†Estimated from *Web100* statistics.

smaller than the set size. The resulting trial dataset consists of 20,220 trials[3].

5.3 Judgments

Set expansion systems consist of an expansion algorithm (such as the one described in Section 4.1) as well as a corpus (such as Wikipedia, a news corpus, or a web crawl). For a given system, each of the 20,220 trials described in the previous section are expanded. In our work, we limited the total number of system expansions, per trial, to 1000.

Before judgment of an expanded set, we first collapse each instance that is a variant of another (determined using the variants in our gold standard) into one single instance (keeping the highest system score)[4]. Then, each expanded instance is judged as *correct* or *incorrect* automatically against the gold standard described in Section 5.1.

5.4 Analysis Metrics

Our experiments in Section 6 consist of precision vs. recall or precision vs. rank curves, where:

a) ***precision*** is defined as the percentage of correct instances in the expansion of a seed set; and

b) ***recall*** is defined as the percentage of non-seed gold standard instances retrieved by the system.

Since the gold standard sets vary significantly in size, we also provide the *R*-precision metric to normalize for set size:

c) ***R-precision*** is defined as the average precision of all trials where precision is taken at rank R = {size of trial's associated gold standard set}, thereby normalizing for set size.

For the above metrics, 95% confidence bounds are computed using the randomly generated samples described in Section 5.2.

6 Experimental Results

Our goal is to study the performance gains on set expansion using our Web-scale term similarity algorithm from Section 3. We present a large empirical study quantifying the importance of corpus and seeds on expansion accuracy.

6.1 Experimental Setup

We extracted statistics to build our model from Section 3 using four different corpora, outlined in Table 2. The *Wikipedia* corpus consists of a snapshot of the *English* articles in December 2008[5]. The *Web100* corpus consists of an extraction from a large crawl of the Web, from Yahoo!, of over 600 million English webpages. For each crawled document, we removed paragraphs containing fewer than 50 tokens (as a rough approximation of the narrative part of a webpage) and then removed all duplicate sentences. The resulting corpus consists of over 200 billion words. The *Web020* corpus is a random sample of $1/5^{th}$ of the sentences in *Web100* whereas *Web004* is a random sample of $1/25^{th}$ of *Web100*.

For each corpus, we tagged and chunked each sentence as described in Section 3. We then computed the similarity between all noun phrase chunks using the model of Section 3.1.

6.2 Quantitative Analysis

Our proposed optimization for term similarity computation produces *exact* scores (unlike randomized techniques) for *all* pairs of terms on a large Web crawl. For our largest corpus, *Web100*, we computed the pairwise similarity between over 500 million words in 50 hours using 200 four-core machines. Web004 is of similar scale to the largest reported randomized technique (Ravichandran et al. 2005). On this scale, we compute the exact similarity matrix in a little over two hours whereas Ravichandran et al. (2005) compute an approximation in 570 hours. On average they only find 73%

[3] Available for download at http://www.patrickpantel.com/cgi-bin/Web/Tools/getfile.pl?type=data&id=sse-gold/wikipedia.20071218.trials.tgz.

[4] Note also that we do not allow seed instances nor their variants to appear in an expansion set.

[5] To avoid biasing our Wikipedia corpus with the test sets, Wikipedia "*List of*" pages were omitted from our statistics as were any page linked to gold standard list members from "List of" pages.

Table 3. Corpora analysis: *R*-precision and *Precision* at various ranks. 95% confidence bounds are all below 0.005†.

CORPORA	R-PREC	PREC@25	PREC@50	PREC@100
Web100	**0.404**	**0.407**	**0.347**	**0.278**
Web020	0.356	0.377	0.319	0.250
Web004	0.264	0.353	0.298	0.239
Wikipedia	0.315	0.372	0.314	0.253

†95% confidence bounds are computed over all trials described in Section 5.2.

of the top-1000 similar terms of a random term whereas we find all of them.

For set expansion, experiments have been run on corpora as large as *Web004* and Wikipedia (Sarmento et al. 2007), a corpora 300 times smaller than our Web crawl. Below, we compare the expansion accuracy of Sarmento et al. (2007) on Wikipedia and our Web crawls.

Figure 2 illustrates the precision and recall tradeoff for our four corpora, with 95% confidence intervals computed over all 20,220 trials described in Section 4.2. Table 3 lists the resulting *R*-precision along with the system precisions at ranks 25, 50, and 100 (see Figure 2 for detailed precision analysis). Why are the *precision* scores so low? Compared with previous work that manually select entity types for expansion, such as *countries* and *companies*, our work is the first to evaluate over a large set of randomly selected entity types. On just the *countries* class, our *R*-Precision was *0.816* using *Web100*.

The following sections analyze the effects of various expansion variables: corpus size, corpus quality, seed size, and seed quality.

6.2.1 Corpus Size and Corpus Quality Effect

Not surprisingly, corpus size and quality have a significant impact on expansion performance. Figure 2 and Table 3 quantify this expectation. On our Web crawl corpora, we observe that the full 200+ billion token crawl (*Web100*) has an average *R*-precision 13% higher than 1/5th of the crawl (*Web020*) and 53% higher than 1/25th of the crawl. Figure 2 also illustrates that throughout the full precision/recall curve, *Web100* significantly outperforms *Web020*, which in turn significantly outperforms *Web004*.

The higher text quality *Wikipedia* corpus, which consists of roughly 60 times fewer tokens than

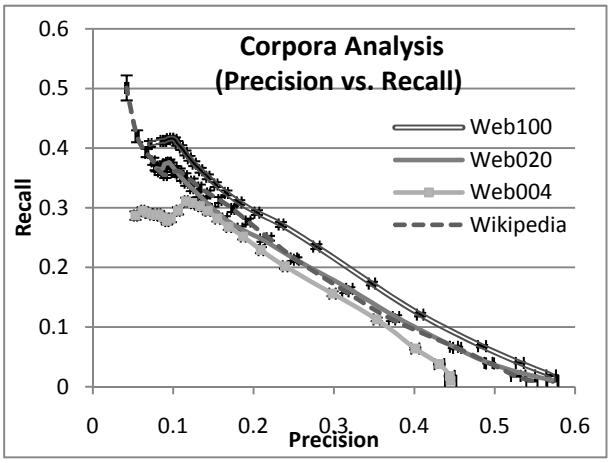

Figure 2. Corpus size and quality improve performance.

Web020, performs nearly as well as *Web020* (see Figure 2). We omitted statistics from Wikipedia "*List of*" pages in order to not bias our evaluation to the test set described in Section 5.1. Inspection of the precision vs. rank graph (omitted for lack of space) revealed that from rank 1 thru 550, *Wikipedia* had the same precision as *Web020*. From rank 550 to 1000, however, *Wikipedia*'s precision dropped off significantly compared with *Web020*, accounting for the fact that the Web corpus contains a higher recall of gold standard instances. The *R*-precision reported in Table 3 shows that this precision drop-off results in a significantly lower *R*-precision for *Wikipedia* compared with *Web020*.

6.2.2 The Effect of Seed Selection

Intuitively, some seeds are better than others. We study the impact of seed selection effect by inspecting the system performance for several randomly selected seed sets of fixed size and we find that ***seed set composition greatly affects performance***. Figure 3 illustrates the precision vs. recall tradeoff on our best performing corpus *Web100* for 30 random seed sets of size 10 for each of our 50 gold standard sets (i.e., 1500 trials were tested.) Each of the trials performed better than the average system performance (the double-lined curve lowest in Figure 3). Distinguishing between the various data series is not important, however important to notice is the very large gap between the precision/recall curves of the best and worst performing random seed sets. On average, the best performing seed sets had 42% higher precision and 39% higher recall than the worst performing seed set. Similar

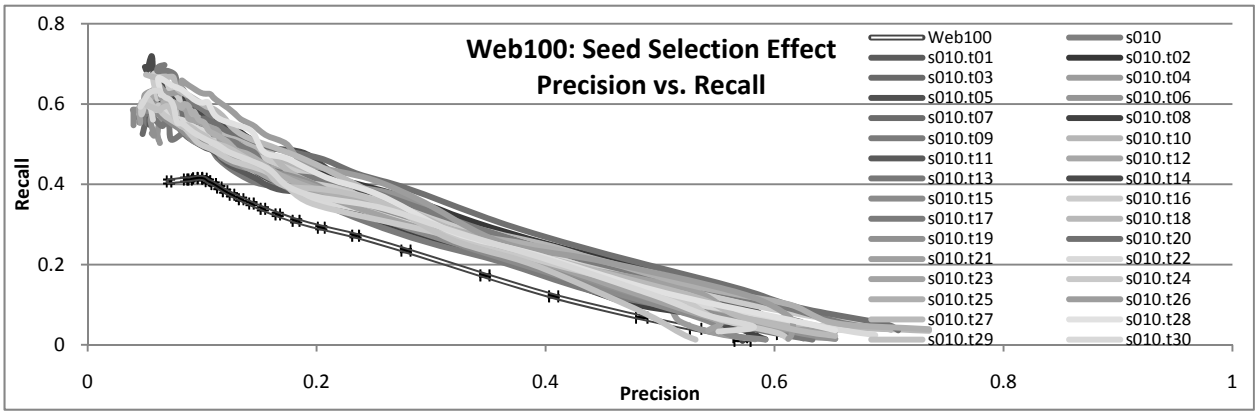

Figure 3. Seed set composition greatly affects system performance (with 30 different seed samples of size 10).

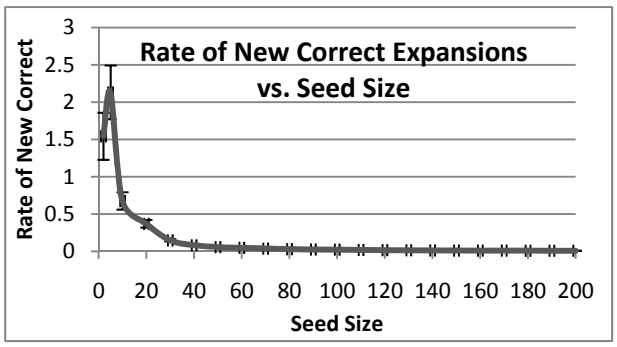

Figure 4. Few new instances are discovered with more than 5-20 seeds on *Web100* (with 95% confidence).

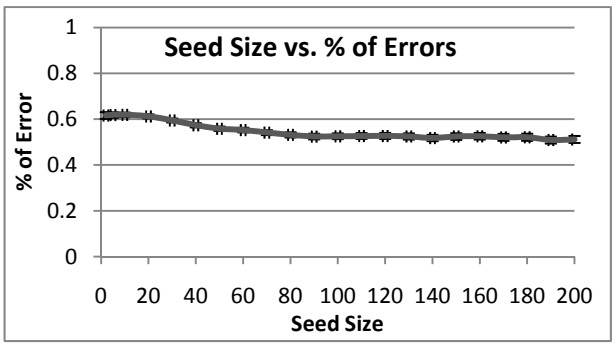

Figure 5. Percentage of errors does not increase as seed size increases on *Web100* (with 95% confidence).

curves were observed for inspected seed sets of size 5, 20, 30, and 40.

Although outside of the scope of this paper, we are currently investigating ways to automatically detect which seed elements are better than others in order to reduce the impact of seed selection effect.

6.2.3 The Effect of Seed Size

Here we aim to confirm, with a large empirical study, the anecdotal claims in (Paşca and Durme 2008) that few seeds are necessary. We found that a) very small seed sets of size 1 or 2 are not sufficient for representing the intended entity set; b) 5-20 seeds yield on average best performance; and c) surprisingly, ***increasing the seed set size beyond 20 or 30 on average does not find any new correct instances***.

We inspected the effect of seed size on *R*-precision over the four corpora. Each seed size curve is computed by averaging the system performance over the 30 random trials of all 50 sets. For each corpus, *R*-precision increased sharply from seed size 1 to 10 and the curve flattened out for seed sizes larger than 20 (figure omitted for lack of space). Error analysis on the *Web100* corpus shows that once our model has seen 10-20 seeds, the distributional similarity model seems to have enough statistics to discover as many new correct instances as it could ever find. Some entities could never be found by the distributional similarity model since they either do not occur or infrequently occur in the corpus or they occur in contexts that vary a great deal from other set elements. Figure 4 illustrates this behavior by plotting for each seed set size the rate of increase in discovery of *new* correct instances (i.e., not found in smaller seed set sizes).

We see that most gold standard instances are discovered with the first 5-10 seeds. After the 30th seed is introduced, no new correct instances are found. An important finding is that the ***error rate does not increase with increased seed set size*** (see Figure 5). This study shows that only few seeds (10-20) yield best performance and that adding more seeds beyond this does not on average affect performance in a positive or negative way.

7 Conclusion

We proposed a highly scalable term similarity algorithm, implemented in the MapReduce framework, and deployed over a 200 billion word crawl of the Web. The pairwise similarity between 500 million terms was computed in 50 hours using 200 quad-core nodes. We evaluated the impact of the large similarity matrix on a set expansion task and found that the Web similarity matrix gave a large performance boost over a state-of-the-art expansion algorithm using Wikipedia. Finally, we release to the community a testbed for experimentally analyzing automatic set expansion, which includes a large collection of nearly random entity sets extracted from Wikipedia and over 22,000 randomly sampled seed expansion trials.

Abstract

Many algorithms extract terms from text together with some kind of taxonomic classification (is-a) link. However, the general approaches used today, and specifically the methods of evaluating results, exhibit serious shortcomings. Harvesting without focusing on a specific conceptual area may deliver large numbers of terms, but they are scattered over an immense concept space, making Recall judgments impossible. Regarding Precision, simply judging the correctness of terms and their individual classification links may provide high scores, but this doesn't help with the eventual assembly of terms into a single coherent taxonomy. Furthermore, since there is no correct and complete gold standard to measure against, most work invents some ad hoc evaluation measure. We present an algorithm that is more precise and complete than previous ones for identifying from web text just those concepts 'below' a given seed term. Comparing the results to WordNet, we find that the algorithm misses terms, but also that it learns many new terms not in WordNet, and that it classifies them in ways acceptable to humans but different from WordNet.

1 Collecting Information with Care

Over the past few years, many algorithms have been published on automatically harvesting terms and their conceptual types from the web and/or other large corpora (Etzioni et al., 2005; Pasca, 2007; Banko et al., 2007; Yi and Niblack, 2005; Snow et al., 2005). But several basic problems limit the eventual utility of the results.

First, there is no standard collection of facts against which results can be measured. As we show in this paper, WordNet (Fellbaum, 1998), the most obvious contender because of its size and popularity, is deficient in various ways: it is neither complete nor is its taxonomic structure inarguably perfect. As a result, alternative ad hoc measures are invented that are not comparable. Second, simply harvesting facts about an entity without regard to its actual subsequent organization inflates Recall and Precision evaluation scores: while it is correct that a *jaguar* is a *animal, mammal, toy, sports-team, car-make*, and *operating-system*, this information doesn't help to create a taxonomy that, for example, places *mammal* and *animal* closer to one another than to some of the others. ((Snow et al., 2005) is an exception to this.) As a result, this work may give a misleading sense of progress. Third, entities are of different formal types, and their taxonomic treatment is consequently different: some are at the level of instances (e.g., *Michelangelo was a painter*) and some at the level of concepts (e.g., *a painter is a human*).

The goal of our research is to learn terms for entities (objects) and their taxonomic organization simultaneously, from text. Our method is to use a single surface-level pattern with several open positions. Filling them in different ways harvests different kinds of information, and/or confirms this information. We evaluate in two ways: against WordNet, since that is a commonly available and popular resource, and also by asking humans to judge the results since WordNet is neither complete nor exhaustively taxonomized.

In this paper, we describe experiments with two rich and common portions of an entity taxonomy: Animals and People. The claim of this paper is: *It is possible to learn terms automatically to populate a targeted portion of a taxonomy (such as below An-*

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 948–957,
Singapore, 6-7 August 2009.

imals or People) both at high precision compared to WordNet and including additional correct ones as well. We would like to also report on Recall relative to WordNet, but given the problems described in Section 4, this turns out to be much harder than would seem.

First, we need to define some basic terminology:
term: An English word (for our current purposes, a noun or a proper name).
seed term: A word we use to initiate the algorithm.
concept: An item in the classification taxonomy we are building. A concept may correspond to several terms (singular form, plural form, the term's synonyms, etc.).
root concept: A concept at a fairly general (high) level in the taxonomy, to which many others are eventually learned to be subtypes/instances of.
basic-level concept: A concept at the 'basic level', corresponding approximately to the Basic Level categories defined in Prototype Theory in Psychology (Rosch, 1978). For our purposes, a concept corresponding to the (proto)typical level of generality of its type; that is, a *dog*, not a *mammal* or a *dachshund*; a *singer*, not a *human* or an *opera diva*.
instance: An item in the classification taxonomy that is more specific than a concept; only one example of the instance exists in 'the real world' at any time. For example, *Michelangelo* is an instance, as well as *Mazda Miata with license plate 3HCY687*, while *Mazda Miata* is not.
classification link: We use a single relation, that, depending on its arguments, is either *is a type of* (when both arguments are concepts), or *is an instance of* or *is an example of* (when the first argument is an instance/example of the second).

Section 2 describes our method for harvesting; Section 3 discusses related work; and Section 4 describes the experiments and the results.

2 Term and Relation Extraction using the Doubly-Anchored Pattern

Our goal is to develop a technique that automatically 'fills in' the concept space in the taxonomy below any root concept, by harvesting terms through repeated web queries. We perform this in two alternating stages.

Stage 1: Basic-level/Instance concept collection: We use the Doubly-Anchored Pattern DAP developed in (Kozareva et al., 2008):

DAP: *[SeedTerm1] such as [SeedTerm2] and <X>*

which learns a list of basic-level concepts or instances (depending on whether SeedTerm2 expresses a basic-level concept or an instance).[1] DAP is very reliable because it is instantiated with examples at both 'ends' of the space to be filled (the higher-level (root) concept SeedTerm1 and a basic-level term or instance (SeedTerm2)), which mutually disambiguate each other. For example, "presidents" for SeedTerm1 can refer to the leader of a country, corporation, or university, and "Ford" for SeedTerm2 can refer to a car company, an automobile pioneer, or a U.S. president. But when the two terms co-occur in a text that matches the pattern *"Presidents such as Ford and <X>"*, the text will almost certainly refer to country presidents.

The first stage involves a series of repeated replacements of SeedTerm2 by newly-learned terms in order to generate even more seed terms. That is, each new basic-level concept or instance is rotated into the pattern (becoming a new SeedTerm2) in a bootstrapping cycle that Kozareva et al. called *reckless bootstrapping*. This procedure is implemented as exhaustive breadth-first search, and iterates until no new terms are harvested. The harvested terms are incorporated in a *Hyponym Pattern Linkage Graph (HPLG)* $G = (V, E)$, where each vertex $v \in V$ is a candidate term and each edge $(u, v) \in E$ indicates that term v was generated by term u. A term u is ranked by *Out-Degree(u)* = $\frac{\sum_{\forall (u,v) \in E} w(u,v)}{|V|-1}$, which represents the weighted sum of u's outgoing edges normalized by the total number of other nodes in the graph. Intuitively, a term ranks highly if it is frequently discovering many different terms during the reckless bootstrapping cycle. This method is very productive, harvesting a constant stream of new terms for basic-level concepts or instances when the taxonomy below the initial root concept SeedTerm1 is extensive (such as for Animals or People).

[1] Strictly speaking, our lowest-level concepts can be instances, basic-level concepts, or concepts below the basic level (e.g., *dachsund*). But for the sake of simplicity we will refer to our lowest-level terms as basic-level concepts and instances.

Stage 2: Intermediate level concept collection: Going beyond (Kozareva et al., 2008), we next apply the Doubly-Anchored Pattern in the 'backward' direction (DAP^{-1}), for any two seed terms representing basic-level concepts or instances:

DAP^{-1}: *<X> such as [SeedTerm1] and [SeedTerm2]*

which harvests a set of concepts, most of them intermediate between the basic level or instance and the initial higher-level seed.

This second stage (DAP^{-1}) has not yet been described in the literature. It proceeds analogously. For pairs of basic-level concepts or instances below the root concept that were found during the first stage, we instantiate DAP^{-1} and issue a new web query. For example, if the term "cats" was harvested by DAP in *"Animals such as dogs and <X>"*, then the pair $< dogs, cats >$ forms the new Web query *"<X> such as dogs and cats"*. We extract up to 2 consecutive nouns from the *<X>* position.

This procedure yields a large number of discovered concepts, but they cannot all be used for further bootstrapping. In addition to practical limitations (such as limits on web querying), many of them are too general–more general than the initial root concept–and could derail the bootstrapping process by introducing terms that stray every further away from the initial root concept. We therefore rank the harvested terms based on the likelihood that they will be productive if they are expanded in the next cycle. Ranking is based on two criteria: (1) the concept should be prolific (i.e., produce many lower-level concepts) in order to keep the bootstrapping process energized, and (2) the concept should be subordinate to the root concept, so that the process stays within the targeted part of the search space.

To perform ranking, we incorporate both the harvested concepts and the basic-level/instance pairs into a *Hypernym Relation Graph (HRG)*, which we define as a bipartite graph $HRG = (V, E)$ with two types of vertices. One set of vertices represents the concepts *(the category vertices (V_c)*, and a second set of vertices represents the basic-level/instance pairs that produced the concepts (*the member pair vertices (V_{mp})*). We create an edge $e(u, v) \in E$ between $u \in V_c$ and $v \in V_{mp}$ when the concept represented by u was harvested by the basic-level/instance pair represented by v, with the weight of the edge defined as the number of times that the lower pair found the concept on the web.

We use the Hypernym Relation Graph to rank the intermediate concepts based on each node's *In-Degree*, which is the sum of the weights on the node's incoming edges. Formally, *In-Degree(u)* = $\sum_{\forall(u,v)\in E} w(u, v)$. Intuitively, a concept will be ranked highly if it was harvested by many different combinations of basic-level/instance terms.

However, this scoring function does not determine whether a concept is more or less general than the initial root concept. For example, when harvesting animal categories, the system may learn the word *"species"*, which is a very common term associated with animals, but also applies to non-animals such as plants. To prevent the inclusion of overgeneral terms and constrain the search to remain 'below' the root concept, we apply a *Concept Positioning Test (CPT)*: We issue the following two web queries:

(a) *Concept such as RootConcept and <X>*
(b) *RootConcept such as Concept and <X>*

If (b) returns more web hits than (a), then the concept passes the test, otherwise it fails. The first (most highly ranked) concept that passes CPT becomes the new seed concept for the next bootstrapping cycle. In principle, we could use all the concepts that pass the CPT for bootstrapping[2]. However, for practical reasons (primarily limitations on web querying), we run the algorithm for 10 iterations.

3 Related Work

Many algorithms have been developed to automatically acquire semantic class members using a variety of techniques, including co-occurrence statistics (Riloff and Shepherd, 1997; Roark and Charniak, 1998), syntactic dependencies (Pantel and Ravichandran, 2004), and lexico-syntactic patterns (Riloff and Jones, 1999; Fleischman and Hovy, 2002; Thelen and Riloff, 2002).

The work most closely related to ours is that of (Hearst, 1992) who introduced the idea of applying *hyponym patterns* to text, which explicitly identify a hyponym relation between two terms (e.g.,

[2]The number of ranked concepts that pass CPT changes in each iteration. Also, the wildcard * is important for counts, as can be verified with a quick experiment using Google.

"such authors as <X>"). In recent years, several researchers have followed up on this idea using the web as a corpus. (Pasca, 2004) applies lexico-syntactic hyponym patterns to the Web and use the contexts around them for learning. KnowItAll (Etzioni et al., 2005) applies the hyponym patterns to extract instances from the Web and ranks them by relevance using mutual information. (Kozareva et al., 2008) introduced a bootstrapping scheme using the doubly-anchored pattern (DAP) that is guided through graph ranking. This approach reported a significant improvement from 5% to 18% over approaches using singly-anchored patterns like those of (Pasca, 2004) and (Etzioni et al., 2005).

(Snow et al., 2005) describe a dependency path based approach that generates a large number of weak hypernym patterns using pairs of noun phrases present in WordNet. They build a classifier using the different hypernym patterns and find among the highest precision patterns those of (Hearst, 1992). Snow et al. report performance of 85% precision at 10% recall and 25% precision at 30% recall for 5300 hand-tagged noun phrase pairs. (McNamee et al., 2008) use the technique of (Snow et al., 2005) to harvest the hypernyms of the proper names. The average precision on 75 automatically detected categories is 53%. The discovered hypernyms were intergrated in a Question Answering system which showed an improvement of 9% when evaluated on a TREC Question Answering data set.

Recently, (Ritter et al., 2009) reported hypernym learning using (Hearst, 1992) patterns and manually tagged common and proper nouns. All hypernym candidates matching the pattern are acquired, and the candidate terms are ranked by mutual information. However, they evaluate the performance of their hypernym algorithm by considering only the top 5 hypernyms given a basic-level concept or instance. They report 100% precision at 18% recall, and 66% precision at 72% recall, considering only the top-5 list. Necessarily, using all the results returned will result in lower precision scores. In contrast to their approach, our aim is to first acquire automatically with minimal supervision the basic-level concepts for given root concept. Thus, we almost entirely eliminate the need for humans to provide hyponym seeds. Second, we evaluate the performance of our approach not by measuring the top-ranked 5 hypernyms given a basic-level concept, but considering all harvested hypernyms of the concept.

Unlike (Etzioni et al., 2005), (Pasca, 2007) and (Snow et al., 2005), we learn both instances and concepts simultaneously.

Some researchers have also worked on reorganizing, augmenting, or extending semantic concepts that already exist in manually built resources such as WordNet (Widdows and Dorow, 2002; Snow et al., 2005) or Wikipedia (Ponzetto and Strube, 2007). Work in automated ontology construction has created lexical hierarchies (Caraballo, 1999; Cimiano and Volker, 2005; Mann, 2002), and learned semantic relations such as meronymy (Berland and Charniak, 1999; Girju et al., 2003).

4 Evaluation

The root concepts discussed in this paper are Animals and People, because they head large taxonomic structures that are well-represented in WordNet. Throughout these experiments, we used as the initial SeedTerm2 *lions* for Animals and *Madonna* for People (by specifically choosing a proper name for People we force harvesting down to the level of individual instances). To collect data, we submitted the DAP patterns as web queries to Google, retrieved the top 1000 web snippets per query, and kept only the unique ones. In total, we collected 1.1 GB of snippets for Animals and 1.5 GB for People. The algorithm was allowed to run for 10 iterations.

The algorithm learns a staggering variety of terms that is much more diverse than we had anticipated. In addition to many basic-level concepts or instances, such as *dog* and *Madonna* respectively, and many intermediate concepts, such as *mammals*, *pets*, and *predators*, it also harvested categories that clearly seemed useful, such as *laboratory animals*, *forest dwellers*, and *endangered species*. Many other harvested terms were more difficult to judge, including *bait*, *allergens*, *seafood*, *vectors*, *protein*, and *pests*. While these terms have an obvious relationship to Animals, we have to determine whether they are legitimate and valuable subconcepts of Animals.

A second issue involves relative terms that are hard to define in an absolute sense, such as *native animals* and *large mammals*.

A complete evaluation should answer the following three questions:

- Precision: What is the correctness of the harvested concepts? (How many of them are simply wrong, given the root concept?)
- Recall: What is the coverage of the harvested concepts? (How many are missing, below a given root concept?)
- How correct is the taxonomic structure learned?

Given the number and variety of terms obtained, we initially decided that an automatic evaluation against existing resources (such as WordNet or something similar) would be inadequate because they do not contain many of our harvested terms, even though many of these terms are clearly sensible and potentially valuable. Indeed, the whole point of our work is to learn concepts and taxonomies that go above and beyond what is currently available.

However, it is necessary to compare with *some*thing, and it is important not to skirt the issue by conducting evaluations that measure subsets of results, or that perhaps may mislead. We therefore decided to compare our results against WordNet *and* to have human annotators judge as many results as we could afford (to obtain a measure of Precision and the legitimate extensions beyond WordNet).

Unfortunately, it proved impossible to measure Recall against WordNet, because this requires ascertaining the number of synsets in WordNet between the root and its basic-level categories. This requires human judgment, which we could not afford. We plan to address this question in future work. Also, assessing the correctness of the learned taxonomy structure requires the manual assessment of each classification link proposed by the system that is not already in WordNet, a task also beyond our budget to complete in full. Some results—for just basic-level terms and intermediate concepts, but not among intermediate-level concepts–are shown in Section 4.3.

We provide Precision scores using the following measures, where *terms* refers to the harvested terms:

$$Pr_{WN} = \frac{\#terms\ found\ in\ WordNet}{\#terms\ harvested\ by\ system}$$

$$Pr_{H} = \frac{\#terms\ judged\ correct\ by\ human}{\#terms\ harvested\ by\ system}$$

$$NotInWN = \#terms\ judged\ correct\ by\ human\ but\ not\ in\ WordNet$$

We conducted three sets of experiments. **Experiment 1** evaluates the results of using DAP to learn basic-level concepts for Animals and instances for People. **Experiment 2** evaluates the results of using DAP^{-1} to harvest intermediate concepts between each root concept and its basic-level concepts or instances. **Experiment 3** evaluates the taxonomy structure that is produced via the links between the instances and intermediate concepts.

4.1 Experiment 1: Basic-Level Concepts and Instances

In this section we discuss the results of harvesting the basic-level Animal concepts and People instances. The bootstrapping algorithm ranks the harvested terms by their *Out-Degree* score and considers as correct only those with *Out-Degree* > 0. In ten iterations, the bootstrapping algorithm produced 913 Animal basic-level concepts and $1,344$ People instances that passed this *Out-Degree* criterion.

4.1.1 Human Evaluation

The harvested terms were labeled by human judges as either correct or incorrect with respect to the root concept. Table 1 shows the Precision of the top-ranked N terms, with N shown in increments of 100. Overall, the Animal terms yielded 71% (649/913) Precision and the People terms yielded 95% Precision (1,271/1,344). Figure 1 shows that higher-ranked Animal terms are more accurate than lower-ranked terms, which indicates that the scoring function did its job. For People terms, accuracy was very high throughout the ranked list. Overall, these results show that the bootstrapping algorithm generates a large number of correct instances of high quality.

4.1.2 WordNet Evaluation

Table 1 shows a comparison of the harvested terms against the terms present in WordNet. Note that the Precision measured against WordNet (Pr_{WN}) for People is dramatically different from the Precision based on human judgments (Pr_H). This can be explained by looking at the *NotInWN* column, which shows that 48 correct Animal terms

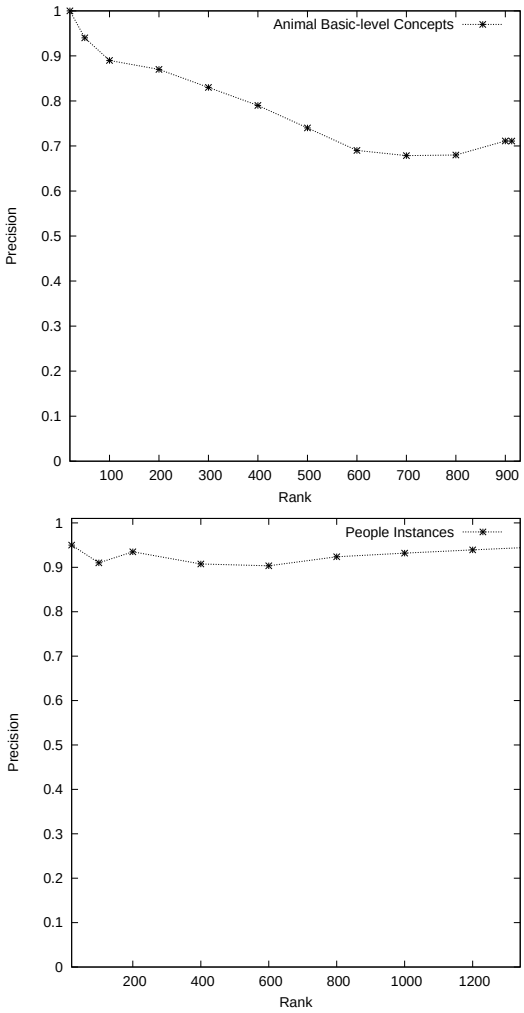

Figure 1: *Ranked Basic-Concepts and Instances.*

and 986 correct People instances are not present in WordNet (primarily, for people, because WordNet contains relatively few proper names). These results show that there is substantial room for improvement in WordNet's coverage of these categories. For Animals, the precision measured against WordNet is actually higher than the precision measured by human judges, which may indicate that the judges failed to recognize some correct animal terms.

	Pr_{WN}	Pr_H	$NotInWN$
Animal	.79	.71	48
People	.23	.95	986

Table 1: *Instance Evaluation.*

4.1.3 Evaluation against Prior Work

To assess how well our algorithm compares with previous semantic class learning methods, we compared our results to those of (Kozareva et al., 2008). Our work was inspired by that approach–in fact, we use that previous algorithm as the first step of our bootstrapping process. The novelty of our approach is the insertion of an additional bootstrapping stage that iteratively learns new intermediate concepts using DAP^{-1} and the Concept Positioning Test, followed by the subsequent use of the newly learned intermediate concepts in DAP to expand the search space beyond the original root concept. This leads to the discovery of additional basic-level terms or instances, which are then recycled in turn to discover new intermediate concepts, and so on.

Consequently, we can compare the results produced by the first iteration of our algorithm (before intermediate concepts are learned) to those of (Kozareva et al., 2008) for the Animal and People categories, and then compare again after 10 bootstrapping iterations of intermediate concept learning. Figure 2 shows the number of harvested concepts for Animals and People after each bootstrapping iteration. Bootstrapping with intermediate concepts produces nearly 5 times as many basic-level concepts and instances than (Kozareva et al., 2008) obtain, while maintaining similar levels of precision.

The intermediate concepts help so much because they steer the learning process into new (yet still correct) regions of the search space after each iteration. For instance, in the first iteration, the pattern *"animals such as lions and *"* harvests about 350 basic-level concepts, but only animals that are mentioned in conjunction with lions are learned. Of these, animals typically quite different from lions, such as grass-eating kudu, are often not discovered.

However, in the second iteration, the intermediate concept Herbivore is chosen for expansion. The pattern *"herbivore such as antelope and *"* discovers many additional animals, including *kudu*, that co-occur with *antelope* but do not co-occur with *lions*.

Table 2 shows examples of the 10 top-ranked basic-level concepts and instances that were learned for 3 randomly-selected intermediate Animal and People concepts (*IConcepts*) that were acquired during bootstrapping. In the next section, we present an

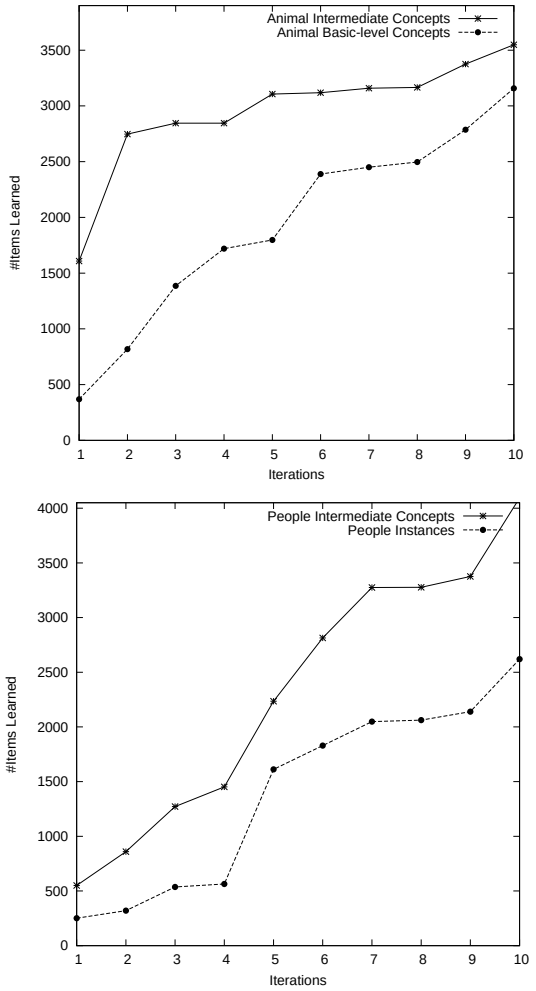

Figure 2: *Learning Curves.*

evaluation of the intermediate concept terms.

4.2 Experiment 2: Intermediate Concepts

In this section we discuss the results of harvesting the intermediate-level concepts. Given the variety of the harvested results, manual judgment of correctness required an in-depth human annotation study. We also compare our harvested results against the concept terms in WordNet.

4.2.1 Human Evaluation

We hired 4 annotators (undergraduates at a different institution) to judge the correctness of the intermediate concepts. We created detailed annotation guidelines that define 14 annotation labels for each of the Animal and People classes, as shown in Table 3. The labels are clustered into 4 major types: *Correct*, *Borderline*, *BasicConcept, and NotConcept*. The details of our annotation guidelines, the reasons for the intermediate labels, and the annotation study can be found in (Kozareva et al., 2009).

PEOPLE	
IConcept	*Instances*
Dictators:	Adolf Hitler, Joseph Stalin, Benito Mussolini, Lenin, Fidel Castro, Idi Amin, Slobodan Milosevic, Hugo Chavez, Mao Zedong, Saddam Hussein

Table 3: *Intermediate Concept Annotation Labels*

We measured pairwise inter-annotator agreement across the four labels using the Fleiss kappa (Fleiss, 1971). The κ scores ranged from 0.61–0.71 for Animals (average κ=0.66) and from 0.51–0.70 for People (average κ=0.60). These agreement scores seemed good enough to warrant using these human judgments to estimate the accuracy of the algorithm.

The bootstrapping algorithm harvested $3,549$ Animal and $4,094$ People intermediate concepts in ten iterations. After *In-Degree* ranking was applied,

we chose a random sample of intermediate concepts with frequency over 1, which was given to four human judges for annotation. Table 4 summarizes the labels assigned by the four annotators (A_1 – A_4). The top portion of Table 4 shows the results for all the intermediate concepts (437 Animal terms and 296 People terms), and the bottom portion shows the results only for the concepts that passed the Concept Positioning Test (187 Animal terms and 139 People terms). Accuracy is computed in two ways: **Acc1** is the percent of intermediate concepts labeled as *Correct*; **Acc2** is the percent of intermediate concepts labeled as either *Correct* or *Borderline*.

Without the CPT, accuracies range from 53–66% for Animals and 75–85% for People. After applying the CPT, the accuracies increase to 71–84% for animals and 82–94% for people. These results confirm that the Concept Positioning Test is effective at removing many of the undesirable terms. Overall, these results demonstrate that our algorithm produced many high-quality intermediate concepts, with good precision.

Figure 3 shows accuracy curves based on the rankings of the intermediate concepts (based on In-Degree scores). The CPT clearly improves accuracy even among the most highly ranked concepts. For example, the **Acc1** curves for animals show that nearly 90% of the top 100 intermediate concepts were correct after applying the CPT, whereas only 70% of the top 100 intermediate concepts were correct before. However, the CPT also eliminates many desirable terms. For People, the accuracies are still relatively high even without the CPT, and a much larger set of intermediate concepts is learned.

Table 4: *Human Intermediate Concept Evaluation.*

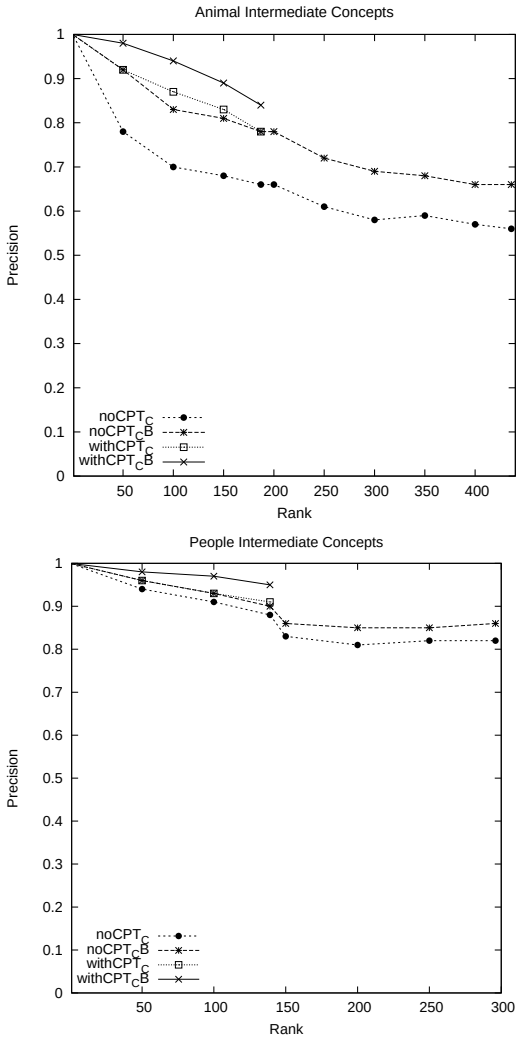

Figure 3: *Intermediate Concept Precision at Rank N.*

4.2.2 WordNet Evaluation

We also compared the intermediate concepts harvested by the algorithm to the contents of WordNet. The results are shown in Table 5. WordNet contains 20% of the Animal concepts and 51% of the People concepts learned by our algorithm, which confirms that many of these concepts were considered to be valuable taxonomic terms by the WordNet developers. However, our human annotators judged 57% of the Animal and 84% of the People concepts to be correct, which suggests that our algorithm generates a substantial number of additional concepts that could be used to enrich taxonomic structure in WordNet.

	Pr_{WN}	Pr_H	NotInWN
Animal	.20 (88/437)	.57 (248/437)	204
People	.51 (152/296)	.85 (251/296)	108

Table 5: *WordNet Intermediate Concept Evaluation.*

4.3 Experiment 3: Taxonomic Links

In this section we evaluate the classification (taxonomy) that is learned by evaluating the links between the intermediate concepts and the basic-level concept/instance terms. That is, when our algorithm claims that *isa(X,Y)*, how often is *X* truly a subconcept of *Y*? For example, *isa(goat, herbivore)* would be correct, but *isa(goat, bird)* would not. Again, since WordNet does not contain all the harvested concepts, we conduct both a manual evaluation and a comparison against WordNet.

4.3.1 Manual and WordNet Evaluations

Creating and evaluating the full taxonomic structure between the root and the basic-level or instance terms is future work. Here we evaluate simply the accuracy of the taxonomic links between basic-level concepts/instances and intermediate concepts as harvested, but not between intermediate concepts. For each pair, we extracted all harvested links and determined whether the same links appear in WordNet. The links were also given to human judges. Table 6 shows the results.

ISA	Pr_{WN}	Pr_H	NotInWN
Animal	.47(912/1940)	.88 (1716/1940)	804
People	.23 (318/908)	.94 (857/908)	539

Table 6: *WordNet Taxonomic Evaluation.*

The results show that WordNet lacks nearly half of the taxonomic relations that were generated by the algorithm: 804 Animal and 539 People links.

5 Conclusion

We describe a novel extension to the DAP approach for discovering basic-level concepts or instances and their superconcepts given an initial root concept. By appropriate filling of different positions in DAP, the algorithm alternates between 'downward' and 'upward' learning. A key resulting benefit is that each new intermediate-level term acquired restarts harvesting in a new region of the concept space, which allows previously unseen concepts to be discovered with each bootstrapping cycle.

We also introduce the *Concept Positioning Test*, which serves to confirm that a harvested concept falls into the desired part of the search space relative to either a superordinate or subordinate concept in the growing taxonomy, before it is selected for further harvesting using the DAP.

These algorithms can augment other term harvesting algorithms recently reported. But in order to compare different algorithms, it is important to compare results to a standard. WordNet is our best candidate at present. But WordNet is incomplete. Our results include a significantly large number of instances of People (which WordNet does not claim to cover), a number comparable to the results of (Etzioni et al., 2005; Pasca, 2007; Ritter et al., 2009). Rather surprisingly, our results also include a large number of basic-level and intermediate concepts for Animals that are not present in WordNet, a category WordNet is actually fairly complete about. These numbers show clearly that it is important to conduct manual evaluation of term harvesting algorithms in addition to comparing to a standard resource.

Abstract

Machine learning offers a range of tools for training systems from data, but these methods are only as good as the underlying representation. This paper proposes to acquire representations for machine learning by reading text written to accommodate human learning. We propose a novel form of semantic analysis called *reading to learn*, where the goal is to obtain a high-level semantic abstract of multiple documents in a representation that facilitates learning. We obtain this abstract through a generative model that requires no labeled data, instead leveraging repetition across multiple documents. The semantic abstract is converted into a transformed feature space for learning, resulting in improved generalization on a relational learning task.

1 Introduction

Machine learning offers a range of powerful tools for training systems to act in complex environments, but these methods depend on a well-chosen representation for features. For learning to succeed the representation often must be crafted with knowledge about the application domain. This poses a bottleneck, requiring expertise in both machine learning and the application domain. However, domain experts often express their knowledge through text; one direct expression is through text designed to aid human learning. In this paper we exploit text written by domain experts in order to build a more expressive representation for learning. We term this approach *reading to learn*.

The following scenario demonstrates the motivation for reading to learn. Imagine an agent given a task within its world/environment. The agent has no prior knowledge of the task but can perceive the world through low-level sensors. Learning directly from the sensors may be difficult, as interesting tasks typically require a complex combination of sensors. Our goal is to acquire domain knowledge through the semantic analysis of text, so as to produce higher-level relations through combinations of sensors.

As a concrete example consider the problem of learning how to make legal moves in Freecell solitaire. Relevant sensors may indicate if an object is a card or a freecell, whether a card is a certain value, and whether two values are in sequence. Although it is possible to express the rules with a combination of sensors, learning this combination is difficult. Text can facilitate learning by providing relations at the appropriate level of generalization. For example, the sentence: "You can place a card on an empty freecell," suggests not only which sensors are useful together but also how these sensors should be linked. Assuming the sensors are represented as predicates, one possible relation this sentence suggests is: $\texttt{r}(x, y) = \texttt{card}(x) \wedge \texttt{freecell}(y) \wedge \texttt{empty}(y)$. Armed with this new relation the agent's learning task may be simpler. Throughout the paper we refer to low-level sensory input as *sensor* or *predicate*, and to a higher level concept as a *logical formula* or *relation*.

Our approach to semantic analysis does not require a complete semantic representation of the text. We merely wish to acquire a *semantic abstract* of a document or document collection, and use the discovered relations to facilitate data-driven learning. This will allow us to directly evaluate the contribution of the extracted relations for learning.

We develop an approach to recover semantic abstracts that uses minimal supervision: we assume only a very small set of lexical *glosses*, which map from words to sensors. This marks a substantial departure from previous work on semantic parsing, which requires either annotations of the meanings of each individual sentence (Zettlemoyer and Collins, 2005; Liang et al., 2009), or alignments of sentences to grounded representations of the

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 958–967,
Singapore, 6-7 August 2009.

world (Chen and Mooney, 2008). For the purpose of learning, this approach may be inapplicable, as such text is often written at a high level of abstraction that permits no grounded representation.

There are two properties of our setting that make unsupervised learning feasible. First, it is not necessary to extract a semantic representation of each individual sentence, but rather a summary of the semantics of the document collection. Errors in the semantic abstract are not fatal, as long it guides the learning component towards a more useful representation. Second, we can exploit repetition across documents, which should generally express the same underlying meaning. Logical formulae that are well-supported by multiple documents are especially likely to be useful.

The rest of this paper describes our approach for recovering semantic abstracts and outlines how we apply and evaluate this approach on the Freecell domain. The paper contributes the following key ideas: (1) Interpreting abstract "instructional" text, written at a level that does not correspond to concrete sensory inputs in the world, so that no grounded representation is possible, (2) *reading to learn*, a new setting in which extracted semantic representations are evaluated by whether they facilitate learning; (3) *abstractive semantic summarization*, aimed at capturing broad semantic properties of a multi-document dataset, rather than a semantic parse of individual sentences; (4) a novel, minimally-supervised generative model for semantic analysis which leverages both lexical and syntactic properties of text.

2 Approach Overview

We describe our approach to text analysis as *multidocument semantic abstraction*, with the goal of discovering a compact set of logical formulae to explain the text in a document collection. To this end, we develop a novel generative model in which natural language sentences (e.g., "You can always place cards in empty freecells") are stochastically generated from logical formulae (e.g., $\texttt{card}(x) \wedge \texttt{freecell}(y) \wedge \texttt{empty}(y)$). We formally define a generative process that reflects our intuitions about the relationship between formulae and sentences (Section 3), and perform sampling-based inference to recover the formulae most likely to have generated the observed data (Section 4). The top N such formulae can then be added as additional predicates for relational learning.

Our semantic representation consists of conjunctions of *literals*, each of which includes a single *predicate* (e.g., `empty`) and one or more *variables* (e.g., x). Predicates describe atomic semantic concepts, while variables construct networks of relationships between them. While the importance of the predicates is obvious, the variable assignments also exert a crucial influence on the semantics of the conjunction: modifying a single variable in the formula above from $\texttt{empty}(y)$ to $\texttt{empty}(x)$ yields a formula that is trivially false for all groundings (since cards can never be empty).

Thus, our generative model must account for the influence of both predicates and variables on the sentences in the documents. A natural choice is to use the predicates to influence the lexical items, while letting the variables determine the syntactic structure. For example, the formula $\texttt{card}(x) \wedge \texttt{freecell}(y) \wedge \texttt{empty}(y)$ contains three predicates and two variables. The predicates influence the lexical items in a direct way: we expect that sentences generated from this formula will include a member of the gloss set for each predicate – the sentence "Put the cards on the empty freecells" should be more likely than "Columns are constructed by playing cards in alternating colors."

The impact of the variables on the generative process is more subtle. The sharing of the variable y suggests a relationship between the predicates `freecell` and `empty`. This should be realized in the syntactic structure of the sentence. Modeling syntax using a dependency tree, we expect that the glosses for predicates that share terms will appear in compact sub-trees, while predicates that do not share terms should be more distant. One possible surface realization of this logical formula is the sentence, "Put the card on the empty freecell," whose dependency parse is shown in the left tree of Figure 1. The glosses *empty* and *freecell* are immediately adjacent, while *card* is more remote.

We develop two metrics that quantify the compactness of a set of variable assignments with respect to a dependency tree: *excess terms*, and *shared terms*. The number of excess terms in a subtree is the number of unique terms assigned to words in the subtree, minus the maximum arity of any predicate in the subtree. Shared terms arise whenever a node has multiple subtrees which each contain the same variable. We will use the alternative alignments in Figure 1 to provide a more detailed explanation. In each tree, the variables are written in the nodes belonging to the associated lexical items; variables are written over arrows to indicate membership in some node in the subtree.

Excess Terms Alignment A of Figure 1, corresponding to the formula

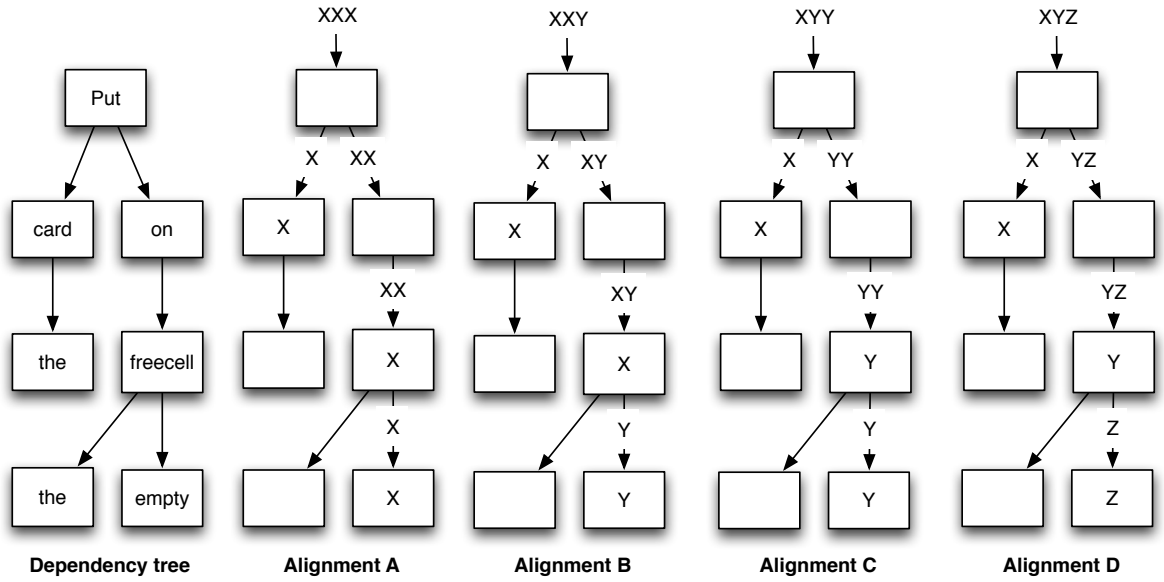

Figure 1: A dependency parse and four different variable assignments. Each literal is aligned to a word (a node in the graph), and the associated variables are written in the box. Variables belonging to descendant nodes are written over the arrows.

$\texttt{card}(x) \wedge \texttt{freecell}(x) \wedge \texttt{empty}(x)$, has zero excess terms in every subtree; there is a total of one variable, and all the predicates are unary. In Alignment B, $\texttt{card}(x) \wedge \texttt{freecell}(x) \wedge \texttt{empty}(y)$, there are excess terms at the root, and in the top two subtrees on the right-hand side. Alignment C contains an excess term at only the root node. Even though it contains the same number of unique variables as Alignment B, it is not penalized as harshly because the alignment of variables better corresponds to the syntactic structure. Alignment D contains the greatest number of excess terms: two at the root of the tree, and one in each of the top two subtrees on the right side.

Shared Terms According to the excess term metric, the best choice is simply to introduce as few variables as possible. For this reason, we also penalize *shared terms* which occur when a node has subtree children that share a variable. In Figure 1, Alignments A and B each contain a shared term at the top node; Alignments C and D contain no shared terms.

Overall, we note that Alignment B is penalized on both metrics, as it contains both excess terms and shared terms; the syntactic structure of the sentence makes such a variable assignment relatively improbable.

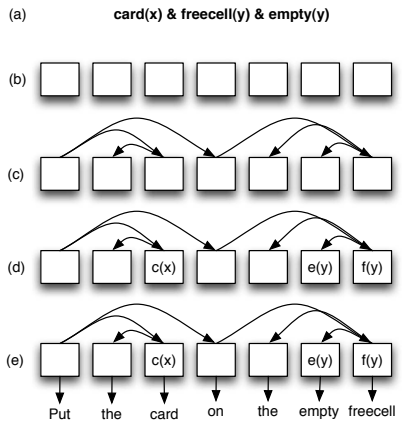

Figure 2: A graphical depiction of the generative process by which sentences are produced from formulae

3 Generative Model

These intuitions are formalized in a generative account of how sentences are stochastically produced from a set of logical formulae. This generative story guides an inference procedure for recovering logical formulae that are likely to have generated any observed set of texts, which is described in Section 4.

The outline of the generative process is depicted in Figure 2. For each sentence, we begin in step (a) by drawing a formula f from a Dirichlet process (Ferguson, 1973). The Dirichlet process de-

fines a non-parametric mixture model, and has the effect of adaptively selecting the appropriate number of formulae to explain the observed sentences in the corpus.[1] We then draw the sentence length from some distribution over positive integers; as the sentence length is always observed, we need not define the distribution (step (b)). In step (c), a dependency tree is drawn from a uniform distribution over spanning trees with a number of nodes equal to the length of the sentence. In step (d) we draw an alignment of the literals in f to nodes in the dependency tree, written $\mathbf{a}_t(f)$. The distribution over alignments is described in Section 3.1. Finally, the aligned literals are used to generate the words at each slot in the dependency tree. A more formal definition of this process is as follows:

- Draw λ, the expected number of literals per formula, from a Gamma distribution $\mathcal{G}(u, v)$.
- Draw an infinite set of formulae $\mathbf{f}$. For each formula f_i,
  - Draw the formula length $\#|f_i|$ from a Poisson distribution, $n_i \sim \text{Poisson}(\lambda)$.
  - Draw n_i literals from a uniform distribution.
- Draw π, an infinite multinomial distribution over formulae: $\pi \sim \text{GEM}(\pi_0)$, where GEM refers to the stick-breaking prior (Sethuraman, 1994) and $\pi_0 = 1$ is the concentration parameter. By attaching the multinomial π to the infinite set of formulae $\mathbf{f}$, we create a Dirichlet process. This is conventionally written $DP(\pi_0, G_0)$, where the base distribution G_0 encodes only the distribution over the number of literals, Poisson(λ).
- For each of D documents, draw the number of sentences $T \sim$ Poisson. For each of the T sentences in the document,
  - Draw a formula $f \sim DP(\pi_0, G_0)$ from the Dirichlet Process described above.
  - Draw a sentence length $\#|s| \sim$ Poisson.
  - Draw a dependency graph t (a spanning tree of size $\#|s|$) from a uniform distribution.
  - Draw an *alignment* $\mathbf{a}_t(f)$, an injective mapping from literals in f to nodes in the dependency structure t. The distribution over alignments is described in Section 3.1.
  - Draw the sentence s from the formula f and the alignment $\mathbf{a}(f)$. For each word token $w_i \in s$ is drawn from $p(w_i|a_t(f, i))$, where $a_t(f, i)$ indicates the (possibly empty) literal assigned to slot i in the alignment $\mathbf{a}_t(f)$ (Section 3.2).

[1] There are many recent applications of Dirichlet processes in natural language processing, e.g. Goldwater et al. (2006).

3.1 Distribution over Alignments

The distribution over alignments reflects our intuition that when literals share variables, they will be aligned to word slots that are nearby in the dependency structure; literals that do not share variables should be more distant. This is formalized by applying the concepts of excess terms and shared terms defined in Section 2. After computing the number of excess and shared terms in each subtree t_i, we can compute a local score (LS) for that subtree:

$$LS(\mathbf{a}_t(f); t_i) = \alpha \cdot NShared(\mathbf{a}_t(f), t_i) + \beta \cdot NExcess(\mathbf{a}_t(f), t_i) \cdot height(t_i).$$

This scoring function can be applied recursively to each subtree in t; the overall score of the tree is the recursive sum,

$$score(\mathbf{a}_t(f); t) = LS(\mathbf{a}_t(f); t) + \sum_i^n score(\mathbf{a}_t(f); t_i), \quad (1)$$

where t_i indicates the i^{th} subtree of t. We hypothesize a generative process that produces all possible alignments, scores them using $score(\mathbf{a}_t(f); t)$, and selects an alignment with probability,

$$p(\mathbf{a}_t(f)) \propto \exp\{-score(\mathbf{a}_t(f); t)\}. \quad (2)$$

In our experiments, we define the parameters $\alpha = 1, \beta = 1$.

3.2 Generation of Lexical Items

Once the logical formula is aligned to the parse structure, the generation of the lexical items in the sentence is straightforward. For word slots to which no literals are aligned, the lexical item is drawn from a language model θ, estimated from the entire document collection. For slots to which at least one literal is aligned, we construct a language model ϕ in which the probability mass is divided equally among all glosses of aligned predicates. The language model θ is used as a backoff, so that there is a strong bias in favor of generating glosses, but some probability mass is reserved for the other lexical items.

4 Inference

This section describes a sampling-based inference procedure for obtaining a set of formulae $\mathbf{f}$ that explain the observed text $\mathbf{s}$ and dependency structures $\mathbf{t}$. We perform Gibbs sampling over the formulae assigned to each sentence. Using the Chinese Restaurant Process interpretation of the Dirichlet Process (Aldous, 1985), we marginalize π, the infinite multinomial over all possible formulae: at each sampling step we select either an existing formula, or stochastically generate a new formula. After each full round of Gibbs sampling, a set of Metropolis-Hastings moves are applied to explore modifications of the formulae. This procedure converges on a stationary Markov chain centered on a set of formulae that cohere well with the lexical and syntactic properties of the text.

4.1 Assigning Sentences to Formulae

For each sentence s_i and dependency tree t_i, a hidden variable y_i indicates the index of the formula that generates the text. We can resample y_i using Gibbs sampling. In the non-parametric setting, y_i ranges over all non-negative integers; the Chinese Restaurant Process formulation marginalizes the infinite-dimensional parameter π, yielding a prior based on the counts for each "active" formula (to which at least one other sentence is assigned), and a pseudo-count representing all non-active formulae. Given K formulae, the prior on selecting formula j is:

$$p(y_i = j|\mathbf{y}_{-i}, \pi_0) \propto \begin{cases} \mathbf{n}_{-i}(j) & j < K \\ \pi_0 & j = K, \end{cases} \quad (3)$$

where $\mathbf{y}_{-i}$ refers to the assignments of all y other than y_i and $\mathbf{n}_{-i}$ refers to the counts over these assignments. Each $j < K$ identifies an existing formula in $\mathbf{f}$, to which at least one other sentence is assigned. When $j = K$, this means a new formula f^* must be generated.

To perform Gibbs sampling, we draw from the posterior distribution over y_i,

$$p(y_i|s_i, t_i\mathbf{f}, f^*, \mathbf{y}_{-i}, \pi_0) \propto p(y_i|\mathbf{y}_{-i}, \pi_0)p(s_i, t_i|\mathbf{y}_i, \mathbf{f}, f^*),$$

where the first term is the prior defined in Equation 3 and the latter term is the likelihood of generating the parsed sentence $\langle s_i, t_i \rangle$ from the formula indexed by y_i.

To compute the probability of a parsed sentence given a formula, we sum over alignments,

$$\begin{aligned} p(s, t|f) &= \sum_{\mathbf{a}_t(f)} p(s, t, \mathbf{a}_t(f)|f) \\ &= \sum_{\mathbf{a}_t(f)} p(s|\mathbf{a}_t(f))p(t, \mathbf{a}_t(f)|f) \\ &= \sum_{\mathbf{a}_t(f)} p(s|\mathbf{a}_t(f))p(\mathbf{a}_t(f)|t, f)p(t|f), \end{aligned} \quad (4)$$

applying the chain rule and independence assumptions from the generative model. The result is a product of three terms: the likelihood of the lexical items given the aligned predicates (defined in Section 3.2; the likelihood of the alignment given the dependency tree and formula (defined in equation 2), and the probability of the dependency tree given the formula, which is uniform.

Equation 4 takes a sum across alignments, but most of the probability mass of $p(s|\mathbf{a}_t(f))$ will be concentrated on alignments in which predicates cover words that gloss them. Thus, we can apply an approximation,

$$p(s, t|f) \approx \sum_{\mathbf{a}_t(f)}^{N} p(s|\mathbf{a}_t(f))p(\mathbf{a}_t(f)|t, f)p(t|f), \quad (5)$$

in which we draw N samples in which predicates are aligned to their glosses whenever possible.

Similarly, Equation 2 quantifies the likelihood of an alignment only to a constant of proportionality; again, a sum over possible alignments is necessary. We do not expect the prior on alignments to be strongly peaked like the sentence likelihood, so we approximate the normalization term by sampling M alignments at random and extrapolating:

$$\begin{aligned} p(\mathbf{a}_t(f)|t, f) &\propto q(\mathbf{a}_t(f); t) \\ &= \frac{q(\mathbf{a}_t(f); t)}{\sum_{\mathbf{a}'_t(f)} q(\mathbf{a}'_t(f); t)} \\ &\approx \frac{\#|\mathbf{a}'_t(f)|}{M} \frac{q(\mathbf{a}_t(f); t)}{\sum_{\mathbf{a}'_t(f)}^{M} q(\mathbf{a}'_t(f); t)}, \end{aligned}$$

where $q(\mathbf{a}_t(f); t) = \exp\{-score(\mathbf{a}_t(f); t)\}$, defined in Equation 2. In our experiments, we set N to at most 10, and $M = 20$. Drawing larger numbers of samples had no discernible effect on system output.

4.1.1 Generating new formulae

Chinese Restaurant Process sampling requires the generation of new candidate formulae at each resampling stage. To generate a new formula, we first sample the number of literals. As described in the generative story (Section 3), the number of literals is drawn from a Poisson distribution with parameter θ. We treat θ as unknown and marginalize, using the Gamma hyperprior $\mathcal{G}(u, v)$. Due to Poisson-Gamma conjugacy, this marginalization can be performed analytically, yielding a Negative-Binomial distribution with parameters $\langle u + \sum_i \#|f_i|, (1 + K + v)^{-1} \rangle$, where $\sum_i \#|f_i|$ is the sum of the number of literals in each formula, and K is the number of formulae which generate at least one sentence. In this sense, the hyperpriors u and v act as pseudo counts. We set $u = 3, v = 1$, reflecting a weak prior expectation of three literals per predicate.

After drawing the size of the formula, the predicates are selected from a uniform random distribution. Finally, the terms are assigned: at each slot, we reuse a previous term with probability 0.5, unless none is available; otherwise a new term is generated.

4.2 Proposing changes to formulae

The assignment resampling procedure has the ability to generate new formulae, thus exploring the space of relational features. However, to explore this space more rapidly, we introduce four Metropolis-Hastings moves that modify existing formulae (Gilks, 1995): adding a literal, deleting a literal, substituting a literal, and rearranging the terms of the formula. For each proposed move, we recompute the joint likelihood of the formula and all aligned sentences. The move is stochastically accepted based on the ratio of the joint likelihoods of the new and old configurations, multiplied by a Hastings correction.

The joint likelihood with respect to formula f is computed as $p(\mathbf{s}, \mathbf{t}, f) = p(f) \prod_i p(s_i, t_i|f)$. The prior on f considers only the number of literals, using a Negative-Binomial distribution as described in section 4.1.1. The likelihood $p(s_i, t_i|f)$ is given in equation 4. The Hastings correction is $\tilde{p}(f' \rightarrow f)/\tilde{p}(f \rightarrow f')$, with $\tilde{p}(f \rightarrow f')$ indicating the probability of proposing a move from f to f',and $\tilde{p}(f' \rightarrow f)$ indicating the probability of proposing the reverse move. The Hastings corrections depend on the arity of the predicates being added and removed; the derivation is straightforward but tedious. We plan to release a technical report with complete details.

4.3 Summary of inference

The final inference procedure iterates between Gibbs sampling of assignments of formulae to sentences, and manipulating the formulae through Metropolis-Hastings moves. A full iteration comprises proposing a move to each formula, and then using Gibbs sampling to reconsider all assignments. If a formula no longer has any sentences assigned to it, then it is dropped from the active set, and can no longer be selected in Gibbs sampling – this is standard in the Chinese Restaurant Process.

Five separate Markov chains are maintained in parallel. To allow the sampling procedure to converge to a stationary distribution, each chain begins with 100 iterations of "burn-in" sampling, without storing the output. At this point, we perform another 100 iterations, storing the state at the end of each iteration.[2] All formulae are ranked according to the cumulative number of sentences to which they are assigned (across all five Markov chains), aggregating the counts for multiple instances of identical formulae. This yields a ranked list of formulae which will be used in our framework as features for relational learning.

5 Evaluation

Our experimental setup is designed to evaluate the quality of the semantic abstraction performed by our model. The logical formulae obtained by our system are applied as features for relational learning of the rules of the game of Freecell solitaire. We investigate whether these features enable better generalization given varying number of training examples of Freecell game states. We also quantify the specific role of syntax, lexical choice, and feature expressivity in learning performance. This section describes the details of this evaluation.

5.1 Relational Learning

We perform relational learning using Inductive Logic Programming (ILP), which constructs generalized rules by assembling smaller logical formulae to explain observed propositional examples (Muggleton, 1995). The lowest level formulae consist of basic sensors that describe the environment. ILP's expressivity enables it to build complex conjunctions of these building blocks, but at the cost of tractability. Our evaluation asks whether the logical formulae abstracted from text

[2] Sampling for more iterations was not found to affect performance on development data, and the model likelihood appeared stationary after 100 iterations.

Predicate	Glosses
card(x)	card
tableau(x)	column, tableau
freecell(x)	freecell, cell
homecell(x)	foundation, cell, homecell
value(x,y)	ace, king, rank, 8, 3, 7, lowest, highest
successor(x,y)	higher, sequence, sequential
color(x,y)	black, red, color
suit(x,y)	suit, club, diamond, spade, heart
on(x,y)	onto
top(x,y)	bottom, available, top
empty(x)	empty

Table 1: Predicates in the Freecell world model, with natural language glosses obtained from the development set text.

can transform the representation to facilitate learning. We compare against both the sensor-level representation as well as richer representations that do not benefit from the full power of our model's semantic analysis.

The ALEPH[3] ILP system, which is primarily based on PROGOL (Muggleton, 1995), was used to induce the rules of game. The search parameters remained constant for all experiments.

5.2 Resources

There are four types of resources required to work in the reading-to-learn setting: a world model, instructional text, a small set of glosses that map from text to elements of the world model, and labeled examples of correct and incorrect actions in the world. In our experiments, we consider the domain of Freecell solitaire, a popular card game (Morehead and Mott-Smith, 1983) in which cards are moved between various types of locations, depending on their suit and rank. We now describe the resources for the Freecell domain in more detail.

World Model Freecell solitaire can be described formally using first order logic; we consider a slightly modified version of the representation from the Planning Domain Definition Language (PDDL), which is used in automatic game-playing competitions. Specifically, there are 87 constants: 52 cards, 16 locations, 13 values, four suits, and two colors. These constants are combined with a fixed set of 11 predicates, listed in Table 1.

Instructional Text Our approach relies on text that describes how to operate in the Freecell solitaire domain. A total of five instruction sets were obtained from the Internet. Due to the popularity of the Microsoft implementation of Freecell, instructions often contain information specific to playing Freecell on a computer. We manually removed sentences which did not focus on the card aspects of Freecell (e.g., how to set up the board and information regarding where to click to move cards). In order to use our semantic abstraction model, the instructions were part-of-speech tagged with the Stanford POS Tagger (Toutanova and Manning, 2000) and dependency parses were obtained using Malt (Nivre, 2006).

Glosses Our reading to learn setting requires a small set of glosses, which are surface forms commonly used to represent predicates from the world model. We envision an application scenario in which a designer manually specifies a few glosses for each predicate. However, for the purposes of evaluation, it would be unprincipled for the experimenters to handcraft the ideal set of glosses. Instead, we gathered a development set of text and annotated the lexical mentions of the world model predicates in text. This annotation is used to obtain glosses to apply to the evaluation text. This approximates a scenario in which the designer has a reasonable idea of how the domain will be described in text, but no prior knowledge of the specific details of the text instructions. Our experiments used glosses that occurred two or more times in the instructions: this yields a total of 32 glosses for 11 predicates, as shown in Table 1.

Evaluation game data Ultimately, the semantic abstraction obtained from the text is applied to learning on labeled examples of correct and incorrect actions in the world model. For evaluation, we automatically generated a set of *move scenarios*: game states with one positive example (a legal move) and one negative example (an illegal move). To avoid bias in the data we generate an equal number of move scenarios from each of three types: moves to the freecells, homecells, and tableaux. For our experiments we vary the number of move scenarios in the training set; the development and test sets consist of 900 and 1500 move scenarios respectively.

5.3 Evaluation Settings

We compare four different feature sets, which will be provided to the ALEPH ILP learner. All feature sets include the sensor-level predicates shown in Table 1. The FULL-MODEL feature set also includes the top logical formulae obtained in our model's semantic abstract (see Sec-

[3]Freely available from http://www.comlab.ox.ac.uk/activities/machinelearning/Aleph/

tion 4.3). The NO-SYNTAX feature set is obtained from a variant of our model in which the influence of syntax is removed by setting parameters $\alpha, \beta = 0$. The SENSORS-ONLY feature set uses only the sensor-level predicates. Finally, the RELATIONAL-RANDOM feature set is constructed by replacing each feature in the FULL-MODEL set with a randomly generated relational feature of identical expressivity (each predicate is replaced by a randomly chosen alternative with identical arity; terms are also assigned randomly). This ensures that any performance gains obtained by our model were not due merely to the greater expressivity of its relational features. The number of features included in each scenario is tuned on a development set of test examples.

The performance metric assesses the ability of the ILP learner to classify proposed Freecell moves as legal or illegal. As the evaluation set contains an equal number of positive and negative examples, accuracy is the appropriate metric. The training scenarios are randomly generated; we repeat each run 50 times and average our results. For the RELATIONAL-RANDOM feature set – in which predicates and terms are chosen randomly – we also regenerate the formulae per run.

6 Results

Table 2 shows a comparison of the results using the setup described above. Our FULL-MODEL achieves the best performance at every training set size, consistently outperforming the SENSORS-ONLY representation by an absolute difference of three to four percent. This demonstrates the semantic abstract obtained by our model does indeed facilitate machine learning in this domain.

RELATIONAL-RANDOM provides a baseline of relational features with equal expressivity to those chosen by our model, but with the predicates and terms selected randomly. We consistently outperform this baseline, demonstrate that the improvement obtained over the sensors only representation is not due merely to the added expressivity of our features.

The third row compares against NO-SYNTAX, a crippled version of our model that incorporates lexical features but not the syntactic structure. The results are stronger than the SENSORS-ONLY and RELATIONAL-RANDOM baselines, but still weaker than our full system. This demonstrates the syntactic features incorporated by our model result in better semantic representations of the underlying text.

Features	Number of training scenarios			
	15	30	60	120
SENSORS-ONLY	79.12	88.07	92.77	93.73
RELATIONAL-RANDOM	82.72	89.14	93.08	94.17
NO-SYNTAX	80.98	89.79	94.11	97.04
FULL-MODEL	**82.89**	**91.00**	**95.23**	**97.45**

Table 2: Results as number of training examples varied. Each value represents the accuracy of the induced rules obtained with the given feature set.

$\texttt{card}(x_1) \wedge \texttt{tableau}(x_2)$
$\texttt{card}(x_1) \wedge \texttt{freecell}(x_2)$
$\texttt{homecell}(x_1) \wedge \texttt{value}(x_2,x_3)$
$\texttt{empty}(x_1) \wedge \texttt{freecell}(x_1)$
$\texttt{card}(x_1) \wedge \texttt{top}(x_1,x_2)$
$\texttt{card}(x_1) \wedge \texttt{homecell}(x_2)$
$\texttt{freecell}(x_1) \wedge \texttt{homecell}(x_2)$
$\texttt{card}(x_1) \wedge \texttt{tableau}(x_1)$
$\texttt{card}(x_1) \wedge \texttt{top}(x_2,x_1)$
$\texttt{homecell}(x_1)$
$\texttt{card}(x_1) \wedge \texttt{homecell}(x_1)$
$\texttt{color}(x_1,x_2) \wedge \texttt{value}(x_3,x_4)$
$\texttt{suit}(x_1,x_2) \wedge \texttt{value}(x_3,x_4)$
$\texttt{value}(x_1,x_2) \wedge \texttt{value}(x_3,x_4)$
$\texttt{homecell}(x_1) \wedge \texttt{successor}(x_2,x_3)$

Figure 3: The top 15 features recovered by the semantic abstraction of our full model.

Figure 3 shows the top 15 formulae recovered by the full model running on the evaluation text. Features such as $\texttt{empty}(x_1) \wedge \texttt{freecell}(x_1)$ are useful because they reuse variables to ensure that objects have key properties – in this case, ensuring that a freecell is empty. Other features, such as $\texttt{homecell}(x_1) \wedge \texttt{value}(x_2, x_3)$, help to focus the search on useful conjunctions of predicates (in Freecell, the legality of playing a card on a homecell depends on the value of the card). Note that three of these 15 formulae are trivially useless, in that they are always false: e.g., $\texttt{card}(x_1) \wedge \texttt{tableau}(x_1)$. This illustrates the importance of term assignment in obtaining useful features for learning. In the NO-SYNTAX system, which ignores the relationship between term assignment and syntactic structure, eight of the top 15 formulae were trivially useless due to term incompatibility.

7 Related Work

This paper draws on recent literature on extracting logical forms from surface text (Zettlemoyer and Collins, 2005; Ge and Mooney, 2005; Downey et al., 2005; Liang et al., 2009), interpreting language in the context of a domain (Chen and Mooney, 2008), and using an actionable domain to guide text interpretation (Branavan et al., 2009). We differentiate our research in several dimensions:

Language Interpretation Instructional text describes generalized statements about entities in the domain and the way they interact, thus the text does not correspond directly to concrete sensory inputs in the world (i.e., a specific world state). Our interpretation captures these generalizations as first-order logic statements that can be evaluated given a specific state. This contrasts to previous work which interprets "directions" and thus assumes a direct correspondence between text and world state (Branavan et al., 2009; Chen and Mooney, 2008).

Supervision Our work avoids supervision in the form of labeled examples, using only a minimal set of natural language glosses per predicate. Previous work also considered the supervision signal obtained by interpreting natural language in the context of a formal domain. Branavan et al. (2009) use feedback from a world model as a supervision signal. Chen and Mooney (2008) use temporal alignment of text and grounded descriptions of the world state. In these approaches, concrete domain entities are grounded in language interpretation, and therefore require only a propositional semantic representation. Previous approaches for interpreting generalized natural language statements are trained from labeled examples (Zettlemoyer and Collins, 2005; Lu et al., 2008).

Level of analysis We aim for an *abstractive semantic summary* across multiple documents, whereas other approaches attempt to produce logical forms for individual sentences (Zettlemoyer and Collins, 2005; Ge and Mooney, 2005). We avoid the requirement that each sentence have a meaningful interpretation within the domain, allowing us to handle relatively unstructured text.

Evaluation We do not evaluate the representations obtained by our model; rather we assess whether these representations improve learning performance. This is similar to work on GeoQuery (Wong and Mooney, 2007; Ge and Mooney, 2005), and also to recent work on following step-by-step directions (Branavan et al., 2009). While these evaluations are performed on the basis of individual sentences, actions, or system responses, we evaluate the holistic semantic analysis obtained by our system.

Model We treat surface text as generated from a latent semantic description. Lu et al. (2008) apply a generative model, but require a complete derivation from semantics to the lexical representation, while we favor a more flexible semantic analysis that can be learned without annotation and applied to noisy text. More similar is the work of Liang et al. (2009), which models the generation of semantically-relevant fields using lexical and discourse features. Our approach differs by accounting for syntax, which enables a more expressive semantic representation that includes ungrounded variables.

Relational learning The output of our semantic analysis is applied to learning in a structured relational space, using ILP. A key difficulty with ILP is that the increased expressivity dramatically expands the hypothesis space, and it is widely agreed that some learning bias is required for ILP to be tractable (Nédellec et al., 1996; Cumby and Roth, 2003). Our work can be viewed as a new method for acquiring such bias from text; moreover, our approach is not specialized for ILP and may be used to transform the feature space in other forms of relational learning as well (Roth and Yih, 2001; Cumby and Roth, 2003; Richardson and Domingos, 2006).

8 Conclusion

This paper demonstrates a new setting for semantic analysis, which we term *reading to learn*. We handle text which describes the world in general terms rather than refereing to concrete entities in the domain. We obtain a semantic abstract of multiple documents, using a novel, minimally-supervised generative model that accounts for both syntax and lexical choice. The semantic abstract is represented as a set of predicate logic formulae, which are applied as higher-order features for learning. We demonstrate that these features improve learning performance, and that both the lexical and syntactic aspects of our model yield substantial contributions.

In the current setup, we produce an "overgenerated" semantic representation comprised of useful features for learning but also some false positives. Learning in our system can be seen as the process of pruning this representation by selecting useful formulae based on interaction with the training data. In the future we hope to explore ways to interleave semantic analysis with exploration of the learning domain, by using the environment as a supervision signal for linguistic analysis.

Supervised Models for Coreference Resolution

Abstract

Traditional learning-based coreference resolvers operate by training a *mention-pair* classifier for determining whether two mentions are coreferent or not. Two independent lines of recent research have attempted to improve these mention-pair classifiers, one by learning a *mention-ranking* model to rank preceding mentions for a given anaphor, and the other by training an *entity-mention* classifier to determine whether a preceding cluster is coreferent with a given mention. We propose a cluster-ranking approach to coreference resolution that combines the strengths of mention rankers and entity-mention models. We additionally show how our cluster-ranking framework naturally allows discourse-new entity detection to be learned jointly with coreference resolution. Experimental results on the ACE data sets demonstrate its superior performance to competing approaches.

1 Introduction

Noun phrase (NP) coreference resolution is the task of identifying which NPs (or *mentions*) refer to the same real-world entity or concept. Traditional learning-based coreference resolvers operate by training a model for classifying whether two mentions are co-referring or not (e.g., Soon et al. (2001), Ng and Cardie (2002b), Kehler et al. (2004), Ponzetto and Strube (2006)). Despite their initial successes, these *mention-pair* models have at least two major weaknesses. First, since each candidate antecedent for a mention to be resolved (henceforth an *active mention*) is considered independently of the others, these models only determine how good a candidate antecedent is relative to the active mention, but not how good a candidate antecedent is relative to other candidates. In other words, they fail to answer the critical question of which candidate antecedent is most probable. Second, they have limitations in their expressiveness: the information extracted from the two mentions alone may not be sufficient for making an informed coreference decision, especially if the candidate antecedent is a pronoun (which is semantically empty) or a mention that lacks descriptive information such as gender (e.g., *Clinton*).

To address the first weakness, researchers have attempted to train a *mention-ranking* model for determining which candidate antecedent is most probable given an active mention (e.g., Denis and Baldridge (2008)). Ranking is arguably a more natural reformulation of coreference resolution than classification, as a ranker allows all candidate antecedents to be considered *simultaneously* and therefore directly captures the competition among them. Another desirable consequence is that there exists a natural resolution strategy for a ranking approach: a mention is resolved to the candidate antecedent that has the highest rank. This contrasts with classification-based approaches, where many clustering algorithms have been employed to co-ordinate the pairwise coreference decisions (because it is unclear which one is the best).

To address the second weakness, researchers have investigated the acquisition of *entity-mention* coreference models (e.g., Luo et al. (2004), Yang et al. (2004)). Unlike mention-pair models, these entity-mention models are trained to determine whether an active mention belongs to a preceding, possibly partially-formed, coreference cluster. Hence, they can employ *cluster-level* features (i.e., features that are defined over any subset of mentions in a preceding cluster), which makes them more expressive than mention-pair models.

Motivated in part by these recently developed models, we propose in this paper a *cluster-ranking* approach to coreference resolution that combines the strengths of mention-ranking mod-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 968–977,
Singapore, 6-7 August 2009.

els and entity-mention models. Specifically, we recast coreference as the problem of determining which of a set of preceding coreference *clusters* is the best to link to an active mention using a learned *cluster ranker*. In addition, we show how discourse-new detection (i.e., the task of determining whether a mention introduces a new entity in a discourse) can be learned *jointly* with coreference resolution in our cluster-ranking framework. It is worth noting that researchers typically adopt a *pipeline* coreference architecture, performing discourse-new detection prior to coreference resolution and using the resulting information to prevent a coreference system from resolving mentions that are determined to be discourse-new (see Poesio et al. (2004) for an overview). As a result, errors in discourse-new detection could be propagated to the resolver, possibly leading to a deterioration of coreference performance (see Ng and Cardie (2002a)). Jointly learning discourse-new detection and coreference resolution can potentially address this error-propagation problem.

In sum, we believe our work makes three main contributions to coreference resolution:

Proposing a simple, yet effective coreference model. Our work advances the state-of-the-art in coreference resolution by bringing learning-based coreference systems to the next level of performance. When evaluated on the ACE 2005 coreference data sets, cluster rankers outperform three competing models — mention-pair, entity-mention, and mention-ranking models — by a large margin. Also, our joint-learning approach to discourse-new detection and coreference resolution consistently yields cluster rankers that outperform those adopting the pipeline architecture. Equally importantly, cluster rankers are conceptually simple and easy to implement and do not rely on sophisticated training and inference procedures to make coreference decisions in dependent relation to each other, unlike relational coreference models (see McCallum and Wellner (2004)).

Bridging the gap between machine-learning approaches and linguistically-motivated approaches to coreference resolution. While machine learning approaches to coreference resolution have received a lot of attention since the mid-90s, popular learning-based coreference frameworks such as the mention-pair model are arguably rather unsatisfactory from a linguistic point of view. In particular, they have not leveraged advances in discourse-based anaphora resolution research in the 70s and 80s. Our work bridges this gap by realizing in a new machine learning framework ideas rooted in Lappin and Leass's (1994) heuristic-based pronoun resolver, which in turn was motivated by classic salience-based approaches to anaphora resolution.

Revealing the importance of adopting the right model. While entity-mention models have previously been shown to be worse or at best marginally better than their mention-pair counterparts (Luo et al., 2004; Yang et al., 2008), our cluster-ranking models, which are a natural extension of entity-mention models, significantly outperformed all competing approaches. This suggests that the use of an appropriate learning framework can bring us a long way towards high-performance coreference resolution.

The rest of the paper is structured as follows. Section 2 discusses related work. Section 3 describes our baseline coreference models: mention-pair, entity-mention, and mention-ranking. We discuss our cluster-ranking approach in Section 4, evaluate it in Section 5, and conclude in Section 6.

2 Related Work

Heuristic-based cluster ranking. As mentioned previously, the work most related to ours is Lappin and Leass (1994), whose goal is to perform pronoun resolution by assigning an anaphoric pronoun to the highest-scored preceding cluster. Nevertheless, Lappin and Leass's work differs from ours in several respects. First, they only tackle pronoun resolution rather than the full coreference task. Second, their algorithm is heuristic-based; in particular, the score assigned to a preceding cluster is computed by summing over the weights associated with the factors applicable to the cluster, where the weights are determined heuristically, rather than learned, unlike ours.

Like many heuristic-based pronoun resolvers (e.g., Mitkov (1998)), they first apply a set of constraints to filter grammatically incompatible candidate antecedents and then rank the remaining ones using salience factors. As a result, their cluster-ranking model employs only factors that capture the salience of a cluster, and can therefore be viewed as a simple model of attentional state (see Grosz and Sidner (1986)) realized by coreference clusters. By contrast, our resolution strategy is learned without applying hand-coded con-

straints in a separate filtering step. In particular, we attempt to determine the compatibility between a cluster and an active mention, using factors that determine not only salience (e.g., the distance between the cluster and the mention) but also lexical and grammatical compatibility, for instance.

Entity-mention coreference models. Luo et al. (2004) represent one of the earliest attempts to investigate learning-based entity-mention models. They use the ANY predicate to generate cluster-level features as follows: given a binary-valued feature X defined over a pair of mentions, they introduce an ANY-X cluster-level feature, which has the value TRUE if X is true between the active mention and *any* mention in the preceding cluster under consideration. Contrary to common wisdom, this entity-mention model underperforms its mention-pair counterpart in spite of the generalization from mention-pair to cluster-level features.

In Yang et al.'s (2004) entity-mention model, a training instance is composed of an active mention m_k, a preceding cluster C, and a mention m_j in C that is closest in distance to m_k in the associated text. The feature set used to represent the instance is primarily composed of features that describe the relationship between m_j and m_k, as well as a few cluster-level features. In other words, the model still relies heavily on features used in a mention-pair model. In particular, the inclusion of m_j in the feature vector representation to some extent reflects the authors' lack of confidence that a strong entity-mention model can be trained without mention-pair-based features. Our ranking model, on the other hand, is trained without such features. More recently, Yang et al. (2008) have proposed another entity-mention model trained by inductive logic programming. Like their previous work, the scarcity of cluster-level predicates (only two are used) under-exploits the expressiveness of entity-mention models.

Mention ranking. The notion of ranking candidate antecedents can be traced back to centering algorithms, many of which use grammatical roles to rank forward-looking centers (see Grosz et al. (1995), Walker et al. (1998), and Mitkov (2002)). However, mention ranking has been employed in learning-based coreference resolvers only recently. As mentioned before, Denis and Baldridge (2008) train a mention-ranking model. Their work can be viewed as an extension of Yang et al.'s (2003) twin-candidate coreference model, which ranks only two candidate antecedents at a time. Unlike ours, however, their model ranks mentions rather than clusters, and relies on an independently-trained discourse-new detector.

Discourse-new detection. Discourse-new detection is often tackled independently of coreference resolution. Pleonastic *it*s have been detected using heuristics (e.g., Kennedy and Boguraev (1996)) and learning-based techniques such as rule learning (e.g., Müller (2006)), kernels (e.g., Versley et al. (2008)), and distributional methods (e.g., Bergsma et al. (2008)). Non-anaphoric definite descriptions have been detected using heuristics (e.g., Vieira and Poesio (2000)) and unsupervised methods (e.g., Bean and Riloff (1999)). General discourse-new detectors that are applicable to different types of NPs have been built using heuristics (e.g., Byron and Gegg-Harrison (2004)) and modeled generatively (e.g., Elsner and Charniak (2007)) and discriminatively (e.g., Uryupina (2003)). There have also been attempts to perform joint *inference* for discourse-new detection and coreference resolution using integer linear programming (ILP), where a discourse-new classifier and a coreference classifier are trained *independently* of each other, and then ILP is applied as a post-processing step to jointly infer discourse-new and coreference decisions so that they are consistent with each other (e.g., Denis and Baldridge (2007)). Joint inference is different from our joint-learning approach, which allows the two tasks to be learned jointly and not independently.

3 Baseline Coreference Models

In this section, we describe three coreference models that will serve as our baselines: the mention-pair model, the entity-mention model, and the mention-ranking model. For illustrative purposes, we will use the text segment shown in Figure 1. Each mention m in the segment is annotated as $[m]^{cid}_{mid}$, where mid is the mention id and cid is the id of the cluster to which m belongs. As we can see, the mentions are partitioned into four sets, with *Barack Obama*, *his*, and *he* in one cluster, and each of the remaining mentions in its own cluster.

3.1 Mention-Pair Model

As noted before, a mention-pair model is a classifier that decides whether or not an active mention m_k is coreferent with a candidate antecedent m_j. Each instance $\boldsymbol{i}(m_j, m_k)$ represents m_j and

[*Barack Obama*]$_1^1$ *nominated* [*Hillary Rodham Clinton*]$_2^2$ *as* [[*his*]$_3^1$ *secretary of state*]$_4^3$ *on* [*Monday*]$_5^4$. [*He*]$_6^1$ ...

Figure 1: An illustrative example

m_k and consists of the 39 features shown in Table 1. These features have largely been employed by state-of-the-art learning-based coreference systems (e.g., Soon et al. (2001), Ng and Cardie (2002b), Bengtson and Roth (2008)), and are computed automatically. As can be seen, the features are divided into four blocks. The first two blocks consist of features that describe the properties of m_j and m_k, respectively, and the last two blocks of features describe the relationship between m_j and m_k. The classification associated with a training instance is either positive or negative, depending on whether m_j and m_k are coreferent.

If one training instance were created from each pair of mentions, the negative instances would significantly outnumber the positives, yielding a skewed class distribution that will typically have an adverse effect on model training. As a result, only a subset of mention pairs will be generated for training. Following Soon et al. (2001), we create (1) a positive instance for each discourse-old mention m_k and its closest antecedent m_j; and (2) a negative instance for m_k paired with each of the intervening mentions, $m_{j+1}, m_{j+2}, \ldots, m_{k-1}$. In our running example shown in Figure 1, three training instances will be generated for *He*: ***i***(*Monday*, *He*), ***i***(*secretary of state*, *He*), and ***i***(*his*, *He*). The first two of these instances will be labeled as negative, and the last one will be labeled as positive. To train a mention-pair classifier, we use the SVM learning algorithm from the SVM^{light} package (Joachims, 2002), converting all multi-valued features into an equivalent set of binary-valued features.

After training, the resulting SVM classifier is used to identify an antecedent for a mention in a test text. Specifically, an active mention m_k selects as its antecedent the closest preceding mention that is classified as coreferent with m_k. If m_k is not classified as coreferent with any preceding mention, it will be considered discourse-new (i.e., no antecedent will be selected for m_k).

3.2 Entity-Mention Model

Unlike a mention-pair model, an entity-mention model is a classifier that decides whether or not an active mention m_k is coreferent with a *partial cluster* c_j that precedes m_k. Each training instance, ***i***(c_j, m_k), represents c_j and m_k. The features for an instance can be divided into two types: (1) features that describe m_k (i.e, those shown in the second block of Table 1), and (2) cluster-level features, which describe the relationship between c_j and m_k. Motivated by previous work (Luo et al., 2004; Culotta et al., 2007; Yang et al., 2008), we create cluster-level features from mention-pair features using four predicates: NONE, MOST-FALSE, MOST-TRUE, and ALL. Specifically, for each feature X shown in the last two blocks in Table 1, we first convert X into an equivalent set of binary-valued features if it is multi-valued. Then, for each resulting binary-valued feature X$_b$, we create four binary-valued cluster-level features: (1) NONE-X$_b$ is true when X$_b$ is false between m_k and each mention in c_j; (2) MOST-FALSE-X$_b$ is true when X$_b$ is true between m_k and less than half (but at least one) of the mentions in c_j; (3) MOST-TRUE-X$_b$ is true when X$_b$ is true between m_k and at least half (but not all) of the mentions in c_j; and (4) ALL-X$_b$ is true when X$_b$ is true between m_k and each mention in c_j. Hence, for each X$_b$, exactly one of these four cluster-level features evaluates to true.

Following Yang et al. (2008), we create (1) a positive instance for each discourse-old mention m_k and the preceding cluster c_j to which it belongs; and (2) a negative instance for m_k paired with each partial cluster whose last mention appears between m_k and its closest antecedent (i.e., the last mention of c_j). Consider again our running example. Three training instances will be generated for *He*: ***i***({*Monday*}, *He*), ***i***({*secretary of state*}, *He*), and ***i***({*Barack Obama*, *his*}, *He*). The first two of these instances will be labeled as negative, and the last one will be labeled as positive. As in the mention-pair model, we train an entity-mention classifier using the SVM learner.

After training, the resulting classifier is used to identify a preceding cluster for a mention in a test text. Specifically, the mentions are processed in a left-to-right manner. For each active mention m_k, a test instance is created between m_k and each of the preceding clusters formed so far. All the test instances are then presented to the classifier. Finally, m_k will be linked to the closest preceding cluster that is classified as coreferent with m_k. If m_k is not classified as coreferent with any

Features describing m_j, a candidate antecedent		
1	PRONOUN_1	Y if m_j is a pronoun; else N
2	SUBJECT_1	Y if m_j is a subject; else N
3	NESTED_1	Y if m_j is a nested NP; else N
Features describing m_k, the mention to be resolved		
4	NUMBER_2	SINGULAR or PLURAL, determined using a lexicon
5	GENDER_2	MALE, FEMALE, NEUTER, or UNKNOWN, determined using a list of common first names
6	PRONOUN_2	Y if m_k is a pronoun; else N
7	NESTED_2	Y if m_k is a nested NP; else N
8	SEMCLASS_2	the semantic class of m_k; can be one of PERSON, LOCATION, ORGANIZATION, DATE, TIME, MONEY, PERCENT, OBJECT, OTHERS, determined using WordNet and an NE recognizer
9	ANIMACY_2	Y if m_k is determined as HUMAN or ANIMAL by WordNet and an NE recognizer; else N
10	PRO_TYPE_2	the nominative case of m_k if it is a pronoun; else NA. E.g., the feature value for *him* is HE
Features describing the relationship between m_j, a candidate antecedent and m_k, the mention to be resolved		
11	HEAD_MATCH	C if the mentions have the same head noun; else I
12	STR_MATCH	C if the mentions are the same string; else I
13	SUBSTR_MATCH	C if one mention is a substring of the other; else I
14	PRO_STR_MATCH	C if both mentions are pronominal and are the same string; else I
15	PN_STR_MATCH	C if both mentions are proper names and are the same string; else I
16	NONPRO_STR_MATCH	C if the two mentions are both non-pronominal and are the same string; else I
17	MODIFIER_MATCH	C if the mentions have the same modifiers; NA if one of both of them don't have a modifier; else I
18	PRO_TYPE_MATCH	C if both mentions are pronominal and are either the same pronoun or different only w.r.t. case; NA if at least one of them is not pronominal; else I
19	NUMBER	C if the mentions agree in number; I if they disagree; NA if the number for one or both mentions cannot be determined
20	GENDER	C if the mentions agree in gender; I if they disagree; NA if the gender for one or both mentions cannot be determined
21	AGREEMENT	C if the mentions agree in both gender and number; I if they disagree in both number and gender; else NA
22	ANIMACY	C if the mentions match in animacy; I if they don't; NA if the animacy for one or both mentions cannot be determined
23	BOTH_PRONOUNS	C if both mentions are pronouns; I if neither are pronouns; else NA
24	BOTH_PROPER_NOUNS	C if both mentions are proper nouns; I if neither are proper nouns; else NA
25	MAXIMALNP	C if the two mentions does not have the same maximial NP projection; else I
26	SPAN	C if neither mention spans the other; else I
27	INDEFINITE	C if m_k is an indefinite NP and is not in an appositive relationship; else I
28	APPOSITIVE	C if the mentions are in an appositive relationship; else I
29	COPULAR	C if the mentions are in a copular construction; else I
30	SEMCLASS	C if the mentions have the same semantic class; I if they don't; NA if the semantic class information for one or both mentions cannot be determined
31	ALIAS	C if one mention is an abbreviation or an acronym of the other; else I
32	DISTANCE	binned values for sentence distance between the mentions
Additional features describing the relationship between m_j, a candidate antecedent and m_k, the mention to be resolved		
33	NUMBER'	the concatenation of the NUMBER_2 feature values of m_j and m_k. E.g., if m_j is *Clinton* and m_k is *they*, the feature value is SINGULAR-PLURAL, since m_j is singular and m_k is plural
34	GENDER'	the concatenation of the GENDER_2 feature values of m_j and m_k
35	PRONOUN'	the concatenation of the PRONOUN_2 feature values of m_j and m_k
36	NESTED'	the concatenation of the NESTED_2 feature values of m_j and m_k
37	SEMCLASS'	the concatenation of the SEMCLASS_2 feature values of m_j and m_k
38	ANIMACY'	the concatenation of the ANIMACY_2 feature values of m_j and m_k
39	PRO_TYPE'	the concatenation of the PRO_TYPE_2 feature values of m_j and m_k

Table 1: The feature set for coreference resolution. Non-relational features describe a mention and in most cases take on a value of **Y**ES or **N**O. Relational features describe the relationship between the two mentions and indicate whether they are **C**OMPATIBLE, **I**NCOMPATIBLE or **N**OT **A**PPLICABLE.

preceding cluster, it will be considered discourse-new. Note that all partial clusters preceding m_k are formed incrementally based on the predictions of the classifier for the first $k-1$ mentions.

3.3 Mention-Ranking Model

As noted before, a ranking model imposes a ranking on all the candidate antecedents of an active mention m_k. To train a ranker, we use the SVM ranker-learning algorithm from the SVM^{light} package. Like the mention-pair model, each training instance $\boldsymbol{i}(m_j, m_k)$ represents m_k and a preceding mention m_j. In fact, the features that represent the instance as well as the method for creating training instances are identical to those employed by the mention-pair model.

The only difference lies in the assignment of class values to training instances. Assuming that S_k is the set of training instances created for anaphoric mention m_k, the class value for an instance $\boldsymbol{i}(m_j, m_k)$ in S_k is the rank of m_j among competing candidate antecedents, which is 2 if m_j is the closest antecedent of m_k, and 1 otherwise.[1] To exemplify, consider our running example. As in the mention-pair model, three training instances will be generated for *He*: ***i***(*Monday*, *He*), ***i***(*secretary of state*, *He*), ***i***(*his*, *He*). The third instance will have a class value of 2, and the remaining two will have a class value of 1.

After training, the mention-ranking model is applied to rank the candidate antecedents for an active mention in a test text as follows. Given an active mention m_k, we follow Denis and Baldridge (2008) and use an independently-trained classifier to determine whether m_k is discourse-new. If so, m_k will not be resolved. Otherwise, we create test instances for m_k by pairing it with each of its preceding mentions. The test instances are then presented to the ranker, and the preceding mention that is assigned the largest value by the ranker is selected as the antecedent of m_k.

The discourse-new classifier used in the resolution step is trained with 26 of the 37 features[2] described in Ng and Cardie (2002a) that are deemed useful for distinguishing between anaphoric and non-anaphoric mentions. These features can be broadly divided into two types: (1) features that encode the form of the mention (e.g., NP type, number, definiteness), and (2) features that compare the mention to one of its preceding mentions.

4 Coreference as Cluster Ranking

In this section, we describe our cluster-ranking approach to NP coreference. As noted before, our approach aims to combine the strengths of entity-mention models and mention-ranking models.

4.1 Training and Applying a Cluster Ranker

For ease of exposition, we will describe in this subsection how to train and apply a cluster ranker when it is used in a pipeline architecture, where discourse-new detection is performed prior to coreference resolution. In the next subsection, we will show how the two tasks can be learned jointly.

[1] A larger class value implies a better rank in SVM^{light}.

[2] The 11 features that we did not employ are CONJ, POSSESSIVE, MODIFIER, POSTMODIFIED, SPECIAL_NOUNS, POST, SUBCLASS, TITLE, and the positional features.

Recall that a cluster ranker ranks a set of preceding clusters for an active mention m_k. Since a cluster ranker is a hybrid of a mention-ranking model and an entity-mention model, the way it is trained and applied is also a hybrid of the two. In particular, the instance representation employed by a cluster ranker is identical to that used by an entity-mention model, where each training instance ***i***(c_j, m_k) represents a preceding cluster c_j and a discourse-old mention m_k and consists of cluster-level features formed from predicates. Unlike in an entity-mention model, however, in a cluster ranker, (1) a training instance is created between each discourse-old mention m_k and *each* of its preceding clusters; and (2) since we are training a model for ranking clusters, the assignment of class values to training instances is similar to that of a mention ranker. Specifically, the class value of a training instance ***i***(c_j, m_k) created for m_k is the rank of c_j among the competing clusters, which is 2 if m_k belongs to c_j, and 1 otherwise.

Applying the learned cluster ranker to a test text is similar to applying a mention ranker. Specifically, the mentions are processed in a left-to-right manner. For each active mention m_k, we first apply an independently-trained classifier to determine if m_k is discourse-new. If so, m_k will not be resolved. Otherwise, we create test instances for m_k by pairing it with each of its preceding clusters. The test instances are then presented to the ranker, and m_k is linked to the cluster that is assigned the highest value by the ranker. Note that these partial clusters preceding m_k are formed incrementally based on the predictions of the ranker for the first $k-1$ mentions; no gold-standard coreference information is used in their formation.

4.2 Joint Discourse-New Detection and Coreference Resolution

The cluster ranker described above can be used to determine which preceding cluster a discourse-old mention should be linked to, but it cannot be used to determine whether a mention is discourse-new or not. The reason is simple: all the training instances are generated from discourse-old mentions. Hence, to jointly learn discourse-new detection and coreference resolution, we must train the ranker using instances generated from *both* discourse-old and discourse-new mentions.

Specifically, when training the ranker, we provide each active mention with the option to start

a new cluster by creating an additional instance that (1) contains features that solely describe the active mention (i.e., the features shown in the second block of Table 1), and (2) has the highest rank value among competing clusters (i.e., 2) if it is discourse-new and the lowest rank value (i.e., 1) otherwise. The main advantage of jointly learning the two tasks is that it allows the ranking model to evaluate *all* possible options for an active mention (i.e., whether to resolve it, and if so, which preceding cluster is the best) *simultaneously*.

After training, the resulting cluster ranker processes the mentions in a test text in a left-to-right manner. For each active mention m_k, we create test instances for it by pairing it with each of its preceding clusters. To allow for the possibility that m_k is discourse-new, we create an additional test instance that contains features that solely describe the active mention (similar to what we did in the training step above). All these test instances are then presented to the ranker. If the additional test instance is assigned the highest rank value by the ranker, then m_k is classified as discourse-new and will not be resolved. Otherwise, m_k is linked to the cluster that has the highest rank. As before, all partial clusters preceding m_k are formed incrementally based on the predictions of the ranker for the first $k-1$ mentions.

5 Evaluation

5.1 Experimental Setup

Corpus. We use the ACE 2005 coreference corpus as released by the LDC, which consists of the 599 training documents used in the official ACE evaluation.[3] To ensure diversity, the corpus was created by selecting documents from six different sources: Broadcast News (bn), Broadcast Conversations (bc), Newswire (nw), Webblog (wb), Usenet (un), and conversational telephone speech (cts). The number of documents belonging to each source is shown in Table 2. For evaluation, we partition the 599 documents into a training set and a test set following a 80/20 ratio, ensuring that the two sets have the same proportion of documents from the six sources.

Mention extractor. We evaluate each coreference model using both *true mentions* (i.e., gold standard mentions[4]) and *system mentions* (i.e., automatically identified mentions). To extract system mentions from a test text, we trained a mention extractor on the training texts. Following Florian et al. (2004), we recast mention extraction as a sequence labeling task, where we assign to each token in a test text a label that indicates whether it **b**egins a mention, is **i**nside a mention, or is **o**utside a mention. Hence, to learn the extractor, we create one training instance for each token in a training text and derive its class value (one of **b**, **i**, and **o**) from the annotated data. Each instance represents w_i, the token under consideration, and consists of 29 linguistic features, many of which are modeled after the systems of Bikel et al. (1999) and Florian et al. (2004), as described below.

Dataset	bn	bc	nw	wl	un	cts
# of documents	60	226	106	119	49	39

Table 2: Statistics for the ACE 2005 corpus

Lexical (7): Tokens in a window of 7: $\{w_{i-3}, \ldots, w_{i+3}\}$.

Capitalization (4): Determine whether w_i `IsAllCap`, `IsInitCap`, `IsCapPeriod`, and `IsAllLower` (see Bikel et al. (1999)).

Morphological (8): w_i's prefixes and suffixes of length one, two, three, and four.

Grammatical (1): The part-of-speech (POS) tag of w_i obtained using the Stanford log-linear POS tagger (Toutanova et al., 2003).

Semantic (1): The named entity (NE) tag of w_i obtained using the Stanford CRF-based NE recognizer (Finkel et al., 2005).

Gazetteers (8): Eight dictionaries containing pronouns (77 entries), common words and words that are not names (399.6k), person names (83.6k), person titles and honorifics (761), vehicle words (226), location names (1.8k), company names (77.6k), and nouns extracted from WordNet that are hyponyms of PERSON (6.3k).

We employ CRF++[5], a C++ implementation of conditional random fields, for training the mention detector, which achieves an F-score of 86.7 (86.1 recall, 87.2 precision) on the test set. These extracted mentions are to be used as system mentions in our coreference experiments.

Scoring programs. To score the output of a coreference model, we employ three scoring programs: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and ϕ_3-CEAF (Luo, 2005).

[3] Since we did not participate in ACE 2005, we do not have access to the official test set.

[4] Note that only mention *boundaries* are used.

[5] Available from http://crfpp.sourceforge.net

There is a complication, however. When scoring a *response* (i.e., system-generated) partition against a *key* (i.e., gold-standard) partition, a scoring program needs to construct a mapping between the mentions in the response and those in the key. If the response is generated using true mentions, then every mention in the response is mapped to some mention in the key and vice versa; in other words, there are no *twinless* (i.e., unmapped) mentions (Stoyanov et al., 2009). However, this is not the case when system mentions are used. The aforementioned complication does not arise from the construction of the mapping, but from the fact that Bagga and Baldwin (1998) and Luo (2005) do not specify how to apply B^3 and CEAF to score partitions generated from system mentions.

We propose a simple solution to this problem: we remove all and only those twinless system mentions that are singletons before applying B^3 and CEAF. The reason is simple: since the coreference resolver has successfully identified these mentions as singletons, it should not be penalized, and removing them allows us to avoid such penalty. Note that we only remove twinless (as opposed to all) system mentions that are singletons: this allows us to reward a resolver for successful identification of singleton mentions that have twins, thus overcoming a major weakness of and common criticism against the MUC scorer. Also, we retain twinless system mentions that are non-singletons, as the resolver should be penalized for identifying spurious coreference relations. On the other hand, we do not remove twinless mentions in the key partition, as we want to ensure that the resolver makes the correct (non-)coreference decisions for them. We believe that our proposal addresses Stoyanov et al.'s (2009) problem of having very low precision when applying the CEAF scorer to score partitions of system mentions.

5.2 Results and Discussions

The mention-pair baseline. We train our first baseline, the mention-pair coreference classifier, using the SVM learning algorithm as implemented in the SVM^{light} package (Joachims, 2002).[6] Results of this baseline using true mentions and system mentions, shown in row 1 of Tables 3 and 4, are reported in terms of recall (R), precision (P), and F-score (F) provided by the three scoring programs. As we can see, this baseline achieves F-scores of 54.3–70.0 and 53.4–62.5 for true mentions and system mentions, respectively.

The entity-mention baseline. Next, we train our second baseline, the entity-mention coreference classifier, using the SVM learner. Results of this baseline are shown in row 2 of Tables 3 and 4. For true mentions, this baseline achieves an F-score of 54.8–70.7. In comparison to the mention-pair baseline, F-score rises insignificantly according to all three scorers.[7] Similar trends can be observed for system mentions, where the F-scores between the two models are statistically indistinguishable across the board. While the insignificant performance difference is somewhat surprising given the improved expressiveness of entity-mention models over mention-pair models, similar trends have been reported by Luo et al. (2004).

The mention-ranking baseline. Our third baseline is the mention-ranking coreference model, trained using the ranker-learning algorithm in SVM^{light}. To identify discourse-new mentions, we employ two methods. In the first method, we adopt a pipeline architecture, where we train an SVM classifier for discourse-new detection independently of the mention ranker on the training set using the 26 features described in Section 3.3. We then apply the resulting classifier to each test text to filter discourse-new mentions prior to coreference resolution. Results of the mention ranker are shown in row 3 of Tables 3 and 4. As we can see, the ranker achieves F-scores of 57.8–71.2 and 54.1–65.4 for true mentions and system mentions, respectively, yielding a significant improvement over the entity-mention baseline in all but one case (MUC/true mentions).

In the second method, we perform discourse-new detection jointly with coreference resolution using the method described in Section 4.2. While we discussed this joint learning method in the context of cluster ranking, it should be easy to see that the method is equally applicable to a mention ranker. Results of the mention ranker using this joint architecture are shown in row 4 of Tables 3 and 4. As we can see, the ranker achieves F-scores of 61.6–73.4 and 55.6–67.1 for true mentions and system mentions, respectively. For both types of mentions, the improvements over the corresponding results for the entity-mention baseline

[6] For this and subsequent uses of the SVM learner in our experiments, we set all parameters to their default values.

[7] We use Approximate Randomization (Noreen, 1989) for testing statistical significance, with p set to 0.05.

Table 4: MUC, CEAF, and B^3 coreference results using system mentions.

are significant, and suggest that mention ranking is a precision-enhancing device. Moreover, in comparison to the pipeline architecture in row 3, we see that F-score rises significantly by 2.2–3.8% for true mentions, and improves by a smaller margin of 0.3–1.7% for system mentions. These results demonstrate the benefits of joint modeling.

Our cluster-ranking model. Finally, we evaluate our cluster-ranking model. As in the mention-ranking baseline, we employ both the pipeline architecture and the joint architecture for discourse-new detection. Results are shown in rows 5 and 6 of Tables 3 and 4, respectively, for the two architectures. When true mentions are used, the pipeline architecture yields an F-score of 61.8–74.8, which represents a significant improvement over the mention ranker adopting the pipeline architecture. With the joint architecture, the cluster ranker achieves an F-score of 63.3–76.0. This also represents a significant improvement over the mention ranker adopting the joint architecture, the best of the baselines, and suggests that cluster ranking is a better precision-enhancing model than mention ranking. Moreover, comparing the results in these two rows reveals the superiority of the joint architecture over the pipeline architecture, particularly in terms of its ability to enhance system precision. Similar performance trends can be observed when system mentions are used.

6 Conclusions

We have presented a cluster-ranking approach that recasts the mention resolution process as the problem of finding the best preceding cluster to link an active mention to. Crucially, our approach combines the strengths of entity-mention models and mention-ranking models. Experimental results on the ACE 2005 corpus show that (1) jointly learning coreference resolution and discourse-new detection allows the cluster ranker to achieve better performance than adopting a pipeline coreference architecture; and (2) our cluster ranker significantly outperforms the mention ranker, the best of the three baseline coreference models, under both the pipeline architecture and the joint architecture. Overall, we believe that our cluster-ranking approach advances the state-of-the-art in coreference resolution both theoretically and empirically.

Abstract

Knowledge of noun phrase anaphoricity might be profitably exploited in coreference resolution to bypass the resolution of non-anaphoric noun phrases. However, it is surprising to notice that recent attempts to incorporate automatically acquired anaphoricity information into coreference resolution have been somewhat disappointing. This paper employs a global learning method in determining the anaphoricity of noun phrases via a label propagation algorithm to improve learning-based coreference resolution. In particular, two kinds of kernels, i.e. the feature-based RBF kernel and the convolution tree kernel, are employed to compute the anaphoricity similarity between two noun phrases. Experiments on the ACE 2003 corpus demonstrate the effectiveness of our method in anaphoricity determination of noun phrases and its application in learning-based coreference resolution.

1 Introduction

Coreference resolution, the task of determining which noun phrases (NPs) in a text refer to the same real-world entity, has long been considered an important and difficult problem in natural language processing. Identifying the linguistic constraints on when two NPs can co-refer remains an active area of research in the community. One significant constraint on coreference, the anaphoricity constraint, specifies that a non-anaphoric NP cannot be coreferent with any of its preceding NPs in a given text. Therefore, it is useful to skip over these non-anaphoric NPs rather than attempt an unnecessary search for an antecedent for them, only to end up with inaccurate outcomes. Although many existing machine learning approaches to coreference resolution have performed reasonably well without explicit anaphoricity determination (e.g., Soon et al 2001; Ng and Cardie 2002b; Strube and Muller 2003; Yang et al 2003, 2008), anaphoricity determination has been studied fairly extensively in the literature, given the potential usefulness of NP anaphoricity in coreference resolution. One common approach involves the design of heuristic rules to identify specific types of non-anaphoric NPs, such as pleonastic pronouns (e.g. Paice and Husk 1987; Lappin and Leass 1994; Kennedy and Boguraev 1996; Denber 1998) and existential definite descriptions (e.g., Vieira and Poesio 2000). More recently, the problem has been tackled using statistics-based (e.g., Bean and Riloff 1999; Bergsma et al 2008) and learning-based (e.g. Evans 2001; Ng and Cardie 2002a; Ng 2004; Yang et al 2005; Denis and Balbridge 2007) methods. Although there is empirical evidence (e.g. Ng and Cardie 2002a, 2004) that coreference resolution might be further improved with proper anaphoricity information, its contribution is still somewhat disappointing and lacks systematic evaluation.

This paper employs a label propagation (LP) algorithm for global learning of NP anaphoricity. Given the labeled data and the unlabeled data, the LP algorithm first represents labeled and unlabeled instances as vertices in a connected graph, then propagates the label information from any vertex to nearby vertices through weighted edges and finally infers the labels of unlabeled instances until a global stable stage is achieved. Here, the labeled data in this paper include all the NPs in the training texts with the anaphoricity labeled and the unlabeled data include all the NPs in a test text with the anaphoricity unlabeled. One major advantage of LP-based anaphoricity determination is that the anaphoricity of all the NPs in a text can be determined together in a global way. Compared with previous methods, the LP algorithm can effectively capture the natural clustering structure in both the labeled and unlabeled data to smooth the labeling function. In particular, two kinds of

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 978–986,
Singapore, 6-7 August 2009.

kernels, i.e. the feature-based RBF kernel and the convolution tree kernel, are employed to compute the anaphoricity similarity between two NPs and weigh the edge between them. Experiments on the ACE 2003 corpus show that our LP-based anaphoricity determination significantly outperforms locally-optimized one, which adopts a classifier (e.g. SVM) to determine the anaphoricity of NPs in a text individually and significantly improves the performance of learning-based coreference resolution. It also shows that, while feature-based anaphoricity determination contributes much to pronoun resolution, its contribution on definite NP resolution can be ignored. In comparison, it shows that tree kernel-based anaphoricity resolution contributes significantly to the resolution of both pronouns and definite NPs due to the inclusion of various kinds of syntactic structured information.

The rest of this paper is organized as follows. In Section 2, we review related work in anaphoricity determination. Then, the LP algorithm is introduced in Section 3 while Section 4 describes different similarity measurements explored in the LP algorithm. Section 5 shows the experimental results. Finally, we conclude our work in Section 6.

2 Related Work

Given its potential usefulness in coreference resolution, anaphoricity determination has been studied fairly extensively in the literature and can be classified into three categories: heuristic rule-based (e.g. Paice and Husk 1987; Lappin and Leass 1994; Kennedy and Boguraev 1996; Denber 1998; Vieira and Poesio 2000), statistics-based (e.g., Bean and Riloff 1999; Cherry and Bergsma 2005; Bergsma et al 2008) and learning-based (e.g. Evans 2001; Ng and Cardie 2002a; Ng 2004; Yang et al 2005; Denis and Balbridge 2007).

For the heuristic rule-based approaches, Paice and Husk (1987), Lappin and Leass (1994), Kennedy and Boguraev (1996), Denber (1998), and Cherry and Bergsma (2005) looked for particular constructions using certain trigger words to identify pleonastic pronouns while Vieira and Poesio (2000) recognized non-anaphoric definite NPs through the use of syntactic cues and case-sensitive rules and found that nearly 50% of definite NPs are non-anaphoric. As a representative, Lappin and Leass (1994), and Kennedy and Boguraev (1996) looked for modal adjectives (e.g. "necessary") or cognitive verbs (e.g. "It is thought that …") in a set of patterned constructions.

For the statistics-based approaches, Bean and Riloff (1999) developed a statistics-based method for automatically identifying existential definite NPs which are non-anaphoric. The intuition behind is that many definite NPs are not anaphoric since their meanings can be understood from general world knowledge. They found that existential NPs account for 63% of all definite NPs and 76% of them could be identified by syntactic or lexical means. Using 1600 MUC-4 terrorism news documents as the training data, they achieved 87% in precision and 78% in recall at identifying non-anaphoric definite NPs. Cherry and Bergsma (2005) extended the work of Lappin and Leass (1994) for large-scale anaphoricity determination by additionally detecting non-anaphoric instances of *it* using Minipar's pleonastic category *Subj*. This is done by both employing Minipar's named entity recognition to identify time expressions, such as "it was midnight…", and providing a number of other linguistic patterns to match common non-anaphoric *it* cases, such as in expressions "darn it" and don't overdo it". Bergsma et al (2008) proposed a distributional method in detecting non-anaphoric pronouns by first extracting the surrounding textual context of the pronoun, then gathering the distribution of words that occurred within that context from a large corpus and finally learning to classify these distributions as representing either anaphoric and non-anaphoric pronoun instances. Experiments on the Science News corpus of It-Bank [1] in identifying non-anaphoric pronoun *it* show that their distributional method achieved the performance of 81.4%, 71.0% and 75.8 in precision, recall and F1-measure, respectively, compared with the performance of 93.4%, 21.0% and 34.3 in precision, recall and F1-measure, respectively using the rule-based approach as described in Lappin and Leass (1994), and the performance of 66.4%, 49.7% and 56.9 in precision, recall and F1-measure, respectively using the rule-based approach as described in Cherry and Bergsma (2005).

Among the learning-based methods, Evans (2001) applied a machine learning approach on identifying the non-anaphoricity of pronoun *it*. Ng and Cardie (2002a) employed various domain-independent features in identifying anaphoric NPs and showed how such information

[1] www.cs.ualberta.ca/~bergsma/ItBank/

can be incorporated into a coreference resolution system. Experiments show that their method improves the performance of coreference resolution by 2.0 and 2.6 to 65.8 and 64.2 in F1-measure on the MUC-6 and MUC-7 corpora, respectively, due to much more gain in precision compared with the loss in recall. Ng (2004) examined the representation and optimization issues in computing and using anaphoricity information to improve learning-based coreference resolution systems. He used an anaphoricity classifier as a filter for coreference resolution. Evaluation on the ACE 2003 corpus shows that, compared with a baseline coreference resolution system of no explicit anaphoricity determination, their method improves the performance by 2.8, 2.2 and 4.5 to 54.5, 64.0 and 60.8 in F1-measure (due to the gain in precision) on the NWIRE, NPAPER and BNEWS domains, respectively, via careful determination of an anaphoricity threshold with proper constraint-based representation and global optimization. However, he did not look into the contribution of anaphoricity determination on coreference resolution of different NP types, such as pronoun and definite NPs. Yang et al (2005) made use of non-anaphors to create a special class of training instances in the twin-candidate model (Yang et al 2003) and thus equipped it with the non-anaphoricity determination capability. Experiments show that the proposed method improves the performance by 2.9 and 1.6 to 67.3 and 67.2 in F1-measure on the MUC-6 and MUC-7 corpora, respectively, due to much more gain in precision compared with the loss in recall. However, surprisingly, their experiments also show that eliminating non-anaphors using an anaphoricity determination module in advance harms the performance. Denis and Balbridge (2007) employed an integer linear programming (ILP) formulation for coreference resolution which models anaphoricity and coreference as a joint task, such that each local model informs the other for final assignments. Experiments on the NWIRE, NPAPER and BNEWS domains of the ACE 2003 corpus shows that this joint anaphoricity-coreference ILP formulation improves the F1-measure by 0.7-1.0 over the coreference-only ILP formulation. However, their experiments assume true ACE mentions(i.e. all the ACE mentions are already known from the annotated corpus). Therefore, the actual effect of this joint anaphoricity-coreference ILP formulation on fully-automatic coreference resolution is still unclear.

3 Label Propagation

In the LP algorithm (Zhu and Ghahramani 2002), the natural clustering structure in data is represented as a connected graph. Given the labeled data and unlabeled data, the LP algorithm first represents labeled and unlabeled instances as vertices in a connected graph, then propagates the label information from any vertex to nearby vertices through weighted edges and finally infers the labels of unlabeled instances until a global stable stage is achieved. Figure 1 presents the label propagation algorithm.

Assume:

Y : the $n*r$ labeling matrix, where y_{ij} represents the probability of vertex $x_i (i = 1 \ldots n)$ with label $r_j (j = 1 \ldots r)$;

Y_L : the top l rows of Y^0. Y_L corresponds to the l labeled instances;

Y_U : the bottom u rows of Y^0. Y_U corresponds to the u unlabeled instances;

$\overline{T}$: a $n*n$ matrix, with $\overline{t}_{ij}$ is the probability jumping from vertex x_i to vertex x_j;

BEGIN (the algorithm)

Initialization:

1) Set the iteration index $t = 0$;
2) Let Y^0 be the initial soft labels attached to each vertex;
3) Let Y_L^0 be consistent with the labeling in the labeled data, where y_{ij}^0 = the weight of the labeled instance if x_i has the label r_j;
4) Initialize Y_U^0;

REPEAT

Propagate the labels of any vertex to nearby vertices by $Y^{t+1} = \overline{T} Y^t$;

Clamp the labeled data, that is, replace Y_L^{t+1} with Y_L^0;

UNTIL Y converges(e.g. Y_L^{t+1} converges to Y_L^0);

Assign each unlabeled instance with a label: for $x_i (l \prec i \le n)$, find its label with $\arg\max_j y_{ij}$;

END (the algorithm)

Figure 1: The LP algorithm

Here, each vertex corresponds to an instance, and the edge between any two instances x_i and x_j is weighted by w_{ij} to measure their similarity. In principle, larger edge weights allow labels to travel through easier. Thus the closer the instances are, the more likely they have similar

labels. The algorithm first calculates the weight w_{ij} using a kernel, then transforms it to $t_{ij} = p(j \to i) = w_{ij} / \sum_{k=1}^{n} w_{kj}$, which measures the probability of propagating a label from instance x_j to instance x_i, and finally normalizes t_{ij} row by row using $\bar{t}_{ij} = t_{ij} / \sum_{k=1}^{n} t_{ik}$ to maintain the class probability interpretation of the labeling matrix Y.

During the label propagation process, the label distribution of the labeled data is clamped in each loop using their initial weights and acts like forces to push out labels through the unlabeled data. With this push originating from the labeled data, the label boundaries will be pushed faster along edges with larger weights and settle in gaps along those with lower weights. Ideally, we can expect that w_{ij} across different classes should be as small as possible and w_{ij} within the same class as big as possible. In this way, label propagation tends to happen within the same class. This algorithm has been shown to converge to a unique solution (Zhu and Ghahramani 2002), which can be obtained without iteration in theory, and the initialization of Y_U^0 (the unlabeled data) is not important since Y_U^0 does not affect its estimation. However, proper initialization of Y_U^0 actually helps the algorithm converge more rapidly in practice. In this paper, each row in Y_U^0, i.e. the label distribution for each test instance, is initialized to the weighted similarity of the test instance with the labeled instances.

4 Kernel-based Similarity

The key issue in label propagation is how to compute the similarity w_{ij} between two instances x_i and x_j. This paper examines two similarity measures: the feature-based RBF kernel and the convolution tree kernel.

Feature Type	Feature	Description
Features related with current NP itself	IsPronoun	1 if current NP is a pronoun, else 0
	IsDefiniteNP	1 if current NP is a define NP, else 0
	IsDemonstrativeNP	1 if current NP is a demonstrative NP, else 0
	IsArg0	1 if the semantic role of current NP is Arg0/agent, else 0
	IsArg0MainVerb	1 if current NP has the semantic role of Arg0/agent for the main predicate of the sentence, else 0
	IsArgs	0 if current NP has no semantic role, else 1
	IsSingularNP	1 if current NP is a singular noun, else 0
	IsMaleFemalePronoun	1 if current NP is a male/female personal pronoun, else 0
Features related with the local context surrounding current NP	StringMatch	1 if there is a full string match between current NP and one of other phrases in the context, else 0
	NameAlias	1 if current NP and one of other phrases in the context is a name alias or abbreviation of the other, else 0
	Appositive	1 if current NP and one of other phrases in the context are in an appositive structure, else 0
	NPNested	1 if current NP is nested in another NP, else 0
	NPNesting	1 if current NP nests another NP, else 0
	WordSenseAgreement	1 if current NP and one of other phrases in the context agree in the WordNet sense, else 0
	IsFirstNPinSentence	1 if current NP is the first NP of this sentence, else 0
	BackwardDistance	The distance between current NP and the nearest backward clause, indicated by coordinating words (e.g. that,which).
	ForwardDistance	The distance between the nearest forward clause, indicated by coordinating words (e.g. that, which), and current NP.

Table 1: Features in anaphoricity determination of NPs. Note: the semantic role-related features are derived from an in-house state-of-the-art semantic role labeling system.

4.1 Feature-based Kernel

In our feature-based RBF kernel to anaphoricity determination, an instance is represented by 17 lexical, syntactic and semantic features, as shown in Table 1, which are specifically designed for distinguishing anaphoric and non-anaphoric NPs, according to common-sense knowledge and linguistic intuitions. Since the local context surrounding an NP plays a critical role in discriminating whether an NP is anaphoric or not, the features in Table 1 can be classified into two categories: (a) current NP (i.e. the NP in anaphoricity consideration) itself, e.g.

types and semantic roles of current NP; (b) contextual information, e.g. whether current NP is nested in another NP, the distance between current NP and a clause structure, indicated by coordinating words (e.g. that, this, which).

4.2 Tree Kernel

Given a NP in anaphoricity determination, a parse tree represents the local context surrounding current NP in a structural way and thus contains much information in determining whether current NP is anaphoric or not. For example, the commonly used knowledge for anaphoricity determination, such as the grammatical role of current NP or whether current NP is nested in other NPs, can be directly captured by a parse tree structure.

Given a parse tree and a NP in consideration, the problem is how to choose a proper parse tree structure to cover syntactic structured information well in the tree kernel computation. Generally, the more a parse tree structure includes, the more syntactic structured information would be provided, at the expense of more noisy/unnecessary information. In this paper, we limit the window size to 5 chunks (either NPs or non-NPs), including previous two chunks, current chunk (i.e. current NP) and following two chunks, and prune out the substructures outside the window. Figure 2 shows the full parse tree for the sentence "Mary said the woman in the room hit her too", using the Charniak parser (Charniak 2001), and the chunk sequence derived from the parse tree using the Perl script[2] written by Sabine Buchholz from Tilburg University.

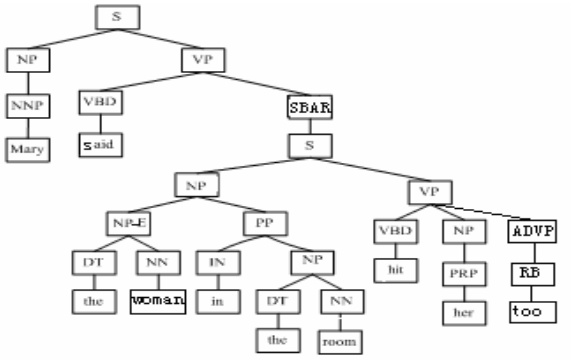
Here, we explore four parse tree structures in NP anaphoricity determination: the common tree (CT), the shortest path-enclosed tree (SPT), the minimum tree (MT) and the dynamically extended tree (DET), motivated by Yang et al (2006) and Zhou et al (2008). Following are the examples of the four parse tree structures, corresponding to the full parse tree and the chunk sequence, as shown in Figure 2, with the NP chunk "(NP (DT the) (NN woman))" in anaphoricity determination.

Common Tree (CT)

As shown in Figure 3(a), CT is the complete sub-tree rooted by the nearest common ancestor of the first chunk "(NP (NNP Mary))" and the last chunk "(NP (DT the) (NN room))" of the five-chunk window.

Shortest Path-enclosed Tree (SPT)

As shown in Figure 3(b), SPT is the smallest common sub-tree enclosed by the shortest path between the first chunk "(NP (NNP Mary))" and the last chunk "(NP (DT the) (NN room))" of the five-chunk window.

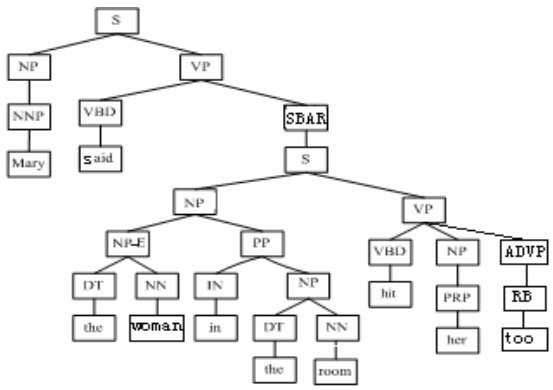


(a) the full parse tree

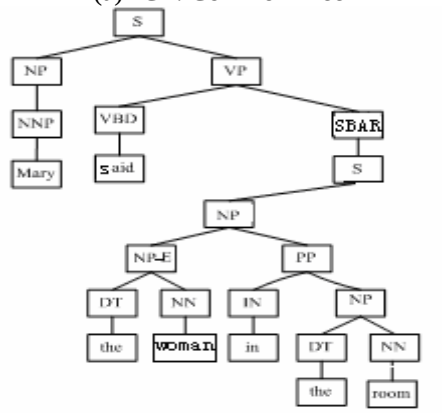
(NP (NNP Mary)) (VP (VBD said)) ***(NP-E (DT the) (NN woman))*** (PP (IN in)) (NP (DT the) (NN room)) (VP (VBD hit)) (NP (PRP her)) (ADVP (RB too))

(b) the chunk sequence

Figure 2: The full parse tree for the sentence "Mary said the woman in the room hit her too", using the Charniak parser, and the corresponding chunk sequence derived from it. Here, the label "E" indicates the NP in consideration.

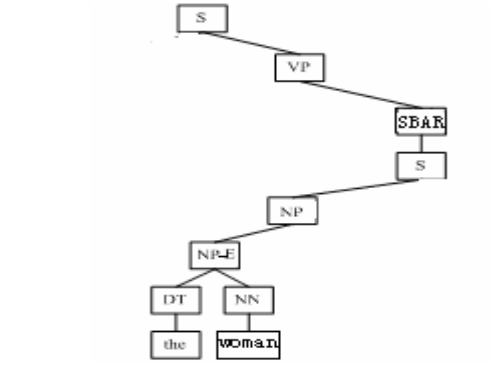


(a) CT: Common Tree

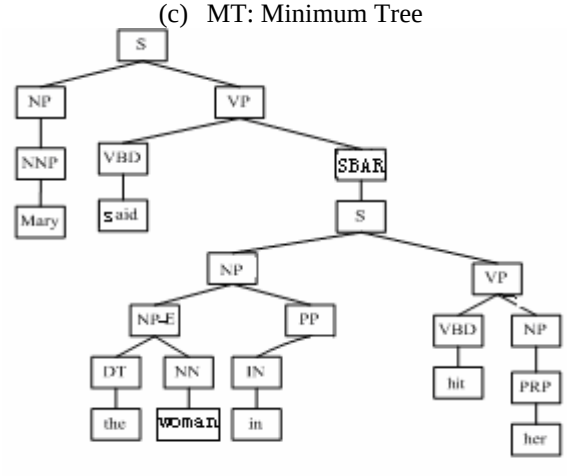


(b) SPT: Shortest Path-enclosed Tree

[2] http://ilk.kub.nl/~sabine/chunklink/



(c) MT: Minimum Tree



(d) DET: Dynamically Extended Tree

Figure 3: Examples of parse tree structures.

Minimum Tree (MT)

As shown in Figure 3(c), MT only keeps the root path from the NP in anaphoricity determination to the root node of SPT.

Dynamically Extended Tree (DET),

The intuitions behind DET are that the information related with antecedent candidates (all the antecedent candidates compatible[3] with current NP in anaphoricity consideration), predicates[4] and right siblings plays a critical role in coreference resolution. Given a MT, this is done by:

1) Attaching all the compatible antecedent candidates and their corresponding paths. As shown in Figure 3(d), "Mary" is attached while "the room" is not since the former is compatible with the NP "the woman" and the latter is not compatible with the NP "the woman". In this way, possible coreference between current NP and the compatible antecedent candidates can be included in the parse tree structure. In some sense, this is a natural extension of the twin-candidate learning method proposed in Yang et al (2003), which explicitly models the competition between two antecedent candidates.
2) For each node in MT, attaching the path from the node to the leaf node of the corresponding predicate, if it is predicate-headed, in the sense that such predicate-related information is useful in identifying certain kinds of expressions with non-anaphoric NPs, e.g. the non-anaphoric *it* in "darn it". As shown in Figure 3(d), "said" and "hit" are attached.
3) Attaching the path to the head word of the first right sibling if the parent of current NP is a NP and current NP has one or more right siblings. Normally, the NP in anaphoricity consideration, NP-E, in the production of "NP->NP-E+PP" introduces a new entity and thus non-anaphoric.
4) Pruning those nodes (except POS nodes) with the single in-arc and the single out-arc and with its syntactic phrase type same as its child node.

In this paper, the similarity between two parse trees is measured using a convolution tree kernel, which counts the number of common sub-trees as the syntactic structure similarity between two parse trees. For details, please refer to Collins and Duffy (2001).

5 Experimentation

We have systematically evaluated the label propagation algorithm on global learning of NP anaphoricity determination on the ACE 2003 corpus, and its application in coreference resolution.

5.1 Experimental Setting

The ACE 2003 corpus contains three domains: newswire (NWIRE), newspaper (NPAPER), and broadcast news (BNEWS). For each domain, there exist two data sets, training and devtest, which are used for training and testing respectively.

As a baseline coreference resolution system, a raw test text is first preprocessed automatically by a pipeline of NLP components, including sentence boundary detection, POS tagging, named entity recognition and phrase chunking, and then a training or test instance is formed by a anaphor and one of its antecedent candidates, similar to Soon et al (2001). Among them, named entity recognition, part-of-speech tagging and noun phrase chunking apply the same Hidden Markov Model (HMM)-based engine with

[3] With matched number, person and gender agreements.

[4] For simplicity, only verbal predicates are considered in this paper. However, this can be extended to nominal predicates with automatic identification of nominal predicates.

error-driven learning capability (Zhou and Su, 2000 & 2002). During training, for each anaphor encountered, a positive instance is created by pairing the anaphor and its closest antecedent while a set of negative instances is formed by pairing the anaphor with each of the non-coreferential candidates. Based on the training instances, a binary classifier is generated using a particular learning algorithm. In this paper, we use SVMLight developed by Joachims (1998). During resolution, an anaphor is first paired in turn with each preceding antecedent candidate to form a test instance, which is presented to a classifier. The classifier then returns a confidence value indicating the likelihood that the candidate is the antecedent. Finally, the candidate with the highest confidence value is selected as the antecedent. As a baseline, the NPs with mismatched number, person and gender agreements are filtered out. On average, an anaphor has ~7 antecedent candidates. In particular, the test corpus is resolved in document-level, i.e. one document by one document.

For anaphoricity determination, we report the performance in Acc^+ and Acc^-, which measure the accuracies of identifying anaphoric NPs and non-anaphoric NPs, respectively. Obviously, higher Acc^+ means that more anaphoric NPs would be identified correctly, while higher Acc^- means that more non-anaphoric NPs would be filtered out. For coreference resolution, we report the performance in terms of recall, precision, and F1-measure using the commonly-used model theoretic MUC scoring program (Vilain et al., 1995). For separate scoring of different NP types, a recognized reference is considered correct if the reconized antecedent is in the coreferential chain of the anaphor. To see whether an improvement is significant, we conduct significance testing using paired t-test. In this paper, '>>>', '>>' and '>' denote p-values of an improvement smaller than 0.01, in-between (0.01, 0,05] and bigger than 0.05, which mean significantly better, moderately better and slightly better, respectively.

5.2 Experimental Results

Table 2 shows the performance of LP-based anaphoricity determination using the feature-based RBF kernel. It shows that our method achieves the accuracies of 74.8/84.4, 76.2/81.3 and 71.8/81.7 on identifying anaphoric/non-anaphoric NPs in the NWIRE, NPAPER and BNEWS domains, respectively. This suggests that our approach can effectively filter out about 82% of non-anaphoric NPs. However, it can only keep about 74% of anaphoric NPs. Table 2 also shows the performance on different NP types. Considering the effectiveness of anaphoricity determination on indefinite NPs (due to that most of anaphoric indefinite NPs are in an appositive structure and thus can be easily captured by the IsAppositive feature) and that most of errors in anaphoricity determination on proper nouns are caused by the named entity recognition module in the preprocessing), it indicates the difficulty of anaphoricity determination in filtering out non-anaphoric pronouns and identifying anaphoric definite NPs. As a comparison, Table 2 also shows the performance of locally-optimized anaphoricity determination using a classifier (SVM with the feature-based RBF kernel, as adopted in this paper) to determine the NPs in a text individually. It shows that the LP-based method systematically outperforms (>>>) the SVM-based method. This suggests the effectiveness of the LP algorithm in global modeling of the natural clustering structure in anaphoricity determination.

Table 3 shows the performance of LP-based anaphoricity determination using the convolution tree kernel on different parse tree structures. It shows that while MT performed worst due to its simple structure, DET outperforms MT(>>>), SPT(>>>) and CT(>>>) on all the three domains due to fine inclusion of necessary structural information, although inclusion of more information in both CT and SPT also improves the performance. It again verifies that LP-based anaphoricity determination outperforms (>>>) SVM-based one, using the tree kernel. Table 4 further indicates that all the three kinds of structural information related with antecedent candidates, predicates and right siblings in DET contribute significantly (>>>). In addition, Table 5 shows the detailed performance of LP-based anaphoricity determination on different anaphor types using DET. Compared with the feature-based RBF kernel as shown in Table 2, it shows that the convolution tree kernel significantly outperforms (>>>) the feature-based RBF kernel in all the three domains, with much contribution due to performance improvement on both pronouns and definite NPs, although the tree kernel performs moderately worse than the feature-based RBF kernel due to the effectiveness of anaphoricity determination on proper nouns and indefinite NPs using the IsNameAlias and IsAppositive features respectively.

Overall	79.2	87.8	81.2	84.5	76.5	85.3

Table 5: The performance of LP-based anaphoricity determination using the tree kernel on DET

Finally, we evaluate the effect of LP-based anaphoricity determination on coreference resolution by including it as a preprocessing step to a baseline coreference resolution system without explicit anaphoricity determination, which employs the same set of features, as adopted in the single-candidate model of Yang et al (2003), using a SVM-based classifier and the feature-based RBF kernel. It shows that anaphoricity determination with the feature-based RBF Kernel much improves (>>>) the performance of coreference resolution with most of the contribution due to pronoun resolution while its contribution on definite NPs can be ignored. It indicates the usefulness of anaphoricity determination in filtering out non-anaphoric pronouns and the difficulty in identifying anaphoric definite NPs, using the feature-based RBF kernel. It also shows that tree kernel-based anaphoricity determination can not only improve (>>>) the performance on pronoun resolution but also improve (>>>) the performance on definite NP resolution due to the much better performance of tree kernel-based anaphoricity determination on definite NPs. This suggests the necessity of exploring structural information in identifying anaphoric definite NPs.

6 Conclusion

This paper systematically studies a global learning method in identifying the anaphoricity of noun phrases via a label propagation algorithm and the application of an explicit anaphoricity determination module in improving learning-based coreference resolution. In particular, two kinds of kernels, i.e. the feature-based RBF kernel and the convolution tree kernel, are employed to compute the anaphoricity similarity

between two NPs. Evaluation on the ACE 2003 corpus indicates that LP-based anaphoricity determination using both the kernels much improves the performance of coreference resolution. It also shows the usefulness of various structural information, related with antecedent candidates, predicates and right siblings, in tree kernel-based anaphoricity determination and in coreference resolution of both pronouns and definite NPs.

To our knowledge, this is the first systematic exploration of both feature-based and tree kernel methods in anaphoricity determination and the application of an explicit anaphoricity determination module in learning coreference resolution.

Abstract

In this paper, we employ the centering theory in pronoun resolution from the semantic perspective. First, diverse semantic role features with regard to different predicates in a sentence are explored. Moreover, given a pronominal anaphor, its relative ranking among all the pronouns in a sentence, according to relevant semantic role information and its surface position, is incorporated. In particular, the use of both the semantic role features and the relative pronominal ranking feature in pronoun resolution is guided by extending the centering theory from the grammatical level to the semantic level in tracking the local discourse focus. Finally, detailed pronominal subcategory features are incorporated to enhance the discriminative power of both the semantic role features and the relative pronominal ranking feature. Experimental results on the ACE 2003 corpus show that the centering-motivated features contribute much to pronoun resolution.

1 Introduction

Coreference accounts for cohesion in a text and is, in a sense, the hyperlink for a natural language. Especially, a coreference instance denotes an identity of reference and holds between two referring expressions, which can be named entities, definite noun phrases, pronouns and so on. Coreference resolution is the process of linking together multiple referring expressions of a given entity in the world. The key in coreference resolution is to determine the antecedent for each referring expression in a text. The ability of linking referring expressions both within a sentence and across the sentences in a text is critical to discourse and language understanding in general. For example, coreference resolution is a key task in information extraction, machine translation, text summarization, and question answering.

There is a long tradition of research on coreference resolution within computational linguistics. While earlier knowledge-lean approaches heavily depend on domain and linguistic knowledge (Carter 1987; Carbonell and Brown 1988) and have significantly influenced the research, the later approaches usually rely on diverse lexical, syntactic and semantic properties of referring expressions (Soon et al., 2001;Ng and Cardie, 2002; Zhou et al., 2004). Current research has been focusing on exploiting semantic information in coreference resolution. For example, Yang et al (2005) proposed a template-based statistical approach to compute the semantic compatibility between a pronominal anaphor and an antecedent candidate, and Yang and Su (2007) explored semantic relatedness information from automatically discovered patterns, while Ng (2007) automatically induced semantic class knowledge from a treebank and explored its application in coreference resolution.

Particularly, this paper focuses on the centering theory (Sidner,1981;Grosz et al.,1995; Tetreault,2001), which reveals the significant impact of the local focus on referring expressions in that the antecedent of a referring expression usually depends on the center of attention throughout the local discourse segment (Mitkov,1998). Although the centering theory has been considered as a critical theory and the driving force behind the coreferential phenomena since its proposal, its application in coreference resolution (in particular pronoun resolution) has been somewhat disappointing: it fails to improve or even harms the performance of the state-of-

Singapore, 6-7 August 2009.

the-art coreference resolution systems in previous research (e.g. Yang et al. 2004). This may be due to that centering was originally proposed as a model of discourse coherence instead of coreference.

The purpose of this paper is to employ the centering theory in pronoun resolution by extending it from the grammatical level to the semantic level. The intuition behind our approach is that, via determining the semantic roles of referring expressions in a sentence, such as agent and patient, we can derive various centering theory-motivated features in tracking the continuity or shift of the local discourse focus, thus allowing us to include document-level event descriptive information in resolving the coreferential relations between referring expressions.

To the best of our knowledge, this is the first research, which successfully applies the centering theory in pronoun resolution from the semantic perspective.

The rest of this paper is organized as follows. Section 2 briefly describes related work in employing the centering theory and semantic information in coreference resolution. Then, the centering theory is introduced in Section 3 while Section 4 details how to employ the centering theory from the semantic perspective. Section 5 reports and discusses the experimental results. Finally, we conclude our work in Section 6.

2 Related Work

This section briefly overviews the related work in coreference resolution from both the centering theory and semantic perspectives.

2.1 Centering Theory

In the literature, there has been much research in the centering theory and its application to coreference resolution.

In the centering theory itself, since the original work of Sidner (1979) on immediate focusing of pronouns and the subsequent work of Joshi and Weinstein (1981) on centering and inferences, much research has been done, including centering and linguistic realizations (Cote 1993; Prince and Walker 1995), empirical and psycholinguistic evaluation of centering predictions (Gordon et al 1993,1995; Brennan 1995; Walker et al 1998; Kibble 2001), and the cross-linguistic work on centering (Ziv and Crosz1994).

In applications of the centering theory to coreference resolution, representative work includes Brennan et al. (1987), Strube (1998), Tetreault (1999) and Yang et al. (2004). Brennan et al. (1987) presented a centering theory-based formalism in modeling the local focus structure in discourse and used it to track the discourse context in binding occurring pronouns to corresponding entities. In particular, a BFP (Brennan, Friedman and Pollard) algorithm is proposed to extend the original centering model to include two additional transitions called smooth shift and rough shift. Strube (1998) proposed an S-list model, assuming that a referring expression prefers a hearer-old discourse entity to other hearer-new candidates. Tetreault (1999) further advanced the BFP algorithm by adopting a left-to-right breadth first walk of the syntactic parse trees to rank the antecedent candidates. However, the above methods have not been systematically evaluated on large annotated corpora, such as MUC and ACE. Thus their effects are still unclear in real coreference resolution tasks. Yang et al (2004) presented a learning-based approach by incorporating several S-list model-based features to improve the performance in pronoun resolution. It shows that, although including S-list model-based features can slightly boost the performance in the ideal case (i.e. given the correct antecedents of anaphor's candidates), it deteriorates the overall performance in F-measure with slightly higher precision but much lower recall, in real cases, where the antecedents of anaphor's candidates are determined automatically by a separate coreference resolution module.

2.2 Semantic Information

It is well known that semantic information plays a critical role in coreference resolution. Besides the common practice of employing a thesaurus (e.g. WordNet) in semantic consistency checking, much research has been done to explore various kinds of semantic information, such as semantic similarity (Harabagiu et al 2000), semantic compatibility (Yang et al 2005, 2007), and semantic class information (Soon et al 2001; Ng 2007). Although these methods have been proven useful in coreference resolution, their contributions are much limited. For example, Ng (2007) showed that semantic similarity information and semantic agreement information could only improve the performance of coreference resolution by 0.6 and 0.5 in F-measure respectively, on the ACE 2003 NWIRE corpus.

3 Centering Theory

The centering theory is a theory about the local discourse structure that models the interaction of referential continuity and the salience of discourse entities in the internal organization of a text. In natural languages, a given entity may be referred by different expressions and act as different grammatical roles throughout a text. For example, people often use pronouns to refer to the main subject of the discourse in focus, which can change over different portions of the discourse. One main goal of the centering theory is to track the focus entities throughout a text.

The main claims of the centering theory can be formalized in terms of C_b (the backward-looking center), C_f (a list of forward-looking centers for each utterance U_n) and C_p (the preferred center, i.e. the most salient candidate for subsequent utterances). Given following two sentences: 1) Susan^i gave Betsy^j a pet hamster^k; 2) She$_i$ reminded her$_j$ that such hamsters$_k$ were quite shy. We can have U_b, U_f and U_p as follows: U_b= "Susan"; U_f={"Susan", "Betsy", "a pet hamster"}; U_p= "Susan".

	$C_b(U_n)=C_b(U_{n-1})$ or $C_b(U_{n-1})$ undefined	$C_b(U_n)\neq C_b(U_{n-1})$
$C_b(U_n)=C_p(U_n)$	Continue	Smooth Shift
$C_b(U_n)\neq C_p(U_n)$	Retain	Rough Shift

Table 1: Transitions in the centering theory

Constraints
C1. There is precisely one C_b.
C2. Every element of $C_f(U_n)$ must be realized in U_n.
C3. $C_b(U_n)$ is the highest-ranked element of $C_f(U_{n-1})$ that is realized in U_n.
Rules
R1. If some element of $C_f(U_{n-1})$ is realized as a pronoun in U_n, then so is $C_b(U_n)$.
R2. Transitions have the descending preference order of "Continue > Retain > Smooth Shift > Rough Shift".

Table 2: Constraints and rules in the centering theory

Furthermore, several kinds of focus transitions are defined in terms of two tests: whether C_b stays the same (i.e. $C_b(U_{n+1})=C_b(U_n)$), and whether C_b is realized as the most prominent referring expression (i.e. $C_b(U_n=C_p(U_n))$. We refer to the first test as cohesion, and the second test as salience. Therefore, there are four possible combinations, which are displayed in Table 1 and can result in four kinds of transitions, namely Continue, Retain, Smooth Shift, and Rough Shift. Obviously, salience, which chooses a proper verb form to make C_b prominent within a clause or sentence, is an important matter for sentence planning, while cohesion, which orders propositions in a text to maintain referential continuity, is an important matter for text planning.

Finally, the centering theory imposes several constraints and rules over C_b/C_f and above transitions, as shown in Table 2.

Given the centering theory as described above, we can draw the following conclusions:

1) The centering theory is discourse-related and centers are discourse constructs.
2) The backward-looking center C_b of U_n depends only on the expressions that constitute the utterance. That is, it is independent of its surface position and grammatical roles. Moreover, it is not constrained by any previous utterance in the segment. While the elements of $C_f(U_n)$ are partially ordered to reflect relative prominence in U_n, grammatical role information is often a major determinant in ranking C_f, e.g. in the descending priority order of "Subject > Object > Others" in English (Grosz and Joshi, 2001).
3) Psychological research (Gordon et al. 1993) and cross-linguistic research (Kameyama 1986, 1988; Walker et al. 1990,1994) have validated that C_b is preferentially realized by a pronoun in English.
4) Frequent rough shifts would lead to a lack of local cohesion. To keep local cohesion, people tend to plan ahead and minimize the number of focus shifts.

In this paper, we extend the centering theory from the grammatical level to the semantic level in attempt to better model the continuity or shift in the local discourse focus and improve the performance of pronoun resolution via centering-motivated semantic role features.

4 Employing Centering Theory from Semantic Perspective

In this section, we discuss how to employ the centering theory in pronoun resolution from the semantic perspective. In Subsection 4.1, we introduce the semantic roles. In Subsection 4.2, we introduce how to employ the centering theory in pronoun resolution via semantic role features. Finally we compare our method with the previous work in Subsection 4.3.

4.1 Semantic Role

A semantic role is the underlying relationship that a participant has with a given predicate in a clause, i.e. the actual role a participant plays in

an event, apart from linguistic encoding of the situation. If, in some situation, someone named "John" purposely hits someone named "Bill", then "John" is the agent and "Bill" is the patient of the hitting event. Therefore, given the predicate "hit" in both of the following sentences, "John" has the same semantic role of agent and "Bill" has the same semantic role of patient: 1) John hit Bill. 2) Bill was hit by John.

In the literature, labeling of such semantic roles has been well defined by the SRL (Semantic Role Labeling) task, which first identifies the arguments of a given predicate and then assigns them appropriate semantic roles. During the last few years, there has been growing interest in SRL. For example, CoNLL 2004 and 2005 have made this problem a well-known shared task. However, there is still little consensus in the linguistic and NLP communities about what set of semantic role labels are most appropriate. Typical semantic roles include core roles, such as agent, patient, instrument, and adjunct roles (such as locative, temporal, manner, and cause). For core roles, only agent and patient are consistently defined across different predicates, e.g. in the popular PropBank (Palmer et al. 2005) and the derived version evaluated in the CoNLL 2004 and 2005 shared tasks, as ARG0 and ARG1.

In this paper, we extend the centering theory from the grammatical level to the semantic level for its better application in pronoun resolution via proper semantic role features due to three reasons:

Sentence	Grammatical Role	Semantic Role
Bob opened the door with a key.	Bob: SUBJECT	Bob: AGENT
The key opened the door.	The key: SUBJECT	The key : INSTRUMENT
The door opened.	The door: SUBJECT	The door: PATIENT

Table 3: Relationship between grammatical roles and semantic roles: an example

1) Semantic roles are conceptual notions, whereas grammatical roles are morph-syntactic. While the original centering theory mainly builds from the grammatical perspective and grammatical roles do not always correspond directly to semantic roles (Table 3 shows an example of various semantic roles which a subject can play), there is a close relationship between semantic roles and grammatical roles. The statistics in the CoNLL 2004 and 2005 shared tasks (Shen and Lapata, 2007) shows that the semantic roles of ARG0/agent and ARG1/patient account for 85% of all arguments and most likely act as the centers of the local focus structure in discourse due to the close relationship between subject/object and agent/patient. Therefore, it is appropriate to model the centers of an utterance from the semantic perspective via semantic roles.
2) In a sense, semantic roles imply the information of grammatical roles, especially for subject/object. For example, the position of an argument and the voice of the predicate verb play a central role in SRL. In intuition, an argument, which occurs before an active verb and has the semantic role of Arg0/agent, tends to be a subject. That is to say, semantic roles (e.g. Arg0/agent and Arg1/patient) can be mapped into their corresponding grammatical roles (e.g. subject and object), using some heuristic rules. Therefore, it would be interesting to represent the centers of the utterances and employ the centering theory from the semantic perspective.
3) Semantic role labeling has been well studied in the literature and there are good ready-to-use toolkits available. For example, Pradhan (2005) achieved 82.2 in F-measure on the CoNLL 2005 version of the Propbank. In contrast, the research on grammatical role labeling is much less with the much lower state-of-the-art performance of 71.2 in F-measure (Buchholz, 1999). Therefore, it may be better to explore the centering theory from the semantic perspective.

4.2 Designing Centering-motivated Features from Semantic Perspective

In this paper, the centering theory is employed in pronoun resolution via three kinds of centering-motivated features:

1) Semantic role features. They are achieved by checking possible semantic roles of referring expressions with regard to various predicates in a sentence. Due to the close relationship between subject/object and agent/patient, semantic role information should be also a major determinant in deciding the center of an utterance, which is likely to be the antecedent of a referring expression in the descending priority order of "Agent > Patient > Others" with regard to their semantic roles, corresponding to the descending priority order of "Subject > Object > Others" with regard to their grammatical roles.

2) Relative pronominal ranking feature. Due to the predominance of pronouns in tracking the local discourse structure[1], the relative ranking of a pronoun among all the pronouns in a sentence should be useful in pronoun resolution. This is realized in this paper according to its semantic roles (with regard to various predicates in a sentence) and surface position (in a left-to-right order) by mapping each pronoun into 5 levels: a) rank 1 for pronouns with semantic role ARG0/agent of the main predicate; b) rank 2 for pronouns with semantic role ARG1/patient of the main predicate; c) rank 3 for pronouns with semantic role ARG0/agent of other predicates; d) rank 4 for pronouns with semantic role ARG1/patient of other predicates; e) rank 5 for remaining pronouns. Furthermore, for those pronouns with the same ranking level, they are ordered according to their surface positions in a left-to-right order, motivated by previous research on the centering theory (Grosz et al. 1995).
3) Detailed pronominal subcategory features. Given a pronominal expression, its detailed pronominal subcategory features, such as whether it is a first person pronoun, second person pronoun, third person pronoun, neuter pronoun or others, are explored to enhance the discriminative power of both the semantic role features and the relative pronominal ranking feature, considering the predominant importance of pronouns in tracking the local focus structure in discourse.

4.3 Comparison with Previous Work

As a representative in explicitly employing semantic role labeling in coreference resolution, Ponzetto and Strube (2006) explored two semantic role features to capture the predicate-argument structure information to benefit coreference resolution: I_SEMROLE, the predicate-argument pairs of one referring expression, and J_SEMROLE, the predicate-argument pairs of another referring expression. Their experiments on the ACE 2003 corpus shows that, while the two semantic role features much improve the performance of common noun resolution by 3.8 and 2.7 in F-measure on the BNEWS and NWIRE domains respectively, they only slightly improve the performance of pronoun resolution by 0.4 and 0.3 in F-measure on the BNEWS and NWIRE domains respectively.

In comparison, this paper proposes various kinds of centering-motivated semantic role features in attempt to better model the continuity or shift in the local discourse focus by extending the centering theory from the grammatical level to the semantic level. For example, the CAARG0MainVerb feature (as shown in Table 5) is designed to capture the semantic role of the antecedent candidate in the main predicate in modeling the discourse center, while, the ANPronounRanking feature (as shown in Table 5) is designed to determinate the relative priority of the pronominal anaphor in retaining the discourse center.

Although both this paper and Ponzetto and Strube (2006) employs semantic role features, their ways of deriving such features are much different due to different driving forces/motivations behind. As a result, their contributions on coreference resolution are different: while the semantic role features in Ponzette and Strube (2006) captures the predicate-argument structure information and contributes much to common noun resolution and their contribution on pronoun resolution can be ignored, the centering-motivated semantic role features in this paper contribute much in pronoun resolution. This justifies our attempt to better model the continuity or shift of the discourse focus in pronoun resolution by extending the centering theory from the grammatical level to the semantic level and employing the centering-motivated features in pronoun resolution..

5 Experimentation and Discussion

We have evaluated our approach of employing the centering theory in pronoun resolution from the semantic perspective on the ACE 2003 corpus.

5.1 Experimental Setting

The ACE 2003 corpus contains three domains: newswire (NWIRE), newspaper (NPAPER), and broadcast news (BNEWS). For each domain, there exist two data sets, training and devtest, which are used for training and testing respectively. Table 4 lists the pronoun distributions with coreferential relationships in the training data and the test data over pronominal subcategories and sentence distances. Table 4(a) shows that third person pronouns occupy most and neu-

[1] According to the centering theory, the backward-looking center C_b is preferentially realized by a pronoun in the subject position in natural languages, such as English, and people tend to plan ahead and minimize the number of focus shifts.

tral pronouns occupy second while Table 4(b) shows that the antecedents of most pronouns occur within the current sentence and the previous sentence, with a little exception in the test data set of BNEWS.

Pronoun Subcategory	NWIRE		NPAPER		BNEWS	
	Train	Test	Train	Test	Train	Test
First Person	263	103	283	120	455	258
Second Person	61	16	29	36	203	68
Third Person	618	179	919	263	736	158
Neuter	395	151	577	190	482	137
Reflexive	23	6	42	12	26	6
Other	0	0	2	0	2	3

(a) Distribution over pronominal subcategories

Distance	NWIRE		NPAPER		BNEWS	
	Train	Test	Train	Test	Train	Test
0	890	254	1281	347	1149	295
1	447	149	529	197	729	188
2	0	27	0	24	0	41

Total	1337	449	1810	609	1878	624

(b) Distribution over sentence distances

Table 4: Pronoun statistics on the ACE 2003 corpus

For preparation, all the documents in the corpus are preprocessed automatically using a pipeline of NLP components, including tokenization and sentence segmentation, named entity recognition, part-of-speech tagging and noun phrase chunking. Among them, named entity recognition, part-of-speech tagging and noun phrase chunking apply the same Hidden Markov Model (HMM)-based engine with error-driven learning capability (Zhou and Su, 2000 & 2002). In particular for SRL, we use a state-of-the-art in-house toolkit, which achieved the precision of 87.07% for ARG0 identification and the precision of 78.97% for ARG1 identification, for easy integration. In addition, we use the SVM-light[2] toolkit with the radial basis kernel and default learning parameters. Finally, we report the performance in terms of recall, precision, and F-measure, where precision measures the percentage of correctly-resolved pronouns (i.e. correctly linked with any referring expression in the coreferential chain), recall measures the coverage of correctly-resolved pronouns, and F-measure gives an overall figure on equal harmony between precision and recall. To see whether an improvement is significant, we also conduct significance testing using paired t-test. In this paper, '>>>', '>>' and '>' denote p-values of an improvement smaller than 0.01, in-between (0.01, 0,05] and bigger than 0.05, which mean significantly better, moderately better and slightly better, respectively.

[2] http://svmlight.joachims.org/

5.2 Experimental Results

Table 5 details various centering-motivated features from the semantic perspective, which are incorporated in our final system. For example, the CAARG0MainVerb feature is designed to capture the semantic role of the antecedent candidate in the main predicate in modeling the discourse center, while the ANPronounRanking feature is designed to determinate the relative priority of the pronominal anaphor in retaining the discourse center. As the baseline, we duplicated the representative system with the same set of 12 basic features, as described in Soon et al (2001). Table 6 shows that our baseline system achieves the state-of-the-art performance of 62.3, 65.3 and 59.0 in F-measure on the NWIRE, NPAPER and BNEWS domains, respectively. It also shows that the centering-motivated features (from the semantic perspective) significantly improve the F-measure by 3.6(>>>), 4.5(>>>) and 7.7(>>>) on the NWIRE, NPAPER and BNEWS domains, respectively. This justifies our attempt to model the continuity or shift of the discourse focus in pronoun resolution via centering-motivated features from the semantic perspective. For comparison, we also evaluate the performance of our final system from the grammatical perspective. This is done by replacing semantic roles with grammatical roles in deriving centering-motivated features. Here, labeling of grammatical roles is achieved using a state-of-the-art toolkit, as described in Buchholz (1999). Table 6 shows that properly employing the centering theory in pronoun resolution from the grammatical perspective can also improve the performance. However, the performance improvement of employing the centering theory from the grammatical perspective is much lower, compared with that from the semantic perspective. This validates our attempt of employing the centering theory in pronoun resolution from the semantic perspective instead of from the grammatical perspective. This also suggests the great potential of applying the centering theory in pronoun resolution since the centering theory is a local coherence theory, which tells how subsequent utterances in a text link together.

Table 7 shows the contribution of the semantic role features and the relative pronominal ranking feature in pronoun resolution when the detailed pronominal subcategory features are included:

Feature category	Feature	Remarks
Semantic Role-based Features	CAARG0	1 if the semantic role of the antecedent candidate is ARG0/agent; else 0
	CAARG0MainVerb	1 if the antecedent candidate has the semantic role of ARG0/agent for the main predicate of the sentence; else 0
	ANCASameTarget	1 if the anaphor and the antecedent candidate share the same predicate with regard to their semantic roles; else 0
Relative Pronominal Ranking Feature	ANPronounRanking	Whether the pronominal anaphor is ranked highest among all the pronouns in the sentence
Detailed Pronominal Subcategory Features	ANPronounType	Whether the anaphor is a first person, second person, third person, neuter pronoun or others
	CAPronounType	Whether the antecedent candidate is a first person, second person, third person, neuter pronoun or others

Table 7: Contribution of the semantic role features (SR) and the relative pronominal ranking feature (PR) in pronoun resolution when the detailed pronominal subcategory features are included

1) The inclusion of the semantic role features improve the performance by 4.0(>>>), 4.6(>>>) and 7.3(>>>) in F-measure on the NWIRE, NPAPER and BNEWS domains, respectively. This suggests the impact of semantic role information in determining the local discourse focus. Since pronouns preferentially occur in the subject position and tend to refer to the main subject (Ehrlich 1980; Brennan 1995; Walker et al. 1998; Cahn 1995; Gordon and Searce 1995; Kibble et al. 2001), this paper only applies semantic features related with the semantic role of ARG0/agent, which is closely related with the grammatical role of subject, with regard to various predicates in a sentence. We have also explored features related with other semantic roles. However, our preliminary experimentation shows that they do not improve the performance, even for ARG1/patient, and thus are not included in the final system. This may be due to that other semantic roles are not discriminative enough to make a difference in deciding the local discourse structure.
2) It is surprising to notice that further inclusion of the relative pronominal ranking feature has only slight impact (slight positive impact on the BNEWS domain and slight negative impact on the NWIRE and NPAPER domains) on the ACE 2003 corpus. This suggests that most of information in the relative pronominal ranking feature has been covered by the semantic role features. This is not surprising since the semantic role of ARG0/agent, which is explored to derive the semantic role features, is also applied to decide the relative pronominal ranking feature.

The inclusion of the relative pronominal ranking feature improve the performance by 1.1(>>>), 3.0(>>>) and 5.5(>>>) in F-measure. Our further evaluation reveals that the performance improvement difference among different domains of the ACE 2003 corpus is due to the distribution of pronouns' antecedents occurring over different sentence distances, as shown in

Table 4. This suggests the usefulness of the relative pronominal ranking feature in resolving pronominal anaphors over longer distance. This is consistent with our observation that, as the percentage of pronominal anaphors referring to more distant antecedents increase, its impact turns gradually from negative to positive, when further including the relative pronominal ranking feature after the semantic role features. The reason that we include the detailed pronominal subcategory information is due to predominant importance of pronouns in tracking the local focus structure in discourse and that such detailed pronominal subcategory information is discriminative in tracking different subcategories of pronouns. This suggests the usefulness of considering the distribution of the local discourse focus over detailed pronominal subcategories. One interesting finding in our preliminary experimentation is that the inclusion of the detailed pronominal subcategory features alone even harms the performance. This may be due to the reason that the detailed pronominal subcategory features do not have the discriminative power themselves and that the semantic role features and the relative pronominal ranking feature provide an effective mechanism to explore the role of such detailed pronominal subcategory features in helping determine the local discourse focus.

	Pronoun Subcategory	NWIRE	NPAPER	BNEWS
Baseline System	First Person	55.7	55.9	56.6
	Second Person	54.6	60.4	44.0
	Third Person	72.6	80.9	75.7
	Neuter	41.5	50.4	50.2
	Reflexive	**85.7**	**70.0**	60.0
	Total	*62.3*	*65.3*	*59.0*
Final System	First Person	**64.7**	**67.0**	**65.6**
	Second Person	**78.6**	**70.0**	**51.9**
	Third Person	**80.9**	**81.8**	**80.4**
	Neuter	**48.3**	**53.0**	**58.3**
	Reflexive	71.4	66.7	**80.0**
	Total	***65.9***	***69.8***	***66.7***

Table 8: Performance comparison of pronoun resolution in F-measure over pronoun subcategories

Table 8 shows the contribution of the centering-motivated features over different pronoun subcategories. It shows that the centering-motivated features contribute much to the resolution of the four major pronoun subcategories (i.e. first person, second person, third person and neuter) while its negative impact on the minor pronoun subcategories (e.g. reflexive) can be ignored due to their much less frequent occurrence in the corpus. In particular, the centering-motivated features improve the performance on the major three pronoun subcategories of third person / neuter / first person, by 8.3(>>>)/6.8(>>>)/9.0(>>>), 0.9(>>)/ 2.6 (>>>)/11.1(>>>) and 4.7(>>>)/8.1(>>>)/9.0 (>>>), on the NWIRE, NPAPER and BNEWS domains of the ACE 2003 corpus, respectively.

	Distance	NWIRE	NPAPER	BNEWS
Baseline System	<=0	61.6	64.5	68.7
	<=1	60.4	67.5	60.0
	<=2	62.9	67.4	63.7
	Total	*62.3*	*65.3*	*59.0*
Final System	<=0	**64.3**	**70.3**	**78.7**
	<=1	**66.8**	**72.3**	**72.5**
	<=2	**66.6**	**71.8**	**71.8**
	Total	***65.9***	***69.8***	***66.7***

Table 9: Performance comparison of pronoun resolution in F-measure over sentence distances

Table 9 shows the contribution of the centering-motivated features over different sentence distances. It shows that the centering-motivated features improve the performance of pronoun resolution on different sentence distances of 0/1/2, by 2.7(>>>) / 5.8(>>>) / 10.0 (>>>), 6.4(>>>) / 4.8(>>>) / 12.5(>>>) and 3.7 (>>>)/4.4(>>>)/8.1(>>>), on the NWIRE, NPAPER and BNEWS domains of the ACE 2003 corpus, respectively. This suggests that the centering-motivated features are helpful for both intra-sentential and inter-sentential pronoun resolution.

6 Conclusion and Further Work

This paper extends the centering theory from the grammatical level to the semantic level and much improves the performance of pronoun resolution via centering-motivated features from the semantic perspective. This is mainly realized by employing various semantic role features with regard to various predicates in a sentence, in attempt to model the continuity or shift of the local discourse focus. Moreover, the relative ranking feature of a pronoun among all the pronouns is explored to help determine the relative priority of the pronominal anaphor in retaining the local discourse focus. Evaluation on the ACE 2003 corpus shows that both the centering-motivated semantic role features and pronominal ranking feature much improve the performance of pronoun resolution, especially when the detailed pronominal subcategory features of both the anaphor and the antecedent candidate are included. It is not surprising due to the predomi-

nance of pronouns in tracking the local discourse structure in a text.

To our best knowledge, this paper is the first research which successfully applies the centering-motivated features in pronoun resolution from the semantic perspective.

For future work, we will explore more kinds of semantic information and structured syntactic information in pronoun resolution. In particular, we will further employ the centering theory in pronoun resolution from both grammatical and semantic perspectives on more corpora.

Person Cross Document Coreference with Name Perplexity Estimates

Octavian Popescu
popescu@racai.ro

.

Abstract

The Person Cross Document Coreference systems depend on the context for making decisions on the possible coreferences between person name mentions. The amount of context required is a parameter that varies from corpora to corpora, which makes it difficult for usual disambiguation methods. In this paper we show that the amount of context required can be dynamically controlled on the basis of the prior probabilities of coreference and we present a new statistical model for the computation of these probabilities. The experiment we carried on a news corpus proves that the prior probabilities of coreference are an important factor for maintaining a good balance between precision and recall for cross document coreference systems.

1 Introduction

The Person Cross Document Coreference (Grishman 1994) task, which requires that all and only the textual mentions of an entity of type Person be individuated in a large collection of text documents, is one of the challenging tasks for natural language processing systems. In the most general case the corpus itself is the only available source of information regarding the persons mentioned and we consider that this is the case in this paper. A PCDC system must be able to use the information existing in the corpus in order to assign to each personal name mention (PNM) a piece of context. The coreference of any two PNMs is decided mainly on the basis of the similarity of the pieces of contexts associated with them. A successful PCDC must accurately extract the relevant context for coreference.

However, the context relevance is not absolute. Whether the contextual information uniquely individuates a person is a matter of probability. This paper presents a statistical technique developed to provide a PCDC system with more information regarding the probability of a correct coreference. The reason for developing this technique is twofold: (i) the relevant coreference context depends on the corpus itself and (ii) valid coreferences require a large amount of information, which is unavailable in the majority of cases.

The first reason is linked to a particularity of the CDC task that makes it more complex than other NLP tasks. Unlike in other disambiguation tasks, in the CDC tasks the relevant coreference context depends on the corpus itself. In word sense disambiguation, for instance, the distribution of the relevant context is mainly regulated by strong syntactic and semantic rules. The existence of such rules makes it possible for the disambiguation decisions to be made considering the local context. On the other hand, the distribution of the PNMs in a corpus is rather random and the relevant coreference context is a dynamic variable depending on the diversity of the corpus, that is, on how many different persons with the same name share a similar context. To exemplify, consider the name "John Smith" and an organization, say "U.N.". The extent to which "works for U.N." in "John Smith works for U.N." is a relevant coreference context depends on the diversity of the corpus itself. If in that corpus, among all the "John Smiths" there is only one person who works for "U.N." then "works for U.N." is a relevant coreference context, but if there are many "John Smiths" working for U.N., then "works for U.N." is not a relevant coreference system; in this last case, more contextual evidence is needed in order to correctly corefer the "John Smith" PNMs. The relevance of a context for coreference also depends on the corpus, not only on the specific relationship that exists between "John Smith" and

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 997–1006,
Singapore, 6-7 August 2009.

"works for U.N.". Thus, A PCDC system must have access to global information regarding the PNMs.

The second reason comes from practical considerations. The amount of information required to correctly infer PNMs coreferences is not present in corpus in a computationally friendly way. In many cases the relevant coreference information is embedded in semantic and ontological deep inferences, which are difficult to program In as much as 60% of the cases, two documents containing the same name, from a news corpus, lack contexts which are directly similar and big enough to correctly decide on the coreference.

We propose a new method to control the amount of contextual coreference required for correct coreferences. Rather than having fixed rules deciding on the size of the context surrounding a PNM, we propose a probabilistic approach that requires contextual evidence for coreference differentially, by considering the prior probability of the coreference of two PNMs; the higher this probability is, the less their correct coreference depends on the context and vice versa. We present a statistical model where the prior coreference probabilities are computed considering only the corpus itself, and we show how these probabilities are used by a PCDC system that dynamically revises the amount of context relevant for coreference.

In Section 2 we review the CDC relevant literature. In section 3 we analyze the data from annotated coreference corpora and we individuate a specific problem, setting up a working hypothesis. In Section 4 we develop a statistical model for computing the prior coreference probabilities and in Section 5 we present the results obtained by applying it to a large news corpus. In section 6 a direct evaluation on CDC is carried on a test corpus. In Section 7 we show how the proposed techniques extends naturally to a strategy of construction relevant test corpora for CDC task. The paper ends with the Conclusion and the Future Research section.

2 Related Work

In a classical paper (Bagga and Baldwin 1998), a PCDC system based on the vector space model (VSM) is proposed. While there are many advantages in representing the context as vectors on which a similarity function is applied, it has been shown that there are inherent limitations associated with the vectorial model (Popescu 2008). These problems, related to the density in the vectorial space (superposition) and to the discriminative power of the similarity power (masking), become visible as more cases are considered.

Testing the system on many names, (Gooi and Allan, 2004), it has been noted empirically that the accuracy of the results varies significantly from name to name. Indeed, considering just the sentence level context, which is a strong requirement for establishing coreference, a PCDC system obtains a good score for "John Smith". This happens because the prior probability of coreference of any two "John Smiths" mentions is low, as this is a very common name and none of the "John Smith" has an overwhelming number of mentions. But for other types of names the same system is not accurate. If it considers, for instance, "Barack Obama", the same system obtains a very low recall, as the probability of any two "Barack Obama" mentions to corefer is very high and the relevant coreference context is found very often beyond the sentence level. Without further adjustments, a vectorial model cannot resolve the problem of considering too much or too little contextual evidence in order to obtain a good precision for "John Smith" and simultaneously a good recall for "Barack Obama".

In an experiment using bigrams (Pederson et al. 2005) on a news corpus, it has been observed that the relationship between the amount of information given to a PCDC system and the performances is not linear. If the system has received in input the correct number of persons with the same name, the accuracy of the system has dropped. A typical case for this situation is when there is a person that is very often mentioned, and few other persons having few mentions; when the number of clusters is passed in the input, the clusters representing the persons who are rarely mentioned are wrongly enriched. However, this situation can be avoided if there is a measure of how probable it is to have a certain number of different persons with the same name, each being mentioned very often in a newspaper.

Recently, there has been a major interest in the PCDC systems, and, in the last two years, three important evaluation campaigns have been organized: Web People Search-1 (Artiles et al. 2007), ACE 2008 (www.nist.gov/speech/tests/ace/). It has been noted that the data variance between training and test is very high (Lefever 2007). Rather than being a particularity of those corpora, the problem is general. The performances of a bag of words VSM depends to a very high extent on the corpus diversity (see Section 3).

For reliable results, a PCDC system must have access to global information regarding the coreference space.

Rich biographic facts have been shown to improve the accuracy of PCDC (Mann and Yarowsky 2003). Indeed, when available, the birth date, the occupation etc. represent a relevant coreference context because the probability that two different persons have the same name, the same birth date and the same occupation is negligible. However, it is equally unlikely to find this information in a news corpus a sufficient number of times. Even for a web corpus, where the amount of this kind of information is higher than in a news corpus, the extended biographic facts, including e-mail address, phones, etc., contribute only with approximately 3% to the total number of coreferences (Elmacioglu et al. 2007).

In order to improve the performances of the PCDC systems based on VSM, some authors have focused on methods that allow a better analysis of the context by extracting the dependency chains (Ng 2007). The special importance of pieces of context has been exploited by implementing a cascade clustering technique (Wei 2006). Other authors have relied on advanced clustering techniques (among others Han et al. 2005, Chen 2006). However, these techniques rely on the precise analysis of the context, which is a time consuming process. It has been also noted that, in spite of deep analysis, the relevant coreference context is hard to find (Vu 2007).

The technique we present in the next sections is complementary to these approaches. We propose a statistical model designed to offer to the PCDC systems information regarding the distribution of PNMs in the corpus. This information is used to reduce the contextual data variation and to attain a good balance between precision and recall.

3 Data Analysis

In this Section we present the data analysis of the PNMs. We are interested in establishing a relationship between the distribution of the PNMs and the relevant context for coreference. As mentioned in the preceding sections, the amount of the relevant context for coreference cannot be decided prior to the investigation of that particular corpus. The performances of a bag of words VSM with a prior defined context approach will vary greatly from corpus to corpus. We have run the following experiment: we have considered the training and test corpora used in Web People Search-1 (WePS-1), which are web page corpora, and we have implemented a bag of word approach with two variants of clustering: agglomerative (A), and hierarchic (H). We have randomly chosen a set of seven names from training and test (14 names in total) and we have compared the results applying the two systems, A and H, on each set of names. In Figure 1 we present the results obtained. The figures on the vertical axes are computed using $F_{\alpha=0.5}$ formula.

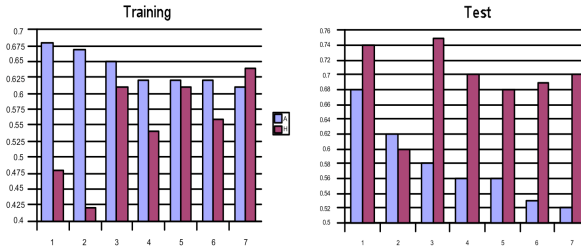

Figure 1. Variation between training and test

We have noticed a great variation in the behavior of the two systems. In order to search for an explanation for this difference we have looked at the distribution in the two corpora of the Named Entities, of the words denoting professions and of the meta-contextual information - e-mails, urls, phones, and addresses. It turns out that these types of contextual information are distributed between training and test approximately evenly. (see Table 1a,b).

Profession	training occ.	test occ.
Doctor	543	668
Lawyer	277	385
Professor	523	490
Researcher	340	166
Teacher	617	569
Coach	467	471
Actor	998	790

Table 1a. Profession words in training and test

Address	training occ.	test occ.
Phone	1,109	1,169
Fax	606	426
e-mail	3,134	2,186

Table 1b. Meta-Context in training and test

By manually investigating the training and test set of our experiment we have reached the conclusion that the reason for the difference is two fold: firstly, while the distribution of the words denoting profession is similar, in the test set the modifiers, for example “internist”, “neurosurgeon” for “doctor”, are more frequent. Secondly, the number of different persons having the same

name is, on average, higher in test than in training. The results plotted in Figure 1 show that it is not a question of which algorithm is better, but rather that there are different cases where one approach is preferred over the other. The problem we face is deciding when it is appropriate to use one or the other.

To induce from the corpus itself when a piece of context is or is not a relevant context requires deep ontological inferences and a very powerful tool of semantic analysis of the context. Consider for example two words denoting profession, "doctor" and "researcher", and their possible modifiers "internist", "neurosurgeon", and "professor" and "PhD". In the first case it is certain that the coreference is not possible, while in the second the coreference is very probable. To find out such relationships is computationally very hard. However, the analysis carried out further shows that we can avoid making such computations in most of the cases.

The number of different persons is a parameter that cannot be known beforehand. However, not all the names behave alike with respect to coreference. There are noticeable differences between names; for example less than 5 000 first names cover approximately 96% of the total of first names, while for the same percentage of coverage more than 70 000 of last names must be considered (Popescu et al. 2007). Let us call perplexity of a name the number of different persons that carry it. The search space depends directly on the name perplexity. The bigger the perplexity, the larger the amount of information required for the correct coreference must be. It seems natural that the amount of contextual evidence required by a PCDC depends on the name perplexity.

In order to evaluate the relationships between the context and the name perplexity, we need an annotated corpus. We have used the I-CAB corpus (Magnini et al. 2006), which is a four-day news corpus fully annotated, coreference relationships included. The documents in this corpus are entire pieces of news. For each PNM we have counted how many contexts containing specific information about the person carrying the respective name is present in that particular document. There are many types of contexts that refer to a person, but some of these types are very infrequent. We considered only those types of information that are present at least 5% of the times in the context surrounding a PNM. Table 2 presents the results of this investigation.

	occ.	diff occ	entities
First Names	2299	676	1592
Last Names	4173	1906	2191
Middle Name	110	44	41
Activity	973	322	569
Affiliation	566	399	409
Role	531	211	317
Family Relation	133	46	94

Table 2. Name perplexity and context

On the second column the total number of occurrences is listed, on the third column how many of these occurrences have different values (no case sensitive string match), and on the fourth column the number of different persons (Entities) having that information. The entries "activity", "affiliation", and "role" represent pieces of context where the respective information is directly expressed (no inferences). We call this type of context professional context and for approximately 30% of the PNMs, one of the above three types of professional contexts is present.

The perplexity of the first names, computed as the ratio between the fourth column and the third column is two times bigger than the perplexity of the last names. The lowest name perplexity is obtained by the names having a middle name - a name with at least three tokens – and it is very close to 1 (1.07). Comparatively, the highest perplexity of two tokens name is 3. The relationship between the number of tokens of a name and its perplexity is straightforward: for names with more than four tokens the perplexity is 1 in 99,6% of the cases (the name by itself is a relevant context for coreference).

In approximately 74% of the cases there is just one entity corresponding to a two-token name. Considering any two PNMs of the same name the similarity of two of the professional contexts guarantees the correct coreference. However, two professional contexts are present in only 4% of the cases. There are just four cases when considering just one professional attribute was misleading, and all these cases are high perplexity names. Moreover, in the case of many low perplexity names, the contexts could be minimally similar in order to correctly corefer any two PNMs of that respective name.

This analysis shows that there is a direct relationship between the name perplexity and the relevant coreference context. However, the average figures are not very informative, as the variance of perplexity is very high. Rather than fo-

cusing on the exact figure for name perplexity, we will try to partition the names according to their perplexity and to link each partition to a specific behavior with respect to coreference. The partitioning technique should ensure that the variance of the name perplexity within the same partition is low and that a specific amount of context should lead to the correct coreference decision for the great majority of names within that partition.

Our working hypothesis is that we can estimate the name perplexity within each partition and use this information to control the amount of contextual evidence required. Let us recall the "John Smith" and "Barack Obama" example from the previous section. Both "John" and "Smith" are American common first and last names. The chance that many different persons carry this name is high. On the other hand, as both "Barack" and "Obama" are rare American first and last names respectively, almost surely many mentions of this name refer only to one person. The argument above does not depend on the context, but just on the prior estimation of the usage of those names. Having an estimation of a name's perplexity, we may decrease/increase the amount of contextual evidence needed.

4 (p, γ) Statistical Model

Let $\mathcal{D}$ be the set of all PNMs from a given corpus $\mathcal{C}$ and let $\mathcal{D}_N$ be the set of corresponding names. We want to find a partition $\mathcal{P}$ of $\mathcal{D}_N$ such that within each partition the name perplexity varies only within predicted margins. Let X be a random variable with uniform distribution over $\mathcal{D}_N$ and let Y be the random variable defined by X's name perplexity. Let us suppose that we want $\mathcal{P} = \{p_1, p_2, \ldots, p_m\}$ to be a partition of $\mathcal{D}_N$, where the percentage of each partition class is p_i: the first partition class contains p_1 percentage of the name population, the second partition class contains p_2 percentage of the name population and the last partition class contains $p_m = 1 - \Sigma p_i$ percentage of the name population.

If we knew the distribution function of Y, let's call it F, we would simply determine ξ_i from equation 1, where $P_i = \Sigma p_k$, $k \le i$:

$$\xi_i = F^{-1}(P_i) \Leftrightarrow F(Y<\xi_i) = P_i \qquad (1)$$

and we would know that in each partition p_i the name perplexity is between ξ_{i-1} and ξ_i, with $\xi_0 = 0$. However we do not know F. Fortunately, we can estimate ξ_i.

There is no restriction that may impose a particular form for F; for example, the normal distribution hypothesis of name perplexity is ruled out by a χ^2 test with 96.5% confidence for the 14 names chosen from WePS-1 (see Section 3, first paragraph).

We are going to present a distributional free method for constructing the partition $\mathcal{P}$. The advantage of this method is that it does not depend on any assumption about the PNMs distribution.

Let us consider $X_1, X_2, \ldots, X_n$ a sample of independent and identical distributed names from $\mathcal{D}_N$. By rearranging the indexes, without losing the generality, let us suppose that $Y_1, Y_2, \ldots, Y_n$ is ordered, that is $Y_1 \le Y_2 \le \ldots \le Y_n$. Even if we do not know what form F has, we can still use equation (1) in order to estimate ξ_i. The expected value of $F(Y_i)$ is (Hogg, Mckean, Craig 2006):

$$E[F(Y_i)] = i/(n+1) \qquad (2)$$

which is an estimation of how much mass probability is on the left of Y_i. In our terms, we estimate that $E[F(Y_i)]$ percentage of the name population has a name perplexity lower than Y_i.

For a given number ξ, the percentage of the name population having the name perplexity at most ξ is determined by finding the smallest Y_i greater than ξ and use the equation (2) to estimate $E[F(Y_i)]$.

In order to build the partition $\mathcal{P}$ we are interested in the percentage of the name population that has the perplexity between two given values. Let (Y_i, Y_j) be the smallest interval that includes these two values. We can estimate the percentage of the name population that has a perplexity between Y_i and Y_j. This estimate is simply $F(Y_j) - F(Y_i)$. We can use directly equation (2) to estimate this difference. However, it is more important to have a confidence interval for this estimate, that is we want to know what the probability is that the interval (F(Yi), F(Yj)) contains at least a given percentage of the population, p. The optimal partition $\mathcal{P}$ is the one that maximizes the confidence in the fact that within each of the partition classes as many names as possible have the name perplexity in a given interval.

Let p be a given real number between (0,1) representing the mass probability that goes into the interval $(F(Y_i), F(Y_j))$. Let $\gamma = P(F(Y_j) - F(Y_i) \ge p)$. Fortunately γ has a distribution that does not depend on F. More precisely, γ has a beta distribution given by the function in formula (3):

$$\gamma = P(F(Y_j) - F(Y_i) \geq p) =$$

$$\int_p^1 \Gamma(n+1)/(\Gamma(j-i))\,\Gamma(n-j+i+1)x^{j-i-1}(1-x)^{n-j+i}dx \quad (3)$$

The Γ, called the gamma function, is the extension of the factorial, $\Gamma(x) = \int_0^\infty t^{x-1}e^{-t}dt$. The gamma function has the property that $\Gamma(x) = \Gamma(x-1)\,\Gamma(x-2)\ldots\,\Gamma(1)$; for x an integer, as the arguments in the formula (3) are, $\Gamma(x) = (x-1)!$

The formula (3) gives us a method of building the partition $\mathcal{P}$. Let us start with a set of perplexity intervals: $(\xi_0, \xi_1]$, $(\xi_1,\xi_2]$, $\ldots(\xi_{m-1}, \xi_m]$. We partition the names in $\mathcal{D}_N$ such that we maximize the confidence γ that at least p_i percentage of the name population has a name perplexity in $(\xi_{i-1}, \xi_i]$. We chose an independent and identical distributed sample X of names to which the ordered sample Y of name perplexity values corresponds. We start with the lowest perplexity interval and determine p_1,γ_1 and Y_0, Y_{i1}, such that $Y_0 \leq \xi_0 \leq \xi_1 \leq Y_{i1}$ and $\gamma_1 = P(F(Y_{i1}) - F(Y_0) \geq p_1)$. The ith index varies according to the desired γ_1, when p_1 is given, and vice-versa. We can choose i1 with m-1 liberty grades. Once we are satisfied with the values (p_1,γ_1), we search for the i2th index such that $Y_{i1} \leq \xi_1 \leq \xi_2 \leq Y_{i2}$ and (p_{i2},γ_{i2}) have the desired value. The process continues till the penultimate (p_{m-1},γ_{m-1}). We have no liberty in choosing the (p_m,γ_m).

We can compute the size of the sample needed for guaranteeing a minimum γ and p.

Let us give an example. Suppose that $(\xi_0, \xi_1] = (0,2]$. Thus we are interested in finding p, the percentage of the name population such that we can be γ sure that at least p names have a perplexity between 1 and 2 inclusive. We take a random sample of n = 30 and suppose the smallest index i1 such that $Y_i \geq 3$ for all $i > i1$ is 17 . We want to compute the confidence γ that at least p = 60% of the name population has the name perplexity within (0,2]:

$$\gamma = 1 - \int_0^{0.6} 30!/(16!15!)x^{15}(1-x^{14})dx =$$

$$= 1 - k(\int_0^{0.6} x^{15}dx + \int_0^{0.6} x^{29}dx) =$$

$$= 1 - k[(1/16)(6/10)^{16} + (1/30)(6/10)^{30}]$$

$$\geq .965$$

In practice we want to have optimal values for p and γ; a large p implies a small γ and vice-versa. The optimality is determined by the accuracy of the CDC system: we want to have the largest possible percentage of names into each partition such that our confidence that the names inside each partition have the same perplexity.

It is useful to work the equation (1) backwards. Suppose that we established the first partition class of $\mathcal{P}$ - we have found the i1th index, p_1, and γ_1. Now we refer only to the names in the partition class. We can compute the probability that a certain percentage of the names *within that particular partition class* have a given name perplexity. That is, we consider a random *sample inside the partition class,* X, and its correspondent random variable Y, as above. The confidence that $p_{1inside}$ percentage of names have the name perplexity ξ_p within the interval (Y_0, Y_{ith}) is:

$$P(Y_0 < \xi_p < Y_{i1}) = \Sigma_k \binom{n}{k} p^k(1-p)^{n-k} \quad (4)$$

$\binom{n}{k}$ represents the k-combinations of size n.

By taking advantage of the bootstrapping method (Efron and Tibshirani 1993) we do not have to resample inside the partition class. We use the $Y_0, .., Y_{i1}$ values with replacement. Using (4) we obtain $p_{1inside}$ which shows us which percentage inside the partition class has the name perplexity within $(Y_0, Y_{i1}]$. And consequently we can compute $\gamma_{1inside}$. Finally we are able to formulate the following statement about each partition class:

> In the ith partition class enter p_i percentage of the name population with a confidence γ_i. Inside this partition class we are $\gamma_{iinside}$ confident that $p_{iinside}$ percentage of the names have a name perplexity within $(Y_{i1-1}, Y_{i1}]$.

The p and γ indicate the theoretical values that define the partition. In practice the exact distribution of the names into the subset is unknown, therefore each heuristics that computes the perplexity creates its own distribution. The values $\gamma_{iinside}$ and $p_{iinside}$ control how much a certain heuristics departs from the theoretical values. The optimal heuristics have very big figures for $\gamma_{iinside}$ and $p_{iinside}$.

In the next section we present an experiment carried on a news corpus. We show how the above model leads to a stable partition of names and that inside each partition class reliable (p,γ) values can be computed.

5 Name Perplexity Partition

For the experiment described in this section, we have used a two-year part of the seven-years Italian local newspaper corpus called Adige500k Corpus (Magnini 2006).

We describe below how we compute the perplexity class for the one-token names and two-tokens names respectively. As mentioned in section 3, the name perplexity decreases rapidly for tree-token or more names. If desired, the same technique could also be applied for those names. In Adige500k there are 106, 187 different one-token names; 429, 243 two-token names; 36, 773 three-token names; 5, 152 four-token names, 940 four token names and less than 300 different four-token or more names.

An estimate of the name perplexity of the one-token names is the size of the different one-token names with which it forms a complete PNM in the corpus. For example for the first name "John" the estimation of its perplexity is the size of the one-token last names it combines with in forming PNMs, like "Smith, Travolta, Kennedy" etc. The bigger the size of its complementary names, the higher is its name perplexity. In Table 3 we present the figures of these estimates.

occurrences (interval)	average perplexity
1-5	4.13
6-20	8.34
21-100	17.44
101-1,000	68.54
1,000-5,000	683.95
5,000-31,091	478.23

Table 3. Average perplexity one-token names

We start with a five name perplexity classes: "very low" (VL) , "low" (L) , "medium", (M) "high" (H) and "very high" (VH). The name perplexity of a two-token name is interpolated from the name perplexity of its components. We used the following heuristics: the name perplexity class is the average name perplexity classes of its one-token name. If the name perplexity classes are the same then the name perplexity class of the whole name is one class less (if possible).

In order to compute the borderline between two consecutive classes we apply the (p, γ) method. We selected 25 two-tokens names and we manually investigate their occurrence in order to know their real name perplexity. The perplexity classes obtained after applying the (p, γ) technique are listed in Tables 4a and 4b respectively.

perplexity class	percentage
very high (VH)	5.3%
high (H)	8.7%
medium (M)	20.9%
low (L)	27.6%
very low (VL)	37.5%

Table 4a. First Name perplexity classes

perplexity class	percentage
very high (VH)	1.8%
high (H)	3.36%
medium (M)	17.51%
low (L)	20.31%
very low (VL)	57.02%

Table 4b. Last Name perplexity classes

Tables 4a and 4b fully describe the partition for one-token names. Ordering the one token names according to their perplexity we chose the first ones according to the percentage listed above. The same process applies to the one-token last names. The values computed for two-token names are listed.

	P	γ	p_{inside}	γ_{inside}
VH	0.04%	70%	70%	80%
H	2.53%	76%	70%	80%
M	10.08%	87%	80%	82%
L	27.97%	90%	99%	90%
VL	59.38%	96.5%	99%	96.5%

Table 5. (p, γ, p_{inside}, γ_{inside}) values

6 CDC with Name Perplexity Estimates

The working hypothesis is that using the name partition obtained with the (p, γ) procedure we can effectively improve the accuracy of a CDC system by reducing/increasing the amount of contextual evidence required for coreferencing according to the perplexity class to each the name belong.

To construct a test corpus we have adopted the following strategy: we chose 20 two-token names such that both sets of one token-names, the first names and the last names respectively, cover the whole space in the perplexity partition. In Table 6a and 6b we present 5 first and last names used in test. As not all the 25 names formed by combin-

ing the names in 6a and 6b are found in the corpus, we consider 11 other two-tokens names having the same distribution. On the first column the names are listed, on the second column the computed perplexity (P), on the third column the number of occurrences as one-token name (O), on the fourth the number of occurrences in a two-token name (T) and on the last column the computed perplexity class (PC).

Name	P	O	T	PC
Dellai	7	31091	10722	VL
Parolari	171	1,619	2207	H
Prodi	52	9184	3382	M
Ruini	15	554	203	L
Rossi	753	7506	8356	VH

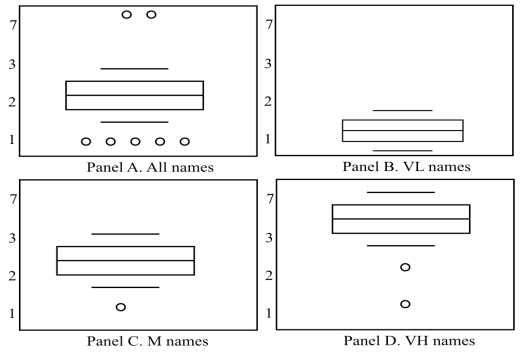
Table 6a. Test Last Names

Name	P	O	T	PC
Camillo	276	664	1731	L
Lorenzo	2088	2167	2198	H
Paolo	5255	4001	51244	VH
Romano	14	886	6414	M
Varena	5	10	85	VH

Table 6b. Test First Names

We compare the results obtained by our CDC system using the name perplexity partition (S) against two baselines: one that considers only the context at the sentence level and (BLS) one that considers the whole news (BLN). We obtain the following figures using the B-CUBED measure: S scores .72, BLS .59 and BLN .61. The gain in accuracy of more than 10% is due to the use of name perplexity classes.

The great advantage of using the (p,γ) estimates can be seen in those case where the ratio between the number of mentions and the rank of the name is close to extremes: either big number of mentions and low name perplexity, or low number of mentions and high name perplexity. In the first case the contextual evidence for coreference may be very scarce and in the second case, the requirement for strong contextual evidence is the best decision. Our results suggest that loosening the contextual requirements in the first case leads to an important gain in recall, up to 40%, while the lose in precision is less than 1.5%. The situation is best described by four panels of the five-number-summary plots of the test corpus. Panel A shows the distribution of the main five quantilies considering all the names together. Panel B shows the distribution for very low perplexity class, Panel C for medium perplexity class and Panel D for the very high perplexity class. The number of outliers in Panel A is high, which makes it difficult for any CDC system, but inside each perplexity class the variation is reduced.



7 Constructing an Evaluation Corpus

The (p, γ) technique could be used for constructing a test corpus for the CDC task. The main problem faced in the construction of the test corpus is data variation. The number of different entities mentioned with the same name is a random variable with a big variance. The distribution of the number of entities is very skew. The average perplexity is 2.01%, but less than 18% of the total number of names have a perplexity greater than 3. In Figure 2 we plot a modified Lorenz curve (the vertical axis is not divided in percentage, as the values are discrete).

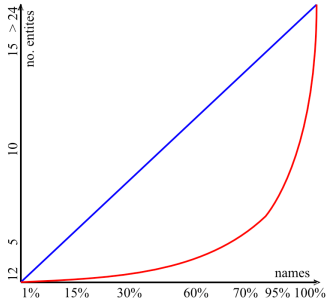


Figure 2. Lorenz Curve names/no. entities

The direct consequence of this situation is the fact that constructing an evaluation corpus by taking random names will result with a great probability in a very skew test corpus. Indeed,

the expectation is that in such corpus, the average perplexity is very low, and consequently, the great majority of cases can be coreferenced by a simple algorithm. Therefore, this test corpus may be largely ineffective in ranking the algorithms. In fact, we want to construct an evaluation corpus that is able to promote the most effective algorithms. The discriminative power of a test corpus is directly related to the variance of the data. Moreover, if only certain names are considered for a test corpus, the variance can be very low; in particular, when the test corpus contains just one name the variance is zero. It is difficult to see the merits of different algorithms when tested on such corpora.

In order to make more informative statements we need to construct an evaluation corpus that is less dependent on the data variance. A possible solution is to form a partition of the set of the PNMs, that is, to split the whole set of PNMs in mutual disjunctive groups. This type of methodology is called stratified sampling, mainly because each group is a stratum. The sampling strategy, the number of sampling elements, the variance and the sampling error can be calculated independently for each strata.

The main advantages of stratified sampling are that we can concentrate on the special groups, that in general this strategy improves the accuracy of the estimation, and that the number of elements in each stratum can be conveniently chosen. The main disadvantages are related to the difficulty in finding a suitable partition of the population. The strata should be chosen prior to the sampling time, but the homogeneity inside the stratum should be guaranteed.

Our proposal is to use the name perplexity intervals. We argue that this proposal is four-fold sustainable. Firstly, the name perplexity is directly connected to the random variable whose distribution we estimate, namely the number of entities. Secondly, for free names it can be computed off - line. Thirdly, it gives us an independent and formally correct way to make a partition. Fourthly, it easily allows a separation between the important and unimportant cases.

To begin with, let us suppose we have a name that has *n* occurrences in the Adige 500K. If *n* is relatively large, than we can be sure that there are some dominant entities that may be represented by the majority of PNMs that have this name as value. However, it is unknown whether the *n* comes from the fact that there are indeed some dominant entities or whether the name by itself is a frequently used name.

In order to deal with the differences between frequency vs. perplexity, we propose to build a matrix defined by the frequency classes as rows and perplexity classes as columns. In Figure 3 we present this matrix.

Frequence/Commoness	VF	F	C	R	VR
Int1					
Int2

very frequent (VF), ..., common (C), ..., very rare(VR) - perplexity

Figure 3. Frequency/Commonness strata matrix.

The number of different names in each of the cells of the matrix may differ according to the departure of the normal distribution of each stratum. In general, if the real distribution is normal, then as much as ten examples are sufficient. Otherwise, for not very skew distributions, which we expect most of the strata to have, an average of 30 examples should suffice. In same cases, as the normal distribution can be appropriately sampled when both *Np* and *N(1-p)* are grater than five – where p is the ratio perplexity/frequency and N the sample dimension – the number of elements in the cell may be around 200, by a maximal rough estimation.

8 Conclusion and Further Research

We have presented a distributional free statistical method to design a name perplexity system, such that each perplexity class maximizes the number of names for which the prior coreference probability belongs to the same interval. This information helps the PCDC systems lower/increase adequately the amount of contextual evidence required for coreference.

The approach presented here is effective in dealing with the problems raised by using a similarity metrics on contextual vectors improving the overall accuracy with more than 10%.

We would like to increase the number of cases considered in the sample required to delimit the perplexity classes. Equation (3) may be developed further in order to obtain exactly the number of required cases.

The (p, γ) procedure is effective is dealing with the problems regarding the construction of an evaluation corpus. The technique presented in the last section could be extended further and we are already working on a new series of experiments whose results will be made available in the near future.

Acknowledgments

The corpus used in this paper is Adige500k, a seven-year news corpus from an Italian local newspaper. The author thanks to all the people involved in the construction of Adige500k.

Abstract

We apply machine learning to the Linear Ordering Problem in order to learn sentence-specific reordering models for machine translation. We demonstrate that even when these models are used as a mere preprocessing step for German-English translation, they significantly outperform Moses' integrated lexicalized reordering model.

Our models are trained on automatically aligned bitext. Their form is simple but novel. They assess, based on features of the input sentence, how strongly each pair of input word tokens w_i, w_j would like to reverse their relative order. Combining all these pairwise preferences to find the best global reordering is NP-hard. However, we present a non-trivial $O(n^3)$ algorithm, based on chart parsing, that at least finds the best reordering within a certain exponentially large neighborhood. We show how to iterate this reordering process within a local search algorithm, which we use in training.

1 Introduction

Machine translation is an important but difficult problem. One of the properties that makes it difficult is the fact that different languages express the same concepts in different orders. A machine translation system must therefore rearrange the source language concepts to produce a fluent translation in the target language.

Phrase-based translation systems rely heavily on the target language model to ensure a fluent output order. However, a target n-gram language model alone is known to be inadequate. Thus, translation systems should also look at *how the source sentence prefers to reorder*. Yet past systems have traditionally used rather weak models of the reordering process. They may look only at the distance between neighboring phrases, or depend only on phrase unigrams. The decoders also rely on search error, in the form of limited reordering windows, for both efficiency and translation quality.

Demonstrating the inadequacy of such approaches, Al-Onaizan and Papineni (2006) showed that even *given* the words in the reference translation, *and* their alignment to the source words, a decoder of this sort charged with merely rearranging them into the correct target-language order could achieve a BLEU score (Papineni et al., 2002) of at best 69%—and that only when restricted to keep most words very close to their source positions.

This paper introduces a more sophisticated model of reordering based on the Linear Ordering Problem (LOP), itself an NP-hard permutation problem. We apply machine learning, in the form of a modified perceptron algorithm, to learn parameters of a linear model that constructs a matrix of weights from each source language sentence. We train the parameters on orderings derived from automatic word alignments of parallel sentences.

The LOP model of reordering is a complete ordering model, capable of assigning a different score to every possible permutation of the source-language sentence. Unlike the target language model, it uses information about the relative positions of the words in the source language, as well as the source words themselves and their parts of speech and contexts. It is therefore a language-pair specific model.

[1]This work is excerpted and adapted from the first author's Ph.D. thesis (Tromble, 2009). Some of the ideas here appeared in (Eisner and Tromble, 2006) without empirical validation. The material is based in part upon work supported by the National Science Foundation under Grant No. 0347822.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1007–1016,
Singapore, 6-7 August 2009.

We apply the learned LOP model as a preprocessing step before both training and evaluation of a phrase-based translation system, namely Moses. Our methods for finding a good reordering under the NP-hard LOP are themselves of interest, adapting algorithms from natural language parsing and developing novel dynamic programs.

Our results demonstrate a significant improvement over translation using unreordered German. Using Moses with only distance-based reordering and a distortion limit of 6, our preprocessing improves BLEU from 25.27 to 26.40. Furthermore, that improvement is significantly greater than the improvement Moses achieves with its lexicalized reordering model, 25.55.

Collins et al. (2005) improved German-English translation using a statistical parser and several hand-written rules for preprocessing the German sentences. This paper presents a similar improvement using fully automatic methods.

2 A Linear Ordering Model

This section introduces a model of word reordering for machine translation based on the Linear Ordering Problem.

2.1 Formalization

The input sentence is $\boldsymbol{w} = w_1 w_2 \ldots w_n$. To distinguish duplicate tokens of the same word, we assume that each token is superscripted by its input position, e.g., $\boldsymbol{w} =$ *die*^{1} *Katze*^{2} *hat*^{3} *die*^{4} *Frau*^{5} *gekauft*^{6} (gloss: "the cat has the woman bought").

For a fixed $\boldsymbol{w}$, a permutation $\boldsymbol{\pi} = \pi_1 \pi_2 \ldots \pi_n$ is any reordering of the tokens in $\boldsymbol{w}$. The set Π_n of all such permutations has size $n!$. We would like to define a scoring model that assigns a high score to the permutation $\boldsymbol{\pi} =$ *die*^{4} *Frau*^{5} *hat*^{3} *gekauft*^{6} *die*^{1} *Katze*^{2} (gloss: "the woman has bought the cat"), since that corresponds well to the desired English order.

To construct a function that scores permutations of $\boldsymbol{w}$, we first construct a pairwise preference matrix $B_{\boldsymbol{w}} \in \mathbb{R}^{n \times n}$, whose entries are

$$B_{\boldsymbol{w}}[\ell, r] \stackrel{\text{def}}{=} \boldsymbol{\theta} \cdot \boldsymbol{\phi}(\boldsymbol{w}, \ell, r), \qquad (1)$$

Here $\boldsymbol{\theta}$ is a vector of weights. $\boldsymbol{\phi}$ is a vector of feature functions, each considering the entire word sequence $\boldsymbol{w}$, as well as any functions thereof, such as part of speech tags.

We will hereafter abbreviate $B_{\boldsymbol{w}}$ as B. Its integer indices ℓ and r are identified with the input tokens w_ℓ and w_r, and it can be helpful to write them that way; e.g., we will sometimes write $B[2, 5]$ as $B[\textit{Katze}^2, \textit{Frau}^5]$.

The idea behind our reordering model is that $B[\textit{Katze}^2, \textit{Frau}^5] > B[\textit{Katze}^5, \textit{Frau}^2]$ expresses a preference to keep *Katze*^{2} before *Frau*^{5}, whereas the opposite inequality would express a preference—other things equal—for permutations in which their order is reversed. Thus, we define[1]

$$\text{score}(\boldsymbol{\pi}) \stackrel{\text{def}}{=} \sum_{i,j:\ 1 \le i < j \le n} B[\pi_i, \pi_j] \qquad (2)$$

$$p(\boldsymbol{\pi}) \stackrel{\text{def}}{=} \frac{1}{Z} \exp(\gamma \cdot \text{score}(\boldsymbol{\pi})) \qquad (3)$$

$$\hat{\boldsymbol{\pi}} \stackrel{\text{def}}{=} \operatorname*{argmax}_{\boldsymbol{\pi} \in \Pi_n} \text{score}(\boldsymbol{\pi}) \qquad (4)$$

Note that i and j denote positions in $\boldsymbol{\pi}$, whereas π_i, π_j, ℓ, and r denote particular input tokens such as *Katze*^{2} and *Frau*^{5}.

2.2 Discussion

To the extent that the costs B generally discourage reordering, they will particularly discourage long-distance movement, as it swaps more pairs of words.

We point out that our model is somewhat peculiar, since it does not directly consider whether the permutation $\boldsymbol{\pi}$ keeps *die*^{4} and *Frau*^{5} adjacent or even close together, but only whether their order is reversed.

Of course, the model could be extended to consider adjacency, or more generally, the three-way cost of interposing k between i and j. See (Eisner and Tromble, 2006; Tromble, 2009) for such extensions and associated algorithms.

However, in the present paper we focus on the model in the simple form (2) that only considers pairwise reordering costs for all pairs in the sentence. Our goal is to show that these unfamiliar pairwise reordering costs are useful, when modeled with a rich feature set via equation (1). Even *in isolation* (as a preprocessing step), without considering any other kinds of reordering costs or language model, they can achieve useful reorderings

[1] For any $\ell < r$, we may assume without loss of generality that $B[r, \ell] = 0$, since if not, subtracting $B[r, \ell]$ from both $B[\ell, r]$ and $B[r, \ell]$ (exactly one of which appears in each $\text{score}(\boldsymbol{\pi})$) will merely reduce the scores of *all* permutations by this amount, leaving equations (3) and (4) unchanged. Thus, in practice, we take B to be an upper triangular matrix. We use equation (1) only to define $B[\ell, r]$ for $\ell < r$, and train $\boldsymbol{\theta}$ accordingly. However, we will ignore this point in our exposition.

of German that complement existing techniques and thus improve state-of-the-art systems. Our positive results in even this situation suggest that in future, pairwise reordering costs should probably be integrated into MT systems.

The probabilistic interpretation (3) of the score (2) may be useful when thus integrating our model with language models or other reordering models during translation, or simply when training our model to maximize likelihood or minimize expected error. However, in the present paper we will stick to purely discriminative training and decoding methods that simply try to maximize (2).

2.3 The Linear Ordering Problem

In the combinatorial optimization literature, the maximization problem (4) (with input B) is known as the Linear Ordering Problem. It has numerous practical applications in fields including economics, sociology, graph theory, graph drawing, archaeology, and task scheduling (Grötschel et al., 1984). Computational studies on real data have often used "input-output" matrices representing resource flows among economic sectors (Schiavinotto and Stützle, 2004).

Unfortunately, the problem is NP-hard. Furthermore, it is known to be APX-complete, meaning that there is no polynomial time approximation scheme unless P=NP (Mishra and Sikdar, 2004). However, there are various heuristic procedures for approximating it (Tromble, 2009). We now give an attractive, novel procedure, which uses a CKY-parsing-like algorithm to search various subsets of Π_n in polynomial time.

3 Local Search

"Local search" refers to any hill-climbing procedure that iteratively improves a solution by making an optimal "local" change at each iteration.[2] In this case, we start with the identity permutation, find a "nearby" permutation with a better score (2), and repeat until we have reached a local maximum of the scoring objective.

This section describes a local search procedure that uses a very generous definition of "local." At each iteration, it finds the optimal permutation in a certain *exponentially large* neighborhood $N(\boldsymbol{\pi})$ of the current permutation $\boldsymbol{\pi}$.

[2]One can introduce randomness to obtain MCMC sampling or simulated annealing algorithms. Our algorithms extend naturally to allow this (cf. Tromble (2009)).

$$\begin{aligned} S &\rightarrow S_{0,n} \\ S_{i,k} &\rightarrow S_{i,j}\ S_{j,k} \\ S_{i-1,i} &\rightarrow \pi_i \end{aligned}$$

Figure 1: A grammar for a large neighborhood of permutations, given one permutation $\boldsymbol{\pi}$ of length n. The $S_{i,k}$ rules are instantiated for each $0 \leq i < j < k \leq n$, and the $S_{i-1,i}$ rules for each $0 < i \leq n$.

We say that two permutations are neighbors iff they can be aligned by an Inversion Transduction Grammar (ITG) (Wu, 1997), which is a familiar reordering device in machine translation. Equivalently, $\boldsymbol{\pi}' \in N(\boldsymbol{\pi})$ iff $\boldsymbol{\pi}$ can be transformed into $\boldsymbol{\pi}'$ by swapping various adjacent substrings of $\boldsymbol{\pi}$, as long as these swaps are properly nested. Zens and Ney (2003) used a normal form to show that the size of the ITG neighborhood $N(\boldsymbol{\pi})$ is a large Schröder number, which grows exponentially in n. Asymptotically, the ratio between the size of the neighborhood for $n+1$ and the size for n approaches $3 + 2\sqrt{2} \approx 5.8$.

We show that equation (2) can be optimized within $N(\boldsymbol{\pi})$ in $O(n^3)$ time, using dynamic programming. The algorithm is based on CKY parsing. However, a novelty is that the grammar weights must themselves be computed by $O(n^3)$ dynamic programming.

Our grammar is shown in Figure 1. Parsing the "input sentence" $\boldsymbol{\pi}$ with this grammar simply constructs all binary trees that yield the string $\boldsymbol{\pi}$. There is essentially only one nonterminal, S, but we split it into $O(n^2)$ position-specific nonterminals such as $S_{i,j}$, which can only yield the span $\pi_{i+1}\pi_{i+2}\ldots\pi_j$. An example parse is shown in Figure 2.

The important point is that we will place a score on each binary grammar rule. The score of the rule $S_{i,k} \rightarrow S_{i,j}\ S_{j,k}$ is $\max(0, \Delta_{i,j,k})$, where $\Delta_{i,j,k}$ is the benefit to swapping the substrings $\pi_{i+1}\pi_{i+2}\ldots\pi_j$ and $\pi_{j+1}\pi_{j+2}\ldots\pi_k$. The rule is considered to be a "swap rule" if its score is positive, showing that a swap will be beneficial (independent of the rest of the tree). If the parse in Figure 2 is the parse with the highest *total* score, and its swap rules are $S_{0,5} \rightarrow S_{0,1}\ S_{1,5}$ and $S_{3,5} \rightarrow S_{3,4}\ S_{4,5}$, then our best permutation in the neighborhood of $\boldsymbol{\pi}$ must be the (linguistically desirable) permutation *die*^{4}*Frau*^{5}*hat*^{3}*gekauft*^{6}*die*^{1}*Katze*^{2}, obtained from

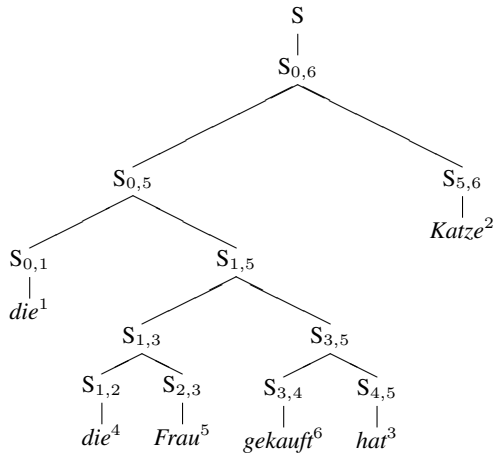

Figure 2: One parse of the current permutation $\boldsymbol{\pi}$. In this example, $\boldsymbol{\pi}$ has somehow gotten the input words into alphabetical order (owing to previous hill-climbing steps). We are now trying to further improve this order.

$\boldsymbol{\pi}$ by two swaps.

How do we find this solution? Clearly the benefit (positive or negative) to swapping $\pi_{i+1}\pi_{i+2}\ldots\pi_j$ with $\pi_{j+1}\pi_{j+2}\ldots\pi_k$ is

$$\Delta_{i,j,k} = \sum_{\ell=i+1}^{j}\sum_{r=j+1}^{k} B[\pi_r, \pi_\ell] - B[\pi_\ell, \pi_r] \quad (5)$$

We can evaluate all $O(n^3)$ possible swaps in total time $O(n^3)$, using the dynamic programming recurrence

$$\begin{aligned}\Delta_{i,j,k} &= \Delta_{i,j,k-1} + \Delta_{i+1,j,k} - \Delta_{i+1,j,k-1} \quad (6)\\ &\quad + B[\pi_k, \pi_{i+1}] - B[\pi_{i+1}, \pi_k]\end{aligned}$$

with the base case $\Delta_{i,j,k} = 0$ if $i = j$ or $j = k$. This gives us the weights for the grammar rules, and then we can use weighted CKY parsing to find the highest-scoring (Viterbi) parse in $O(n^3)$ time. Extracting our new and improved permutation $\boldsymbol{\pi'} \in N(\boldsymbol{\pi})$ from this parse is a simple $O(n)$-time algorithm.

Figure 3 gives pseudocode for our local search algorithm, showing how to compute the quantities (6) during parsing rather than beforehand. $\beta[i,k]$ holds the weight of the best permutation (in the neighborhood) of the subsequence $\pi_{i+1}\pi_{i+1}\ldots\pi_k$.[3]

[3]The use of β is intended to suggest an analogy to inside probability—or more precisely, the Viterbi approximation to inside probability (since we are maximizing rather than summing over parses).

The next two sections describe how to use our local search algorithm to discriminatively learn the weights of the parameters from Section 2, equation (1).

4 Features

Our objective function (2) works only to the extent that we can derive a good pairwise preference matrix $B_{\boldsymbol{w}}$. We do this by using a rich feature set in equation (1).

We adapt the features of McDonald et al. (2005), introduced there for dependency parsing, to the task of machine translation reordering. Because both models construct features for pairs of words given the entire sentence, there is a close correspondence between the two tasks, although the output is quite different.

Each feature $\phi(\boldsymbol{w}, \ell, r)$ in equation (1) is a binary feature that fires when $(\boldsymbol{w}, \ell, r)$ has some conjunction of properties. The properties that are considered include the words w_ℓ and w_r, the parts of speech of $\{w_{\ell-1}, \ldots, w_{r+1}\}$, and the distance $r - \ell$. Table 1 shows the feature templates.

We also tried features based on a dependency parse of the German, with the idea of using LOP features to reorder the dependents of each word, and thus model syntactic movement. This did produce better monolingual reorderings (as in Table 2), but it did not help final translation into English (Table 3), so we do not report the details here.

5 Learning to Reorder

Ideally, we would have a large corpus of desirable reorderings of source sentences—in our case, German sentences permuted into target English word order—from which to train the parameters of our model. Unfortunately, the alignments between German and English sentences are only infrequently one-to-one. Furthermore, human-aligned parallel sentences are hard to come by, and never in the quantity we would like.

Instead, we make do with automatically-generated word alignments, and we heuristically derive an English-like word order for the German sentence based on the alignment. We used GIZA++ (Och and Ney, 2003) to align approximately 751,000 sentences from the German-English portion of the Europarl corpus (Koehn, 2005), in both the German-to-English and English-to-German directions. We combined the

```

Figure 3: Pseudocode for computing the score of the best permutation in the neighborhood of $\boldsymbol{\pi}$ under the Linear Ordering Problem specified by the matrix B. Computing the best neighbor is a simple matter of keeping back pointers to the choices of $\max$ and ordering them as implied.

alignments using the "grow-diag-final-and" procedure provided with Moses (Koehn et al., 2007).

For each of these German sentences, we derived the English-like reordering of it, which we call German$'$, by the following procedure. Each German token was assigned an integer key, namely the position of the leftmost of the English tokens to which it was aligned, or 0 if it was not aligned to any English tokens. We then did a stable sort of the German tokens based on these keys, meaning that if two German tokens had the same key, their order was preserved.

This is similar to the oracle ordering used by Al-Onaizan and Papineni (2006), but differs in the handling of unaligned words. They kept unaligned words with the closest preceding aligned word.[4]

Having found the German$'$ corresponding to each German sentence, we randomly divided the sentences into 2,000 each for development and evaluation, and the remaining approximately 747,000 for training.

We used the averaged perceptron algorithm (Freund and Schapire, 1998; Collins, 2002) to train the parameters of the model. We ran the algorithm multiple times over the training sentences, measuring the quality of the learned parameters by reordering the held-out development set after each iteration. We stopped when the BLEU score on the development set failed to improve for two consecutive iterations, which occurred after fourteen passes over the data.

Each perceptron update should compare the true German$'$ to the German$'$ that would be predicted by the model (2). As the latter is NP-hard to find, we instead substitute the local maximum found by local search as described in Section 3, starting at the identity permutation, which corresponds to the original German word order.

During training, we iterate the local search as described earlier. However, for decoding, we only do a single step of local search, thus restricting reorderings to the ITG neighborhood of the original German. This restriction turns out to improve performance slightly, even though it reduces the quality of our approximation to the LOP problem (4). In other words, it turns out that reorderings found outside the ITG neighborhood tend to be poor German$'$ even if our LOP-based objective function thinks that they are good German$'$.

This is not to say that the gold standard German$'$ is always in the ITG neighborhood of the original German—often it is not. Thus, it might be better in future work to still allow the local search to take more than one step, but to penalize the second step. In effect, score($\boldsymbol{\pi}$) would then include a feature indicating whether $\boldsymbol{\pi}$ is in the neighborhood of the original German.

[4] We tried two other methods for deriving English word order from word alignments. The first alternative was to align only in one direction, from English to German, with null alignments disallowed, so that every German word was aligned to a single English word. The second alternative used BerkeleyAligner (Liang et al., 2006; DeNero and Klein, 2007), which shares information between the two alignment directions to improve alignment quality. Neither alternative produced improvements in our ultimate translation quality.

Table 1: Feature templates for $B[\ell, r]$ (w_ℓ is the ℓth word, t_ℓ its part of speech tag, and b matches any index such that $\ell < b < r$). Each of the above is also conjoined with the distance between the words, $r - \ell$, to form an additional feature template. Distances are binned into 1, 2, 3, 4, 5, > 5, and > 10.

The model is initialized at the start of training using log-odds of the parameters. Let $\Phi_m = \{(\boldsymbol{w}, \ell, r) \mid \phi_m(\boldsymbol{w}, \ell, r) = 1\}$ be the set of word pairs in the training data for which feature m fires. Let $\vec{\Phi}_m$ be the subset of Φ_m for which the words stay in order, and $\overleftarrow{\Phi}_m$ the subset for which the words reverse order. Then in this model,

$$\theta_m = \log\left(\left|\vec{\Phi}_m\right| + \frac{1}{2}\right) - \log\left(\left|\overleftarrow{\Phi}_m\right| + \frac{1}{2}\right). \quad (7)$$

This model is equivalent to smoothed naïve Bayes if converted to probabilities. The learned model significantly outperforms it on the monolingual reordering task.

Table 2 compares the model after perceptron training to the model at the start of training, measuring BLEU score of the predicted German′ against the observed German′. In addition to these BLEU scores, we can measure precision and recall of pairs of reordered words against the observed German′. On the held out test set, the predicted German′ achieves a recall of only 21%, but a precision of 64%. Thus, the learned model is too conservative, but makes moderately good decisions when it does reorder.

Ordering	p_2	p_3	p_4	**BLEU**
German	57.4	38.3	27.7	49.65
Log-odds	57.4	38.4	27.8	49.75
Perceptron	**58.6**	**40.3**	**29.8**	**51.51**

Table 2: Monolingual BLEU score on development data, measured against the "true" German′ ordering that was derived from automatic alignments to known English translations. The table evaluates three candidate orderings: the original German, German reordered using the log-odds initialized model, and German reordered using the perceptron-learned model. In addition to the BLEU score, the table shows bigram, trigram, and 4-gram precisions. The unigram precisions are always 100%, because the correct words are given.

6 Reordering as Preprocessing

This section describes experiments using the model introduced in Section 2 and learned in Section 5 to preprocess German sentences for translation into English. These experiments are similar to those of Collins et al. (2005).

We used the model learned in Section 5 to generate a German′ ordering of the training, development, and test sets. The training sentences are the same that the model was trained on, and the development set is the same that was used as the stopping criterion for the perceptron. The test set was unused in training.

We used the resulting German′ as the input to the Moses training pipeline. That is, Moses recomputed alignments of the German′ training data to the English sentences using GIZA++, then constructed a phrase table. Moses used the development data for minimum error-rate training (Och, 2003) of its small number of parameters. Finally, Moses translated the test sentences, and we measured performance against the English reference sentences. This is the standard Moses pipeline, except German has been replaced by German′.

Table 3 shows the results of translation, both starting with unreordered German, and starting with German′, reordered using the learned Linear Ordering Problems. Note that Moses may itself re-

System	Input	Moses Reord.	p_1	p_2	p_3	p_4	BLEU	METEOR	TER
baseline	German	Distance	59.6	31.4	18.8	11.6	25.27	54.03	60.60
(a)	German	Lexical	60.0	32.0	19.3	12.1	25.55	54.18	59.76
(b)	German′	Distance	60.4	32.7	20.2	12.8	26.40	**54.91**	**58.63**
(a)+(b)	German′	Lexical	59.9	32.4	20.0	12.8	**26.44**	54.61	59.23

Table 3: Machine translation performance of several systems, measured against a single English reference translation. The results vary both the preprocessing—either none, or reordered using the learned Linear Ordering Problems—and the reordering model used in Moses. Performance is measured using BLEU, METEOR (Lavie et al., 2004), and TER (Snover et al., 2006). (For TER, smaller values are better.)

order whatever input that it receives, during translation into English. Thus, the results in the table also vary the reordering model used in Moses, set to either a single-parameter distance-based model, or to the lexicalized bidirectional msd model. The latter model has six parameters for each phrase in the phrase table, corresponding to monotone, swapped, or discontinuous ordering relative to the previous phrase in either the source or target language.

How should we understand the results? The baseline system is Moses phrase-based translation with no preprocessing and only a simple distance-based reordering model. There are two ways to improve this: (a) ask Moses to use the lexicalized bidirectional msd reordering model that is provided with Moses and is integrated with the rest of translation, or (b) keep the simple distance-based model within Moses, but preprocess its training and test data with our linear reordering model. Note that the preprocessing in (b) will obviously change the phrasal substrings that are learned by Moses, for better or for worse.

First, remarkably, (b) is significantly better than (a) on BLEU, with $p < 0.0001$ according to a paired permutation test.

Second, combining (a) with (b) produced no improvement over (b) in BLEU score (the difference between 26.40 and 26.44 is not significant, even at $p < 0.2$, according to the same paired permutation test). Lexicalized reordering in Moses even degraded translation performance according to METEOR and TER. The TER change is significant according to the paired permutation test at $p < 0.001$. (We did not perform a significance test for METEOR.)

Our word-based model surpasses the lexicalized reordering in Moses largely because of long-distance movement. The 518 sentences (26%) in the test set for which our model moves a word more than six words away from its starting position account for more than 67% of the improvement in BLEU from (a) to (b).

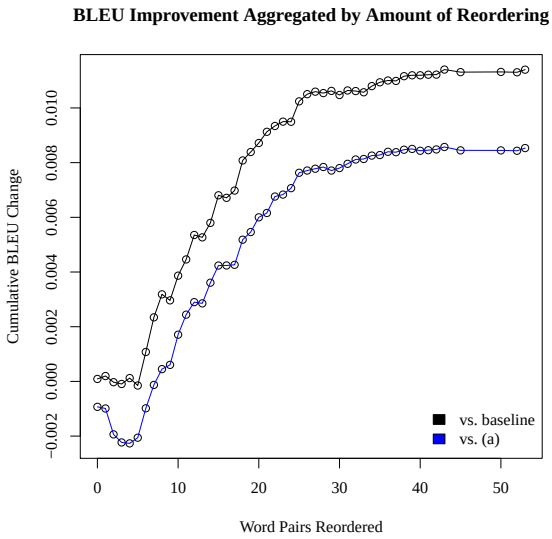

Figure 4: Cumulative change in BLEU score of (b) relative to the baseline and (a), aggregated by the number of reordered word pairs in each sentence. For those sentences where our model reorders fewer than five word pairs, the BLEU score of translation degrades.

Figure 4 shows another view of the BLEU improvement. It shows that, compared to the baseline, our preprocessing has basically no effect for sentences where it does only a little reordering, changing the relative order of fewer than five pairs of words. Compared to Moses with lexicalized reordering, these same sentences actually hurt performance. This more than accounts for the difference between the BLEU scores of (b) and (a)+(b).

Going beyond preprocessing, our model could also be integrated into a phrase-based decoder. We briefly sketch that possibility here.

Phrase-based decoders keep a source coverage vector with every partial translation hypothesis. That coverage vector allows us to incorporate the scores from a LOP matrix B directly. Whenever the decoder extends the hypothesis with a new source phrase, covering $w_{i+1}w_{i+2}\ldots w_j$, it adds

$$\sum_{\ell=i+1}^{j-1}\sum_{r=\ell+1}^{j} B[\ell,r] + \sum_{\ell=i+1}^{j}\sum_{r\in\mathcal{U}} B[\ell,r].$$

The first term represents the phrase-internal score, and the second the score of putting the words in the phrase before all the remaining uncovered words $\mathcal{U}$.

7 Comparison to Prior Work

Preprocessing the source language to improve translation is a common technique. Xia and McCord (2004) improved English-French translation using syntactic rewrite rules derived from Slot Grammar parses. Collins et al. (2005) reported an improvement from 25.2% to 26.8% BLEU on German-English translation using six handwritten rules to reorder the German sentences based on automatically-generated phrase-structure trees. Our work differs from these approaches in providing an explicit model that scores all possible reorderings. In this paper, our model was trained and used only for 1-best preprocessing, but it could potentially be integrated into decoding as well, where it would work together with the translation model and target language model to find a congenial translation.

Costa-jussà and Fonollosa (2006) improved Spanish-English and Chinese-English translation using a two-step process, first reordering the source language, then translating it, both using different versions of a phrase-based translation system. Many others have proposed more explicit reordering models (Tillmann, 2004; Kumar and Byrne, 2005; Koehn et al., 2005; Al-Onaizan and Papineni, 2006). The primary advantage of our model is that it directly accounts for interactions between distant words, leading to better treatment of long-distance movement.

Xiong et al. (2006) proposed a constituent reordering model for a bracketing transduction grammar (BTG) (Wu, 1995), which predicts the probability that a pair of subconstituents will reorder when combined to form a new constituent. The features of their model look only at the *first* source and target word of each constituent, making it something like a sparse version of our model. However, because of the target word features, their reordering model cannot be separated from their translation model.

8 Conclusions and Future Work

We have presented an entirely new model of reordering for statistical machine translation, based on the Linear Ordering Problem, and shown that it can substantially improve translation from German to English.

The model is demonstrably useful in this preprocessing setting—which means that it can be very simply added as a preprocessing step to any MT system. German-to-English is a particularly attractive use case, because the word orders are sufficiently different as to require a good reordering model that requires long-distance reordering. Our preprocessing here gave us a BLEU gain of 0.9 point over the best Moses-based result. English-to-German would obviously be another potential win, as would translating between English and Japanese, for example.

As mentioned in Section 6, our model could also be integrated into a phrase-based, or a syntax-based decoder. That possibility remains future work, but it is likely to lead to further improvements, because it allows the translation system to consider multiple possible reorderings under the model, as well as to tune the weight of the model relative to the other parts of the system during MERT.

Tromble (2009) covers this integration in more detail, and proposes several other ways of integrating our reordering model into machine translation. It also experiments with numerous other parameter estimation procedures, including some that use the probabilistic interpretation of our model from (3). It presents numerous additional neighborhoods for search in the Linear Ordering Problem.

We mentioned several possible extensions to the model, such as going beyond the scoring model of equation (2), or considering syntax-based features. Another extension would try to reorder not words but phrases, following (Xiong et al., 2006), or segment choice models (Kuhn et al., 2006), which assume a single segmentation of the words into phrases. We would have to define the pairwise preference matrix B over phrases rather than

words (Eisner and Tromble, 2006). This would have the disadvantage of complicating the feature space, but might be a better fit for integration with a phrase-based decoder.

Finally, we gave a novel algorithm for approximately solving the Linear Ordering Problem, interestingly combining dynamic programming with local search. Another novel contribution is that we showed how to parameterize a function that constructs a specific Linear Ordering Problem instance from an input sentence $\boldsymbol{w}$, and showed how to learn those parameters from a corpus of parallel sentences, using the perceptron algorithm. Likelihood-based training using equation (3) would also be possible, with modifications to our algorithm, notably the use of normal forms to avoid counting some permutations multiple times (Tromble, 2009).

It would be interesting to compare the speed and accuracy of our dynamic-programming local-search method with an exact algorithm for solving the LOP, such as integer linear programming with branch and bound (cf. Charon and Hudry (2006)). Exact solutions can generally be found in practice for $n \leq 100$.

Abstract

Current statistical machine translation systems usually extract rules from bilingual corpora annotated with 1-best alignments. They are prone to learn noisy rules due to alignment mistakes. We propose a new structure called *weighted alignment matrix* to encode all possible alignments for a parallel text compactly. The key idea is to assign a probability to each word pair to indicate how well they are aligned. We design new algorithms for extracting phrase pairs from weighted alignment matrices and estimating their probabilities. Our experiments on multiple language pairs show that using weighted matrices achieves consistent improvements over using n-best lists in significant less extraction time.

1 Introduction

Statistical machine translation (SMT) relies heavily on annotated bilingual corpora. Word alignment, which indicates the correspondence between the words in a parallel text, is one of the most important annotations in SMT. Word-aligned corpora have been found to be an excellent source for translation-related knowledge, not only for phrase-based models (Och and Ney, 2004; Koehn et al., 2003), but also for syntax-based models (e.g., (Chiang, 2007; Galley et al., 2006; Shen et al., 2008; Liu et al., 2006)). Och and Ney (2003) indicate that the quality of machine translation output depends directly on the quality of initial word alignment.

Modern alignment methods can be divided into two major categories: *generative* methods and *discriminative* methods. Generative methods (Brown et al., 1993; Vogel and Ney, 1996) treat word alignment as a hidden process and maximize the likelihood of bilingual training corpus using the expectation maximization (EM) algorithm. In contrast, discriminative methods (e.g., (Moore et al., 2006; Taskar et al., 2005; Liu et al., 2005; Blunsom and Cohn, 2006)) have the freedom to define arbitrary feature functions that describe various characteristics of an alignment. They usually optimize feature weights on manually-aligned data. While discriminative methods show superior alignment accuracy in benchmarks, generative methods are still widely used to produce word alignments for large sentence-aligned corpora.

However, neither generative nor discriminative alignment methods are reliable enough to yield high quality alignments for SMT, especially for distantly-related language pairs such as Chinese-English and Arabic-English. The F-measures for Chinese-English and Arabic-English are usually around 80% (Liu et al., 2005) and 70% (Fraser and Marcu, 2007), respectively. As most current SMT systems only use 1-best alignments for extracting rules, alignment errors might impair translation quality.

Recently, several studies have shown that offering more alternatives of annotations to SMT systems will result in significant improvements, such as replacing 1-best trees with packed forests (Mi et al., 2008) and replacing 1-best word segmentations with word lattices (Dyer et al., 2008). Similarly, Venugopal et al. (2008) use n-best alignments instead of 1-best alignments for translation rule extraction. While they achieve significant improvements on the IWSLT data, extracting rules from n-best alignments might be computationally expensive.

In this paper, we propose a new structure named *weighted alignment matrix* to represent the alignment distribution for a sentence pair compactly. In a weighted matrix, each element that corresponds to a word pair is assigned a probability to measure the confidence of aligning the two words. Therefore, a weighted matrix is capable of using a lin-

Singapore, 6-7 August 2009.

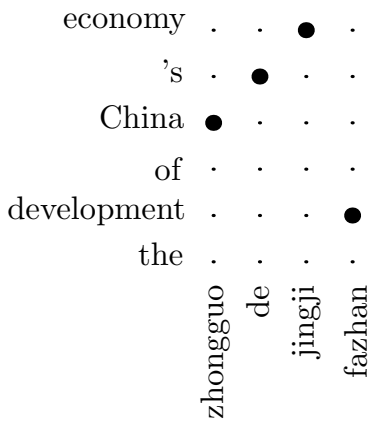

Figure 1: An example of word alignment between a pair of Chinese and English sentences.

ear space to encode the probabilities of exponentially many alignments. We develop a new algorithm for extracting phrase pairs from weighted matrices and show how to estimate their relative frequencies and lexical weights. Experimental results show that using weighted matrices achieves consistent improvements in translation quality and significant reduction in extraction time over using n-best lists.

2 Background

Figure 1 shows an example of word alignment between a pair of Chinese and English sentences. The Chinese and English words are listed horizontally and vertically, respectively. The dark points indicate the correspondence between the words in two languages. For example, the first Chinese word "*zhongguo*" is aligned to the fourth English word "*China*".

Formally, given a source sentence $\mathbf{f} = f_1^J = f_1, \ldots, f_j, \ldots, f_J$ and a target sentence $\mathbf{e} = e_1^I = e_1, \ldots, e_i, \ldots, e_I$, we define a link $l = (j, i)$ to exist if f_j and e_i are translation (or part of translation) of one another. Then, an alignment $\mathbf{a}$ is a subset of the Cartesian product of word positions:

$$\mathbf{a} \subseteq \{(j, i) : j = 1, \ldots, J; i = 1, \ldots, I\} \quad (1)$$

Usually, SMT systems only use the 1-best alignments for extracting translation rules. For example, given a source phrase $\tilde{f}$ and a target phrase $\tilde{e}$, the phrase pair $(\tilde{f}, \tilde{e})$ is said to be *consistent* (Och and Ney, 2004) with the alignment if and only if: (1) there must be at least one word inside one phrase aligned to a word inside the other phrase and (2) no words inside one phrase can be aligned to a word outside the other phrase.

After all phrase pairs are extracted from the training corpus, their translation probabilities can be estimated as *relative frequencies* (Och and Ney, 2004):

$$\phi(\tilde{e}|\tilde{f}) = \frac{count(\tilde{f}, \tilde{e})}{\sum_{\tilde{e}'} count(\tilde{f}, \tilde{e}')} \quad (2)$$

where $count(\tilde{f}, \tilde{e})$ indicates how often the phrase pair $(\tilde{f}, \tilde{e})$ occurs in the training corpus.

Besides relative frequencies, *lexical weights* (Koehn et al., 2003) are widely used to estimate how well the words in $\tilde{f}$ translate the words in $\tilde{e}$. To do this, one needs first to estimate a lexical translation probability distribution $w(e|f)$ by relative frequency from the same word alignments in the training corpus:

$$w(e|f) = \frac{count(f, e)}{\sum_{e'} count(f, e')} \quad (3)$$

Note that a special source NULL token is added to each source sentence and aligned to each unaligned target word.

As the alignment $\tilde{a}$ between a phrase pair $(\tilde{f}, \tilde{e})$ is retained during extraction, the lexical weight can be calculated as

$$p_w(\tilde{e}|\tilde{f}, \tilde{a}) = \prod_{i=1}^{|\tilde{e}|} \frac{1}{|\{j|(j, i) \in \tilde{a}\}|} \sum w(e_i|f_j) \quad (4)$$

If there are multiple alignments $\tilde{a}$ for a phrase pair $(\tilde{f}, \tilde{e})$, Koehn et al. (2003) choose the one with the highest lexical weight:

$$p_w(\tilde{e}|\tilde{f}) = \max_{\tilde{a}} \left\{ p_w(\tilde{e}|\tilde{f}, \tilde{a}) \right\} \quad (5)$$

Simple and effective, relative frequencies and lexical weights have become the standard features in modern discriminative SMT systems.

3 Weighted Alignment Matrix

We believe that offering more candidate alignments to extracting translation rules might help improve translation quality. Instead of using n-best lists (Venugopal et al., 2008), we propose a new structure called *weighted alignment matrix*.

We use an example to illustrate our idea. Figure 2(a) and Figure 2(b) show two alignments of a Chinese-English sentence pair. We observe that some links (e.g., (1,4) corresponding to the word

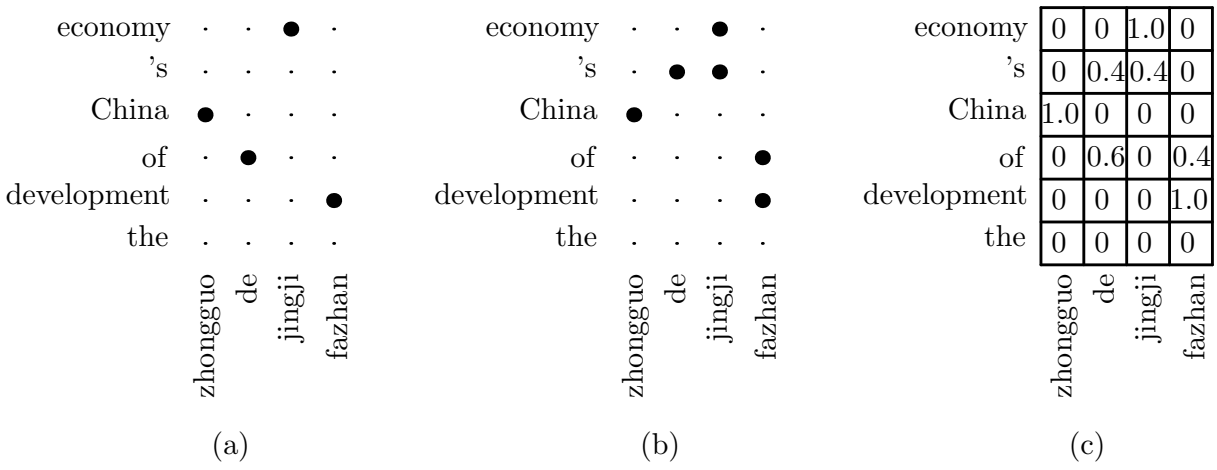

Figure 2: (a) One alignment of a sentence pair; (b) another alignment of the same sentence pair; (c) the resulting weighted alignment matrix that takes the two alignments as samples, of which the initial probabilities are 0.6 and 0.4, respectively.

pair ("*zhongguo*", "*China*")) occur in both alignments, some links (e.g., (2,3) corresponding to the word pair ("*de*","*of*")) occur only in one alignment, and some links (e.g., (1,1) corresponding to the word pair ("*zhongguo*", "*the*")) do not occur. Intuitively, we can estimate how well two words are aligned by calculating its relative frequency, which is the probability sum of alignments in which the link occurs divided by the probability sum of all possible alignments. Suppose that the probabilities of the two alignments in Figures 2(a) and 2(b) are 0.6 and 0.4, respectively. We can estimate the relative frequencies for every word pair and obtain a weighted matrix shown in Figure 2(c). Therefore, each word pair is associated with a probability to indicate how well they are aligned. For example, in Figure 2(c), we say that the word pair ("*zhongguo*", "*China*") is definitely aligned, ("*zhongguo*", "the") is definitely unaligned, and ("*de*", "*of*") has a 60% chance to get aligned.

Formally, a weighted alignment matrix m is a $J \times I$ matrix, in which each element stores a *link probability* $p_m(j,i)$ to indicate how well f_j and e_i are aligned. Currently, we estimate link probabilities from an n-best list by calculating relative frequencies:

$$p_m(j,i) = \frac{\sum_{a \in \mathcal{N}} p(a) \times \delta(a,j,i)}{\sum_{a \in \mathcal{N}} p(a)} \quad (6)$$

$$= \sum_{a \in \mathcal{N}} p(a) \times \delta(a,j,i) \quad (7)$$

where

$$\delta(a,j,i) = \begin{cases} 1 & (j,i) \in a \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

Note that $\mathcal{N}$ is an n-best list, $p(a)$ is the probability of an alignment a in the n-best list, $\delta(a,j,i)$ indicates whether a link (j,i) occurs in the alignment a or not. We assign 0 to any unseen alignment. As $p(a)$ is usually normalized (i.e., $\sum_{a \in \mathcal{N}} p(a) \equiv 1$), we remove the denominator in Eq. (6).

Accordingly, the probability that the two words f_j and e_i are not aligned is

$$\bar{p}_m(j,i) = 1.0 - p_m(j,i) \quad (9)$$

For example, as shown in Figure 2(c), the probability for the two words "*de*" and "*of*" being aligned is 0.6 and the probability that they are not aligned is 0.4.

Intuitively, the probability of an alignment a is the product of link probabilities. If a link (j,i) occurs in a, we use $p_m(j,i)$; otherwise we use $\bar{p}_m(j,i)$. Formally, given a weighted alignment matrix m, the probability of an alignment a can be calculated as

$$p_m(a) = \prod_{j=1}^{J} \prod_{i=1}^{I} (p_m(j,i) \times \delta(a,j,i) + \bar{p}_m(j,i) \times (1 - \delta(a,j,i))) \quad (10)$$

It proves that the sum of all alignment probabilities is always 1: $\sum_{a \in \mathcal{A}} p_m(a) \equiv 1$, where $\mathcal{A}$

Figure 3: Algorithm for extracting phrase pairs from a sentence pair $\langle f_1^J, e_1^I \rangle$ annotated with a weighted alignment matrix m.

is the set of all possible alignments. Therefore, a weighted alignment matrix is capable of encoding the probabilities of $2^{J \times I}$ alignments using only a $J \times I$ space.

Note that $p_m(a)$ is not necessarily equal to $p(a)$ because the encoding of a weighted alignment matrix changes the alignment probability distribution. For example, while the initial probability of the alignment in Figure 2(a) (i.e., $p(a)$) is 0.6, the probability of the same alignment encoded in the matrix shown in Figure 2(c) (i.e., $p_m(a)$) becomes 0.1296 according to Eq. (10). It should be emphasized that a weighted matrix encodes all possible alignments rather than the input n-best list, although the link probabilities are estimated from the n-best list.

4 Phrase Pair Extraction

In this section, we describe how to extract phrase pairs from the training corpus annotated with weighted alignment matrices (Section 4.1) and how to estimate their relative frequencies (Section 4.2) and lexical weights (Section 4.3).

4.1 Extraction Algorithm

Och and Ney (2004) describe a "phrase-extract" algorithm for extracting phrase pairs from a sentence pair annotated with a 1-best alignment. Given a source phrase, they first identify the target phrase that is consistent with the alignment. Then, they expand the boundaries of the target phrase if the boundary words are unaligned.

Unfortunately, this algorithm cannot be directly used to manipulate a weighted alignment matrix, which is a compact representation of all possible alignments. The major difference is that the "tight" phrase that has both boundary words aligned is not necessarily the smallest candidate in a weighted matrix. For example, in Figure 2(a), the "tight" target phrase corresponding to the source phrase "*zhongguo de*" is "*of China*". According to Och's algorithm, the target phrase "*China*" breaks the alignment consistency and therefore is not valid candidate. However, this is not true for using the weighted matrix shown in Figure 2(c). The target phrase "*China*" is treated as a "potential" candidate [1], although it might be assigned only a small fractional count (see Table 1).

Therefore, we enumerate all potential phrase pairs and calculate their fractional counts for eliminating less promising candidates. Figure 3 shows the algorithm for extracting phrases from a weighted matrix. The input of the algorithm is a source sentence f_1^J, a target sentence e_1^I, a weighted alignment matrix m, and a phrase length limit l (line 1). After initializing $\mathcal{R}$ that stores collected phrase pairs (line 2), we identify the corresponding target phrases for all possible source phrases (lines 3-5). Given a source phrase $f_{j_1}^{j_2}$, we find the lower and upper bounds of target positions (i.e., i_l and i_u) that have positive link probabilities (lines 6-8). For example, the lower bound is 3 and the upper bound is 5 for the source phrase "*zhongguo de*" in Figure 2(c). Finally, we enumerate all target phrases that allow for unaligned boundary words with varying phrase lengths (lines 9-14). Note that we need to ensure that $1 \leq i_1 \leq I$ and $1 \leq i_2 \leq I$ in lines 10-11, which are omitted for simplicity.

4.2 Calculating Relative Frequencies

To estimate the relative frequency of a phrase pair, we need to estimate how often it occurs in the training corpus. Given an n-best list, the fractional count of a phrase pair is the probability sum of the alignments with which the phrase pair is consistent. Obviously, it is unrealistic for a weighted alignment matrix to enumerate all possible alignments explicitly to calculate fractional counts. Instead, we resort to link probabilities to calculate

[1] By potential, we mean that the fractional count of a phrase pair is positive. Section 4.2 describes how to calculate fractional counts.

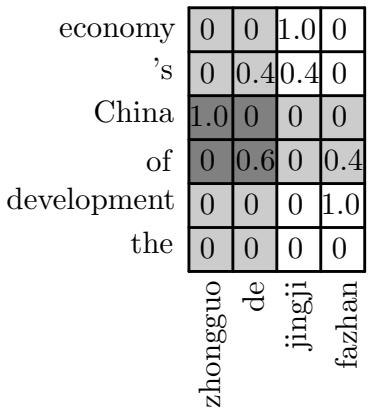

Figure 4: An example of calculating fractional count. Given the phrase pair ("*zhongguo de*", "*of China*"), we divide the matrix into three areas: inside (heavy shading), outside (light shading), and irrelevant (no shading).

counts efficiently. Equivalent to explicit enumeration, we interpret the fractional count of a phrase pair as the probability that it satisfies the two alignment consistency conditions (see Section 2).

Given a phrase pair, we divide the elements of a weighted alignment matrix into three categories: (1) *inside* elements that fall inside the phrase pair, (2) *outside* elements that fall outside the phrase pair while fall in the same row or the same column, and (3) *irrelevant* elements that fall outside the phrase pair while fall in neither the same row nor the same column. Figure 4 shows an example. Given the phrase pair ("*zhongguo de*", "*of China*"), we divide the matrix into three areas: inside (heavy shading), outside (light shading), and irrelevant (no shading).

To what extent a phrase pair satisfies the alignment consistency is measured by calculating *inside* and *outside* probabilities. Although there are the same terms in the parsing literature, they have different meanings here. The inside probability indicates the chance that there is at least one word inside one phrase aligned to a word inside the other phrase. The outside probability indicates the chance that no words inside one phrase are aligned to a word outside the other phrase.

Given a phrase pair $(f_{j_1}^{j_2}, e_{i_1}^{i_2})$, we denote the inside area as $in(j_1, j_2, i_1, i_2)$ and the outside area as $out(j_1, j_2, i_1, i_2)$. Therefore, the inside probability of a phrase pair is calculated as

$$\alpha(j_1, j_2, i_1, i_2) = 1 - \prod_{(j,i) \in in(j_1, j_2, i_1, i_2)} \bar{p}_m(j, i) \quad (11)$$

target phrase	α	β	$count$
of China	1.0	0.36	0.36
of China 's	1.0	0.36	0.36
China 's	1.0	0.24	0.24
China	1.0	0.24	0.24
's economy	0.4	0	0

Table 1: Some candidate target phrases of the source phrase "*zhongguo de*" in Figure 4, where α is inside probability, β is outside probability, and $count$ is fractional count.

For example, the inside probability for ("*zhongguo de*", "*of China*") in Figure 4 is 1.0, which means that there always exists at least one aligned word pair inside.

Accordingly, the outside probability of a phrase pair is calculated as

$$\beta(j_1, j_2, i_1, i_2) = \prod_{(j,i) \in out(j_1, j_2, i_1, i_2)} \bar{p}_m(j, i) \quad (12)$$

For example, the outside probability for ("*zhongguo de*", "*of China*") in Figure 4 is 0.36, which means the probability that there are no aligned word pairs outside is 0.36.

Finally, we use the product of inside and outside probabilities as the fractional count of a phrase pair:

$$count(f_{j_1}^{j_2}, e_{i_1}^{i_2}) = \alpha(j_1, j_2, i_1, i_2) \times \beta(j_1, j_2, i_1, i_2) \quad (13)$$

Table 1 lists some candidate target phrases of the source phrase "*zhongguo de*" in Figure 4. We also give their inside probabilities, outside probabilities, and fractional counts.

After collecting the fractional counts from the training corpus, we then use Eq. (2) to calculate relative frequencies in two translation directions.

Often, our approach extracts a large amount of phrase pairs from training corpus as we soften the alignment consistency constraint. To maintain a reasonable phrase table size, we discard any phrase pair that has a fractional count lower than a threshold t. During extraction, we first obtain a list of candidate target phrases for each source phrase, as shown in Table 1. Then, we prune the list according to the threshold t. For example, we only retain the top two candidates in Table 1 if $t = 0.3$. Note that we perform the pruning locally. Although it is more reasonable to prune a phrase table after accumulating all fractional counts from

training corpus, such global pruning strategy usually leads to very large disk and memory requirements.

4.3 Calculating Lexical Weights

Recall that we need to obtain two translation probability tables $w(e|f)$ and $w(f|e)$ before calculating lexical weights (see Section 2). Following Koehn et al. (2003), we estimate the two distributions by relative frequencies from the training corpus annotated with weighted alignment matrices. In other words, we still use Eq. (3) but the way of calculating fractional counts is different now.

Given a source word f_j, a target word e_i, and a weighted alignment matrix, the fractional count $count(f_j, e_i)$ is $p_m(j, i)$. For NULL words, the fractional counts can be calculated as

$$count(f_j, e_0) = \prod_{i=1}^{I} \bar{p}_m(j, i) \quad (14)$$

$$count(f_0, e_i) = \prod_{j=1}^{J} \bar{p}_m(j, i) \quad (15)$$

For example, in Figure 4, $count$(*de*, *of*) is 0.6, $count$(*de*,*NULL*) is 0.24, and $count$(*NULL*,*of*) is 0.24.

Then, we adapt Eq. (4) to calculate lexical weight:

$$p_w(\tilde{e}|\tilde{f}, m) = \prod_{i=1}^{|\tilde{e}|} \left(\left(\frac{1}{\{j|p_m(j,i) > 0\}} \times \sum_{\forall j: p_m(j,i)>0} p(e_i|f_j) \times p_m(j, i) \right) + p(e_i|f_0) \times \prod_{j=1}^{|\tilde{f}|} \bar{p}_m(j, i) \right) \quad (16)$$

For example, for the target word "*of*" in Figure 4, the sum of aligned and unaligned probabilities is

$$\frac{1}{2} \times (p(\textit{of}|\textit{de}) \times 0.6 + p(\textit{of}|\textit{fazhan}) \times 0.4) + p(\textit{of}|\text{NULL}) \times 0.24$$

Note that we take link probabilities into account and calculate the probability that a target word translates a source NULL token explicitly.

5 Experiments

5.1 Data Preparation

We evaluated our approach on Chinese-to-English translation. We used the FBIS corpus (6.9M + 8.9M words) as the training data. For language model, we used the SRI Language Modeling Toolkit (Stolcke, 2002) to train a 4-gram model on the Xinhua portion of GIGAWORD corpus. We used the NIST 2002 MT evaluation test set as our development set, and used the NIST 2005 test set as our test set. We evaluated the translation quality using *case-insensitive* BLEU metric (Papineni et al., 2002).

To obtain weighted alignment matrices, we followed Venugopal et al. (2008) to produce n-best lists via GIZA++. We first ran GIZA++ to produce 50-best lists in two translation directions. Then, we used the refinement technique "grow-diag-final-and" (Koehn et al., 2003) to all 50×50 bidirectional alignment pairs. Suppose that p_{s2t} and p_{t2s} are the probabilities of an alignment pair assigned by GIZA++, respectively. We used $p_{s2t} \times p_{t2s}$ as the probability of the resulting symmetric alignment. As different alignment pairs might produce the same symmetric alignments, we followed Venugopal et al. (2008) to remove duplicate alignments and retain only the alignment with the highest probability. Therefore, there were 550 candidate alignments on average for each sentence pair in the training data. We obtained n-best lists by selecting the top n alignments from the 550-best lists. The probability of each alignment in the n-best list was re-estimated by re-normalization (Venugopal et al., 2008). Finally, these n-best alignments served as samples for constructing weighted alignment matrices.

After extracting phrase pairs from n-best lists and weighted alignment matrices, we ran Moses (Koehn et al., 2007) to translate the development and test sets. We used the simple distance-based reordering model to remove the dependency of lexicalization on word alignments for Moses.

5.2 Effect of Pruning Threshold

Our first experiment investigated the effect of pruning threshold on translation quality (BLEU scores on the test set) and the phrase table size (filtered for the test set), as shown in Figure 5. To save time, we extracted phrase pairs just from the first 10K sentence pairs of the FBIS corpus. We used 12 different thresholds: 0.0001, 0.001, 0.01, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, and 0.9. Obviously, the lower the threshold is, the more phrase pairs are extracted. When $t = 0.0001$, the number of phrase pairs used on the test set was 460,284

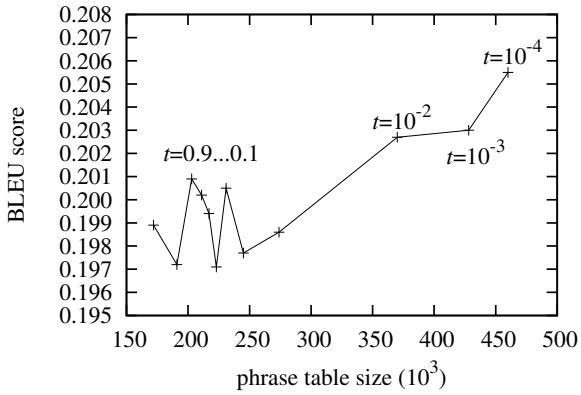

Figure 5: Effect of pruning threshold on translation quality and phrase table size.

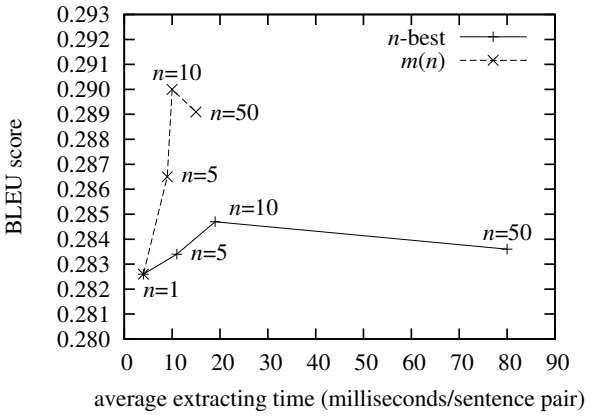

Figure 6: Comparison of n-best alignments and weighted alignment matrices. We use $m(n)$ to denote the matrices that take n-best lists as samples.

and the BLEU score was 20.55. Generally, both the number of phrase pairs and the BLEU score went down with the increase of t. However, this trend did not hold within the range [0.1, 0.9]. To achieve a good tradeoff between translation quality and phrase table size, we set $t = 0.01$ for the following experiments.

5.3 N-best lists Vs. Weighted Matrices

Figure 6 shows the BLEU scores and average extraction time using n-best alignments and weighted matrices, respectively. We used the entire training data for phrase extraction. When using 1-best alignments, Moses achieved a BLEU score of 0.2826 and the average extraction time was 4.19 milliseconds per sentence pair (see point $n = 1$). The BLEU scores rose with the increase of n for using n-best alignments. However, the score went down slightly when $n = 50$. This suggests that including more noisy alignments might be harmful. These improvements over 1-best alignments are not statistically significant. This finding failed to echo the promising results reported by Venogopal et al. (2008). We think that there are two possible reasons. First, they evaluated their approach on the IWSLT data while we used the NIST data. It might be easier to obtain significant improvements on the IWSLT data in which the sentences are shorter. Second, they used the hierarchical phrase-based system while we used the phrase-based system, which might be less sensitive to word alignments because the alignments inside the phrase pairs hardly have an effect.

When using weighted alignment matrices, we obtained higher BLEU scores than using n-best lists with much less extraction time. We achieved a BLEU score of 0.2901 when using the weighted matrices estimated from 10-best lists. The absolute improvement of 0.75 over using 1-best alignments (from 0.2826 to 0.2901) is statistically significant at $p < 0.05$ by using *sign-test* (Collins et al., 2005). Although the improvements over n-best lists are not always statistically significant, weighted alignment matrices maintain consistent superiority in both translation quality and extraction speed.

5.4 Comparison of Parameter Estimation

In theory, the set of phrase pairs extracted from n-best alignments is the subset of the set extracted from the corresponding weighted matrices. In practice, however, this is not true because we use the pruning threshold t to maintain a reasonable table size. Even so, the phrase tables produced by n-best lists and weighted matrices still share many phrase pairs.

Table 2 gives some statistics. We use m(10) to represent the weighted matrices estimated from 10-best lists. "all" denotes the full phrase table, "shared" denotes the intersection of two tables, and "non-shared" denotes the complement. Note that the probabilities of "shared" phrase pairs are different for the two approaches. We obtained 6.13M and 6.34M phrase pairs for the test set by using 10-best lists and the corresponding matrices, respectively. There were 4.58M phrase pairs included by both tables. Note that the relative frequencies and lexical weights for the same phrase

method	shared		non-shared		all	
	phrases	BLEU	phrases	BLEU	phrases	BLEU
10-best	4.58M	**28.35**	1.55M	12.32	6.13M	28.47
m(10)	4.58M	**28.90**	1.76M	13.21	6.34M	29.01

Table 2: Comparison of phrase tables learned from n-best lists and weighted matrices. We use m(10) to represent the weighted matrices estimated from 10-best lists. "all" denotes the full phrase table, "shared" denotes the intersection of two tables, and "non-shared" denotes the complement. Note that the probabilities of "shared" phrase pairs are different for the two approaches.

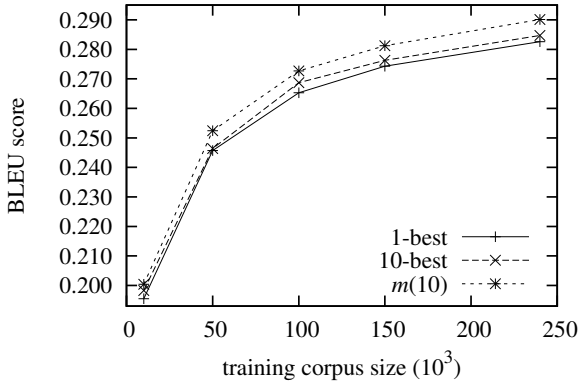

Figure 7: Comparison of n-best alignments and weighted alignment matrices with varying training corpus sizes.

pairs might be different in two tables. We found that using matrices outperformed using n-best lists even with the same phrase pairs. This suggests that our methods for parameter estimation make better use of noisy data. Another interesting finding was that using the shared phrase pairs achieved almost the same results with using full phrase tables.

5.5 Effect of Training Corpus Size

To investigate the effect of training corpus size on our approach, we extracted phrase pairs from n-best lists and weighted matrices trained on five training corpora with varying sizes: 10K, 50K, 100K, 150K, and 239K sentence pairs. As shown in Figure 7, our approach outperformed both 1-best and n-best lists consistently. More importantly, the gains seem increase when more training data are used.

5.6 Results on Other Language Pairs

To further examine the efficacy of the proposed approach, we scaled our experiments to large data with multiple language pairs. We used the Europarl training corpus from the WMT07 shared task. [2] Table 3 shows the statistics of the training data. There are four languages (Spanish, French, German, and English) and six translation directions (Foreign-to-English and English-to-Foreign). We used the "dev2006" data in the "dev" directory as the development set and the "test2006" data in the "devtest" directory as the test set. Both the development and test sets contain 2,000 sentences with single reference translations.

We tokenized and lowercased all the training, development, and test data. We trained a 4-gram language model using SRI Language Modeling Toolkit on the target side of the training corpus for each task. We ran GIZA++ on the entire training data to obtain n-best alignments and weighted matrices. To save time, we just used the first 100K sentences of each aligned training corpus to extract phrase pairs.

	S↔E	F↔E	G↔E
Sentences	1.26M	1.29M	1.26M
Foreign words	33.16M	33.18M	29.58M
English words	31.81M	32.62M	31.93M

Table 3: Statistics of the Europarl training data. "S" denotes Spanish, "E" denotes English, "F" denotes French, "G" denotes German.

	1-best	10-best	m(10)
S→E	30.90	30.97	31.03
E→S	31.16	31.25	31.34
F→E	30.69	30.76	30.82
E→F	26.42	26.65	26.54
G→E	24.46	24.58	24.66
E→G	18.03	18.30	18.20

Table 4: BLEU scores (case-insensitive) on the Europarl data. "S" denotes Spanish, "E" denotes English, "F" denotes French, "G" denotes German.

[2] http://www.statmt.org/wmt07/shared-task.html

Table 4 lists the case-insensitive BLEU scores of 1-best, 10-best, and m(10) on the Europarl data. Using weighted packed matrices continued to show advantage over using 1-best alignments on multiple language pairs. However, these improvements were very small and not significant. We attribute this to the fact that GIZA++ usually produces high quality 1-best alignments for closely-related European language pairs, especially when trained on millions of sentences.

6 Related Work

Recent studies has shown that SMT systems can benefit from making the annotation pipeline wider: using packed forests instead of 1-best trees (Mi et al., 2008), word lattices instead of 1-best segmentations (Dyer et al., 2008), and n-best alignments instead of 1-best alignments (Venugopal et al., 2008). We propose a compact representation of multiple word alignments that enables SMT systems to make a better use of noisy alignments.

Matusov et al. (2004) propose "cost matrices" for producing symmetric alignments. Kumar et al. (2007) describe how to use "posterior probability matrices" to improve alignment accuracy via a bridge language. Although not using the term "weighted matrices" directly, they both assign a probability to each word pair.

We follow Och and Ney (2004) to develop a new phrase extraction algorithm for weighted alignment matrices. The methods for calculating relative frequencies (Och and Ney, 2004) and lexical weights (Koehn et al., 2003) are also adapted for the weighted matrix case.

Many researchers (e.g., (Venugopal et al., 2003; Deng et al., 2008)) observe that softening the alignment consistency constraint help improve translation quality. For example, Deng et al. (2008) define a feature named "within phrase pair consistency ratio" to measure the degree of consistency. As each link is associated with a probability in a weighted matrix, we use these probabilities to evaluate the validity of a phrase pair.

We estimate the link probabilities by calculating relative frequencies over n-best lists. Niehues and Vogel (2008) propose a discriminative approach to modeling the alignment matrix directly. The difference is that they assign a boolean value instead of a probability to each word pair.

7 Conclusion and Future Work

We have presented a new structure called weighted alignment matrix that encodes the alignment distribution for a sentence pair. Accordingly, we develop new methods for extracting phrase pairs and estimating their probabilities. Our experiments show that the proposed approach achieves better translation quality over using n-best lists in less extraction time. An interesting finding is that our approach performs better than the baseline even they use the same phrase pairs.

Although our approach consistently outperforms using 1-best alignments for varying language pairs, the improvements are comparatively small. One possible reason is that taking n-best lists as samples sometimes might change alignment probability distributions inappropriately. A more principled solution is to directly model the weighted alignment matrices, either in a generative or a discriminative way. We believe that better estimation of alignment distributions will result in more significant improvements.

Another interesting direction is applying our approach to extracting translation rules with hierarchical structures such as hierarchical phrases (Chiang, 2007) and tree-to-string rules (Galley et al., 2006; Liu et al., 2006). We expect that these syntax-based systems could benefit more from our approach.

Sinuhe — Statistical Machine Translation using a Globally Trained Conditional Exponential Family Translation Model

Matti Kääriäinen
Department of Computer Science
FI-00014 University of Helsinki, Finland
matti.kaariainen@cs.helsinki.fi

Abstract

We present a new phrase-based conditional exponential family translation model for statistical machine translation. The model operates on a feature representation in which sentence level translations are represented by enumerating all the known phrase level translations that occur inside them. This makes the model a good match with the commonly used phrase extraction heuristics. The model's predictions are properly normalized probabilities. In addition, the model automatically takes into account information provided by phrase overlaps, and does not suffer from reference translation reachability problems.

We have implemented an open source translation system Sinuhe based on the proposed translation model. Our experiments on Europarl and GigaFrEn corpora demonstrate that finding the unique MAP parameters for the model on large scale data is feasible with simple stochastic gradient methods. Sinuhe is fast and memory efficient, and the BLEU scores obtained by it are only slightly inferior to those of Moses.

1 Introduction

In current phrase-based statistical machine translation systems such as Moses[1] (Koehn et al., 2007), the translation model is defined in terms of phrase pairs (biphrases) extracted from a bilingual corpus as follows. The corpus is first word-aligned using a word alignment heuristic (Och and Ney, 2003). The phrase extraction heuristic then extracts all the biphrases that are compatible with the word alignment (Och et al., 1999). This way, each sentence pair may generate any number of potentially overlapping biphrases. However, when defining the phrase-based sentence level translation model, phrase overlaps are explicitly disallowed: The source sentence is segmented into disjoint phrases, which are translated independently using conditional phrase-level translation models that have been estimated from extracted biphrase counts.

The disparity between the phrase extraction heuristic and the use of the extracted biphrases can be addressed in at least three ways. One approach is to simply ignore the disparity as is done, e.g., in Moses. While empirically succesful, this approach is hard to justify theoretically, and begs the question of whether more principled methods might lead to better translation results. The other extensively studied approach is to replace the phrase extraction heuristic with a method that better matches the use of the extracted phrases (see, e.g., (Marcu and Wong, 2002; DeNero et al., 2008) and the references therein). While theoretically sound, this approach is computationally challenging both in practice (DeNero et al., 2008) and in theory (DeNero and Klein, 2008), may suffer from reference reachability problems (DeNero et al., 2006), and in the end may lead to inferior translation quality (Koehn et al., 2003).

In this paper, we study a third alternative. We propose a new translation model that is compatible with the phrase extraction heuristic. The proposed machine learning inspired translation model takes the form of a conditional exponential family probability distribution over a feature representation for word-aligned sentence pairs. The feature representation represents a word-aligned sentence pair by essentially enumerating the (multi)set of biphrases that would have been extracted from it,

[1] Throughout this paper, we refer to Moses for concreteness, but most of the discussion applies to other standard phrase-based statistical machine translation systems as well.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1027–1036,
Singapore, 6-7 August 2009.

together with the source positions at which the biphrases occur. The model's predictions are conditional probabilities for such sets of biphrases given the source sentence.

The chosen feature representation has many advantages. Since all word-aligned sentence pairs can be represented, reference reachability problems are automatically circumvented. For example, if the translation of a sentence consisted solely of words that do not occur in the phrase table, then the feature vector for the translation would be the all zero vector. As the training data receives nonzero probability, maximum likelihood or maximum a posteriori (MAP) parameters for the model can be estimated in a principled way without resorting to pseudo-references. The fact that the model is not restricted to using disjoint biphrases means that the information in biphrase overlaps is automatically taken into account. This may help in smoothing the model's predictions on long and rare phrases, and in enhancing fluency at places that otherwise would be phrase boundaries. Also, the model can be extended in a principled way by introducing additional features (e.g., translations from a dictionary, biphrases with gaps, biphrases over POS tags,...).

The proposed model has one parameter per biphrase feature, so the total number of parameters is easily millions or more. Still, the model structure is designed so that feature expectations and related quantities can be computed efficiently by dynamic programming. It is thus feasible to compute the gradient of the MAP objective, and simple gradient ascent can be used to efficiently find the globally optimal model parameters (with respect to a suitably scaled Gaussian prior used for regularization). Exact inference is also possible by dynamic programming when translations are predicted by the translation model alone. When other features like a language model are included, one needs to resort to beam search type approximate dynamic programming for decoding.

We have implemented a translation system called `Sinuhe` based on the proposed translation model. The system has been released under the GPLv3 open source license (Kääriäinen, 2009). Our experiments on Europarl and GigaFrEn corpora demonstrate that the proposed translation model scales well to large data, and offers translation quality that is only slightly worse than that of the baseline system `Moses`. In terms of translation speed, `Sinuhe` is already clearly better.

The rest of this paper is organized as follows. After briefly reviewing related work in Section 2, we describe the proposed translation model in Section 3. Finally, experimental results are presented in Section 4, and conclusions in Section 5.

2 Related work

The proposed translation model is strongly influenced by machine learning techniques for solving sequence prediction tasks, most notably the work on conditional random fields (Lafferty et al., 2001). The modelling task in machine translation is, however, more complicated than sequence labelling (not one-to-one, reorderings), so the standard methods cannot be directly applied here. The model we propose is also related to standard phrase-based translation models through the use of the same phrase-level translation features. However, the way we use the features is quite different.

There exists a number of discriminative approaches whose model structure, training criteria, or both, are similar to ours. However, to our knowledge, none of the other systems operates directly on biphrase features, scales up to bilingual corpora with millions of sentence pairs, and achieves translation quality comparable to fully tuned standard phrase-based systems. The approach most closely resembling ours is the independently developed global discriminative log-linear model based on synchronous context-free grammars (Blunsom and Osborne, 2008; Blunsom et al., 2008). The version presented in (Blunsom and Osborne, 2008) operates on millions of rule count features analogous to our biphrase features, and integrates a language model into training and decoding. The system can be trained on tens of thousands of short sentences yielding better translations than a baseline system `Hiero` on this data. The version presented in (Blunsom et al., 2008) scales to more than a hundred thousand short training sentences, but does not integrate a language model and thus has performance that improves upon `Hiero` without a language model only. Both versions deal with derivational ambiguity by treating derivations as a latent variables that are integrated out to get conditional probabilities for translations[2]. The downside of this

[2]In our translation model, coping with multiple derivations is not needed as there is just one derivation for each word-aligned sentence pair. However, dealing with alternative word alignments might be beneficial, though as argued

is that approximations are needed in computing the maximum probability translation in decoding, and also in computing model expectations in training when a language model is used. In addition, since the models operate directly on translations, using probabilistic training criteria for learning the model parameters is possible only if all reference translations in the training data can be generated by the model. In practice, this problem can be circumvented by discarding the training sentence pairs with unreachable reference translations, but this may mean a significant reduction in the amount of training data (24% in (Blunsom et al., 2008)).

Another closely related approach is the independently developed discriminative block bigram prediction model presented in (Tillmann and Zhang, 2007). This work proposes a global phrase-based translation model very similar to ours, but due to computational reasons, resorts to a localized approximation thereof, and is restricted to biphrases of length at most two. In (Liang et al., 2006) a standard phrase-based model is augmented with more than a million features whose weights are trained discriminatively by a variant of the perceptron algorithm. Reference reachability is again a problem, and the method has not been scaled up to use biphrase features directly.

3 The proposed translation model

3.1 Biphrase extraction

The biphrases used in `Sinuhe` are extracted from the training data with the `Moses` phrase extraction heuristics. The sentence-aligned training corpus S is first word-aligned by running Giza++ in both directions and then symmetrizing the alignments. This maps the original aligned sentence pairs (x, y) into word-aligned sentence pairs (x, a, y), where a is a many-to-many alignment between the words in x and y. Second, using a heuristic proposed in (Och et al., 1999), all the aligned phrase pairs (x', a', y') satisfying the following criteria are extracted: (1) x' and y' consist of consecutive words of x and y, and both have length at most k, (2) a' is the alignment between words of x' and y' induced by a, (3) a' contains at least one link, and (4) there are no links in a that have just one end in x' or y'. Each aligned training sentence (x, a, y) thus generates a number of potentially overlapping aligned biphrase features (x', a', y'). In our experiments, we chose $k = 7$ which is the default in `Moses`. Unlike in `Moses`, we do not map the aligned biphrases (x', a', y') back to non-aligned biphrases (x', y').

To reduce the number of extracted biphrases, for each source phrase x', only biphrases (x', a', y') whose occurrence count is among the top $K = 20$ in the training data are retained (rank ties broken by including all biphrases with rank equal to the limit K). For technical reasons related to our dynamic programming algorithms, we also drop biphrases whose source phrase begins or ends with unlinked words. Finally, we drop all biphrases that occur only once in the training data. This can be motivated by a leave-one-out argument (cf the derivation of Good-Turing estimates): Dropping the biphrases that occur only once in the training data means that the feature representation for a training sentence pair (see Section 3.2) contains only biphrases that occur also in other training examples. Without the leave-one-out pruning, the feature vectors for training sentence pairs would be maximally dense, whereas such feature density cannot be expected on test data. Our system can also be used without the leave-one-out pruning, but according to our preliminary experiments this has little effect on translation quality. An exception seems to be morphologically rich languages with scarce training data on which pruning seems to reduce translation quality.

All the pruning steps combined reduce the phrase table size considerably, but in our experiments, millions of biphrases per language pair still remain (2-4 million for Europarl data and over 95 million for GigaFrEn data).

3.2 Features

Our primary feature representation is a binary feature vector that indicates which aligned biphrases in the phrase table occur in an aligned sentence pair and where. More specifically, a source sentence x aligned to a target sentence y by an alignment a is represented by a binary feature vector $\phi(x, a, y)$ whose component $\phi(x, a, y)_{(x', a', y'), i}$ is 1 iff the aligned biphrase (x', a', y') occurs at source position i in (x, a, y), and 0 otherwise. Here, (x', a', y') occurs in (x, a, y) at source position i iff the phrase extraction process described in Section 3.1 would have extracted it from (x, a, y) at source position i.

in (DeNero et al., 2006), the ambiguity in word alignment is less prevalent than in phrase segmentation.

The weights for the aligned biphrases are tied together by mapping the binary feature vector ϕ (indexed by pairs of an aligned biphrase and a source position) to an integral feature vector $\tilde{\phi}$ (indexed by aligned biphrases only) using the formula $\tilde{\phi}_{(x',a',y')} = \sum_i \phi_{(x',a',y'),i}$. The "real" features that drive the translation process are thus the lowest level binary features ϕ, whereas the higher level representation $\tilde{\phi}$ is convenient in defining the conditional probabilities given by the translation model.

3.3 The model

Instead of modelling the conditional distribution $P(y|x)$ directly, we model the conditional distribution $P(\phi(x,a,y)|x)$ by the following conditional exponential model:

$$P(\phi(x,a,y)|x) = \frac{\exp(w \cdot \tilde{\phi}(x,a,y))}{\sum_{\phi \in \Phi_x} \exp(w \cdot \tilde{\phi})}.$$

Here, w is a parameter vector with one component for each aligned biphrase feature in the phrase table. The set Φ_x defines the set of possible predictions given x, and includes all feature vectors ϕ satisfying the following criteria:

1. There exists a translation y' and an alignment a' such that all active features in ϕ occur in (x, a', y')
2. Features corresponding to aligned biphrases that occur inside aligned biphrases whose features are active in ϕ are also active in ϕ.

Thus, the set Φ_x has a feature representation for all possible aligned sentence pairs (x, a', y') that have x as the source side, so all reference translations y' word-aligned to x in any way a' are representable by features in Φ_x. By condition 1, the predictions given by the model never contain conflicting biphrases, so given any prediction of the model, there always exists a translation y' where all the predicted biphrases do occur. However, since our dynamic programming algorithms can only force active super-phrases implying active sub-phrases (condition 2) but not active sub-phrases implying active super-phrases, the set Φ_x also contains some feature vectors in which the latter type of implications are not enforced. Having such redundant representations for some translations is a waste of probability mass, but we hope it has little effect in practice.

The choice of modelling $P(\phi(x,a,y)|x)$ instead of modelling $P(y|x)$ directly is crucial, both from a modelling and from a computational perspective. From the modelling perspective, the crucial point is that in our approach, any aligned sentence pair (x,a,y) has an associated feature vector $\phi(x,a,y) \in \Phi_x$ that is reachable (i.e., receives non-zero probability) by the model. This means it is straightforward to use probabilistic criteria in learning the model parameters. In contrast, systems modelling $P(y|x)$ directly are often plagued by the reference reachability problem. To use probabilistic training criteria for such systems one needs to circumvent the reference reachability problem, e.g., by using pseudo-references or by dropping out the non-reachable portion of training data.

Working with the feature vectors $\phi(x,a,y)$ instead of working with a and y directly means that we model the ordering and choice of words in y only partially. This way, when computing the normalizing constants and feature expectations, we can partition the unbounded set of potential translations y and alignments a into a smaller set of equivalence classes given by $\phi(x,a,y)$. Though the number of feature vectors $\phi \in \Phi_x$ may be large (exponential in length of x), all the necessary computations can be done exactly and efficiently by dynamic programming. For more details, see Section 3.4.3.

3.4 Learning the model parameters

3.4.1 The objective

We use maximum a posteriori (MAP) estimation to estimate the model parameters w. To control overfitting, we regularize the parameters by a suitably scaled Gaussian prior. This can be also viewed as $L2$ regularization. The prior guarantees that the MAP parameters are unique, and models our belief that the observed feature occurrence counts randomly deviate from their "true" values roughly proportionally to the standard deviations of the occurrence count distributions. The prior variance $\sigma^2_{(x',a',y')}$ for feature (x',a',y') is given by the formula $\sigma^2_{(x',a',y')} = \alpha/\rho_{(x',a',y')}$, where $\alpha > 0$ is a free regularization parameter, and $\rho^2_{(x',a',y')}$ is an empirical estimate of the variance of the occurrence count of (x',a',y') in the training data. This is similar to (Chen and Rosenfeld, 2000), except that we use standard deviations in place of variances. As the estimate for the vari-

ance of a feature we use the occurrence count of the corresponding biphrase in the training data. This could be justified by assuming that the occurrence counts follow a Poisson distribution. We have also run preliminary experiments with other forms of regularization (different ways of computing $\sigma_{(x',a',y')}$, exponential priors corresponding to $L1$ regularization, no regularization), and it looks like the system is not very sensitive to the chosen prior.

Combining the prior with the model, we see that the negative log-posterior $\mathcal{L}(w)$ is given by the formula

$$\sum_{(x',a',y')} \frac{w^2_{(x',a',y')}}{2\sigma^2_{(x',a',y')}} - \sum_{(x,a,y)\in S} \log P(\phi(x,a,y)|x) + C,$$

where the sum over (x', a', y') is understood to go over all aligned biphrase features in the model. This is our criterion for learning w.

3.4.2 Optimization

We solve the optimization problem related to learning w by first order gradient ascent methods. The gradient $\nabla\mathcal{L}(w)$ of $\mathcal{L}(w)$ with respect to w can be written as

$$\sum_{(x',a',y')} \frac{w_{(x',a',y')}}{\sigma^2_{(x',a',y')}} - \sum_{(x,a,y)\in S} \left[\tilde{\phi}(x,a,y) - \mathbb{E}_w[\tilde{\phi}|x]\right],$$

where $\mathbb{E}_w[\tilde{\phi}|x]$ denotes the conditional expectation of the aligned biphrase occurrence count features given x with respect to model parameters w. Feature expectations can be computed by combining the results of a left-to-right and right-to-left dynamic programming sweep over the source sentence. For more details, see Section 3.4.3.

Inspired by the empirical results in (Vishwanathan et al., 2006), we use classic stochastic gradient ascent to solve the optimization problem. At each step t, we sample with replacement a batch S_t of b examples from S. We start from $w_0 = 0$, and use the update rule

$$w_{t+1} = w_t - \eta_t \nabla\mathcal{L}_t(w_t), \qquad (1)$$

where $\eta_t > 0$ is the learning rate, and $\nabla\mathcal{L}_t(w)$ is the stochastic gradient of the negative log-posterior

$$\mathcal{L}_t(w) = \frac{|S_t|}{|S|} \sum_i \frac{w_i^2}{2\sigma_i^2} - \sum_{(x,a,y)\in S_t} \log P(\phi(x,a,y)|x)$$

restricted to batch S_t. The second term of the stochastic gradient involves only biphrases whose source sides match the source sentences in the batch. Though the gradient of the regularizer is non-zero for all non-zero biphrase features, the updates of features that are not active in the second term of the gradient can be postponed until they become active again. Due to feature sparsity, the number of features that are active in a small batch is small, and thus also the updates are sparse. Hence, it is possible to handle even feature vectors that do not fit into memory.

Another advantage of the stochastic gradient method is that many processes can apply updates (1) to a weight vector asynchronously in parallel. We have implemented two strategies for dealing with this. The simpler one is to store the weight vector in a database that takes care of the necessary concurrency control. This way, no process needs to store the entire weight vector in memory. The downside is that all training processes must be able to `mmap()` to the common file-system due to limitations in the underlying Berkeley DB database system. We have also implemented a client-server architecture in which a server process stores w in memory and manages read and update requests to its components that come from training clients. In this approach, the degree of parallelism is limited only by the number of available machines and server capacity. The server could be further distributed for managing models that do not fit into the memory of a single server.

3.4.3 Computing gradients etc

The computationally most challenging part in learning the model parameters is computing $\nabla \log P(\phi(x,a,y)|x)$, i.e., the vector of differences between the observed occurrence counts of biphrase features in (x, a, y) and their conditional expectations under the current model parameters.

The conditional feature expectations can be computed by a dynamic programming procedure similar to the one used in training conditional random fields. We combine the results of a left-to-right and right-to-left dynamic programming

sweep over x. In the left-to-right sweep, we have for each biphrase feature $(x', a', y'), i$ a state $s_{(x',a',y'),i}$ for translations starting from the beginning of x and ending in an occurrence of the biphrase (x', a', y') at source position i. This state records the contribution of all partial translations whose right-most active biphrase feature on the source side is $(x', a', y'), i$ to the conditional expectation of feature $(x', a', y'), i$ (in log scale). The score for $s_{\text{empty},0} = 0$, and $s_{(x',a',y'),i}$ is obtained from the recurrence

$$\text{score}\left(s_{(x',a',y'),i}\right) = \sum_{(x'',a'',y''),i'' \in A((x',a',y'),i)} \Big[\text{score}\left(s_{(x'',a'',y''),i''}\right) + \sum_{(x''',a''',y'''),i''' \in B} w_{(x''',a''',y'''),i'''}\Big]$$

Here, $A((x', a', y'), i)$ is the set of predecessor states of $s_{(x',a',y'),i}$ and includes all states $s_{(x'',a'',y''),i''}$ such that a proper suffix of $(x'', a'', y''), i''$ (i.e., a biphrase whose source and target are proper suffices of x'' and y'' respectively) is equal to a prefix of $(x', a', y'), i$. As a special case, A includes all states $s_{(x'',a'',y''),i''}$ for which $(x'', a'', y''), i''$ ends before or at position i. This takes care of translation paths that leave some words in x untranslated. Since the starting position of a proper suffix of a biphrase is always after the biphrase's original starting position, going through the states in order of increasing i guarantees that the scores for biphrases in $A((x', a', y'), i)$ are available when computing score $\left(s_{(x',a',y'),i}\right)$.

The set B that depends on $((x', a', y'), i)$ and $((x'', a'', y''), i'')$ is defined by the formula

$$B = \text{sub}\left((x', a', y'), i\right) \setminus \text{sub}\left((x'', a'', y''), i''\right),$$

where sub $((x', a', y'), i)$ denotes the set of sub-biphrases of $(x', a', y'), i$ (including the biphrase $(x', a', y'), i$ itself). Thus, summing over the weights of biphrases in B adds the contribution of features introduced by extending translation paths ending in $(x'', a'', y''), i''$ by $(x', a', y'), i'$.

From the right-to-left dynamic programming, we get analogously the contribution of right-to-left partial translations whose left-most active biphrase is $(x', a', y'), i$. The partition function used for normalizing the expectations can be obtained as a side product of either of the sweeps.

In conditional random fields, the (unnormalized) expectations for the feature can be obtained by multiplying the scores of the states corresponding to the same feature in the left-to-right and right-to-left dynamic programming memories. In our case, combining the two values stored in the states for a feature $(x', a', y'), i$ only gives the contribution of the translation paths where $(x', a', y'), i$ is active but not covered by any longer biphrase that extends $(x', a', y'), i$ both left and right. To include the contribution of the remaining translation paths, we need to go through states corresponding to super-biphrases of $(x', a', y'), i$. Special care has to be taken in order to include the contribution of all feature vectors in which such super-biphrases are active exactly once. An efficient way to do this is to process the states for super-biphrases in topological order with respect to biphrase inclusion, and to include only the contributions of states for super-biphrases that extend the previously included states both left and right.

Another complication in the dynamic programming is that a biphrase can extend the source side of another overlapping biphrase to the right, but the target side to the left, or visa versa. Such overlaps are not directly covered by our dynamic programming. To deal with them, we construct new virtual biphrases that correspond to the results of such overlaps in a pre-processing step. The number of such virtual combinations can in theory grow exponentially, but in practice only a small number of virtual biphrases seems to suffice.

3.5 Prediction with translation model alone

Prediction is done in two phases. First, we find (by a dynamic programming procedure similar to the one outlined in Section 3.4.3) the highest probability feature vector $\hat{\phi}(x)$ defined by

$$\hat{\phi}(x) = \underset{\phi \in \Phi_x \,:\, x \text{ covered by biphrases in } \phi}{\arg\max} P(\phi|x).$$

Note that we restrict the search to feature vectors that cover the whole of x, i.e., to feature vectors $\phi(x, a, y)$ in which each word in x is covered by at least one active aligned biphrase (x', a', y'). This forces the system to translate all words in the source sentence even if the translation model predicts that none of the translations are very likely.

To translate words that are not covered by any aligned biphrase feature in the model, we use the following strategy: If the word is found from an

optional out-of-vocabulary dictionary, we use the translation from the dictionary, and otherwise resort to an implicit zero weight aligned biphrase that copies the input word to the output as is. In our experiments, the out-of-vocabulary dictionary is constructed from the word translations that occur once in the training data, so the out-of-vocabulary dictionary only compensates for the word translations lost in phrase table pruning. If available, a real dictionary could be used as well.

The second step in predicting a translation is solving the pre-image problem, i.e., constructing a translation y from the predicted feature vector $\hat{\phi}(x)$. Since $\hat{\phi}(x) \in \Phi_x$, there always exists an alignment a and a translation y such that all the aligned biphrases in $\hat{\phi}(x)$ occur in $\phi(x, a, y)$, but the a and y may not be unique. We choose the a and y given by concatenating the target sides of the biphrases active in $\hat{\phi}(x)$ in the order induced by their positions in the source sentence. Thus, there is no phrase-level reordering, and the fluency of the target language output is induced by the phrase overlaps only.

3.6 Predicting with an integrated LM

The prediction strategy outlined in the previous section is simple and conceptually clean. However, biphrase overlaps alone may not be enough to enforce fluent output, especially given that bilingual data is typically more scarce than monolingual data. Also, the lack of a reverse translation model means the system is unable to identify phrase extraction errors in which rarely seen source phrases are translated to common target phrases by chance.

To address these shortcomings, we augment the translation model with the following additional features that have been observed to enhance translation quality in other SMT systems.

1. **Language model:** $\log P(y)$, where $P(y)$ is given by a smoothed n-gram language model
2. **Lexical translation model (reverse direction):** $\log P(x|y, a)$ given by a word-level reverse translation model
3. **Translation length:** number of words in y
4. **Distortion:** number of source words in phrases with swapped translations

The final score driving the translation process is given by a linear combination of the translation model score $\log P(\phi(x, a, y)|x)$ and these features. Besides the translation model, the language model feature is clearly the most influential, while the lexical translation feature has only a minor positive effect on translation quality.

We use an approximate dynamic programming variant of the commonly used beam search procedure to find the highest scoring candidate translation. We compute the translation model log-probability $\log P(\phi(x, a, y)|x)$ incrementally while building up the corresponding candidate translation y and word alignment a from left to right. We allow phrase-level distortions given by swapping the order of translations of consecutive non-overlapping source phrases. Unlike in `Moses`, our beam search is structured around state transitions, not around states. This means that we apply each biphrase (state transition) simultaneously to all applicable partial translations (states). This strategy is in our experience more efficient, does not rely on future score estimates, and is implementationally very similar to the dynamic programming procedures that we use in training the model parameters and in prediction with a language model alone.

The weights of the features are tuned by optimizing the BLEU score of development set translations with amoeba search. This simplistic strategy is feasible given our system's fast translation speed, and extends easily to cover non-linear feature combinations. The reason for using amoeba is that it is simpler to implement — we do not believe amoeba yields any better values for the parameters in the end.

4 Experiments

4.1 Experimental setup

Our experiments are on the Europarl translation tasks following the setup used in the shared translation task of the ACL 2008 Third Workshop on Statistical Machine Translation (Callison-Burch et al., 2008), and on the French-to-English translation task of the EACL 2009 Fourth Workshop on Statistical Machine Translation (Callison-Burch et al., 2009). The size of the Europarl training corpora is about 1M sentence pairs per language pair, while the larger GigaFrEn corpus contains about 22M sentence pairs. The corpora were used for biphrase extraction and translation model training. Decoder feature weights were tuned on the provided development sets. In case of Europarl, language models were trained on the target sides of

	es-en	en-es	fr-en	en-fr	de-en	en-de	time
Sinuhe	31.38	30.94	31.50	28.91	25.03	19.26	338.0
Moses	32.18	31.88	32.63	29.92	27.30	20.57	3729.5
$\text{Sinuhe}_{\text{trans}}$	29.14	27.12	28.74	26.06	22.38	17.14	44.2
$\text{Moses}_{\text{trans}}$	24.32	22.75	23.84	21.22	19.62	13.59	1321.5

Table 1: Left: The translation quality of the SMT systems as measured by the BLEU score. Translations were detokenized but not recased before evaluating their quality against lowercased reference translations by the `mteval-v11b.pl` script. Right: Average total translation time in seconds.

the bilingual corpora. In the GigaFrEn experiments we used the provided monolingual news domain data. All data was tokenized and lowercased using the tools in the Moses distribution.

We experimented with four translation systems: $\text{Sinuhe}_{\text{trans}}$, Sinuhe, $\text{Moses}_{\text{trans}}$, and Moses. $\text{Sinuhe}_{\text{trans}}$ uses only the translation model in producing translations (see Section 3.5), while the full system Sinuhe uses also a language model and some additional features (see Section 3.6). As a baseline, we used the Moses translation system, which is known to be very competitive on the Europarl translation tasks as evidenced by the University of Edinburgh entries in the translation challenge (Callison-Burch et al., 2008). The other comparison point $\text{Moses}_{\text{trans}}$ was obtained from Moses by disabling distortions and setting setting the weights of all features except the forward translation model to 0. By comparing $\text{Sinuhe}_{\text{trans}}$ and $\text{Moses}_{\text{trans}}$, we hope to indirectly compare the performance of the underlying translation models. A more direct comparison was not possible as it is not feasible to normalize the "probabilities" predicted by the Moses translation model.

4.1.1 Training the models

We trained Moses exactly as suggested in (Callison-Burch et al., 2008), except that we used the `-unk` option for SRILM in training the language models (both for Sinuhe and Moses). The translation model for Sinuhe (and $\text{Sinuhe}_{\text{trans}}$) was built from the phrases extracted by Moses as described in Section 3.1. We chose $\alpha = 1.0$ and set batch size to 1. The learning rate was initially set to 0.1, and decayed proportional to $1/t$ after 2M or 100M iterations of training for Europarl and GigaFrEn tasks, respectively. These choices may not be optimal as we did not experiment with other choices yet. In case of Europarl, training was run for 70-100M iterations using the Berkeley DB based distribution strategy (4 CPU cores per language pair). This took 10 days. For GigaFrEn, we used the client-server architecture, and trained the model for 620M stochastic gradient iterations on about 200 CPUs. This took 2 days, which is a lot less than the time needed to run (parallel) Giza on this data. The number of biphrase features in Sinuhe's model was 2-4 million on the Europarl tasks, and about 95 million on the GigaFrEn task.

The decoder parameters for Sinuhe were tuned on the development sets by amoeba, and for Moses by MERT. As both amoeba and MERT try to solve the same optimization problem, we believe the difference in optimization methods has little influence on the results.

4.1.2 Translation results

Europarl tasks The systems were tested on the 2000 sentence Europarl domain development test sets provided for the shared translation task (Callison-Burch et al., 2008). The resulting BLEU scores and total translation times averaged over the datasets are reported in Table 1. While Moses has the highest BLEU score for all the language pairs, the BLEU score for Sinuhe is worse by only at most 1.31 BLEU points except on the de-en task, where the difference is 2.27. $\text{Sinuhe}_{\text{trans}}$ is clearly inferior to Sinuhe but equally clearly superior to $\text{Moses}_{\text{trans}}$.

It takes less than a minute to translate the development test set by the fastest system $\text{Sinuhe}_{\text{trans}}$. The slowest system Moses needs around an hour for the same task. Memory usage follows a similar pattern. For example, Sinuhe requires roughly one tenth of the memory used by Moses. Thus, in terms of resource usage, $\text{Sinuhe}_{\text{trans}}$ and Sinuhe seem clearly superior to Moses. The quantitative results would change if the systems' parameters were optimized for speed rather than quality, but the differences

are so clear that the general pattern would probably remain the same. For example, Moses with no distortion is still clearly slower than Sinuhe.

GigaFrEn task The fr-en model was tested on the 2525 sentence news domain test data used in the preliminary evaluation of the translation challenge results. The BLEU scores for Sinuhe and Moses were 26.32 and 26.98, respectively. The total translation time was 13m 50s with Sinuhe, whereas Moses needed 82m 28s. Thus, the pattern that was observed on Europarl tasks is repeated here: The translation quality of Moses is slightly better, but Sinuhe is significantly faster. Surprisingly, both Sinuhe and Moses fare well in comparison to the participants of the actual challenge: According to the preliminary results on the same test data we used (Koehn, 2009), the Moses baseline would have been beaten only by Google, and Sinuhe would have been sixth among the 23 participating systems with a difference of only 0.57 BLEU points to the second best entry. A partial explanation for the good relative performance could be that the challenge participants had only a week to train their models on the full version of GigaFrEn data, so they may not have had time to take full advantage of it. On the other hand, many of the top ranked systems relied on external resources that were not available for us.

Based on an informal human evaluation of the outputs of Sinuhe and Moses, it looks like the translations of Sinuhe are slightly more accurate in conveying the meaning of the original sentences, but especially the translations of long rare expressions (e.g., multi-word names of institutions) are less fluent. This hints that the parameters for (rare) biphrases may have been regularized too heavily — it looks like Sinuhe is underfitting rather than overfitting. We will conduct more experiments to see how much the translation quality can be improved by a better choice of α or by using a different prior for regularization. Of course, there is room for tuning elsewhere, too. For example, it would be a surprise if the phrase extraction pipeline that has been optimized for Moses would be optimal for Sinuhe.

5 Conclusions

In this paper, we have shown that phrase-based SMT can be viewed as an instance of structural prediction. The word alignment and phrase extraction heuristics serve as a strategy for feature extraction, and the translation task can be modelled as a structural prediction problems over these features. Our methods scale to large corpora and are fast at predicting translations. While speed is not the primary goal, the faster translation times may be a key to success in applications where the amount of text that needs to be translated is large. In terms of BLEU scores, the results do not improve the state-of-the-art so far. However, fine-tuning the standard phrase-based approach over the years has increased its performance significantly, and we see no reason why the same would not happen with the proposed approach, especially if the model is augmented with additional features like gapped biphrases and biphrases over POS tags.

The fact that our translation model is a properly normalized conditional probability distribution opens up many new possibilities. For instance, instead of predicting translations, it is possible to efficiently compute the expected number of times each word would appear in them. Such output might be useful, e.g., if the translations are to be post-processed by models relying on bag-of-words representation. Another research direction we are currently looking into is training the proposed translation model in the reverse direction, and then predicting translations using the noisy channel approach, i.e., by maximizing $P(x|y)P(y)$. The key difference to previous work here is that since $P(x|y)$ is properly normalized, the noisy channel approach would not in our case suffer from the potentially negative effects caused by ignoring the normalizer that depends on y. Besides being a viable (though computationally demanding) alternative criterion for predicting translations, the noisy channel approach could easily be used for, e.g., reranking n-best lists and for system combination.

Acknowledgments

This work has been partially funded by the SMART EU project. We wish to thank the anonymous reviewers for their constructive comments and especially for pointing out the related paper (Blunsom and Osborne, 2008) that we had missed. Special thanks to Vladimir Poroshin for all the bugs he found in beta-testing and to Esther Galbrun for her comments on a draft version of this paper.

Abstract

In a linguistically-motivated syntax-based translation system, the entire translation process is normally carried out in two steps, translation rule matching and target sentence decoding using the matched rules. Both steps are very time-consuming due to the tremendous number of translation rules, the exhaustive search in translation rule matching and the complex nature of the translation task itself. In this paper, we propose a hyper-tree-based fast algorithm for translation rule matching. Experimental results on the NIST MT-2003 Chinese-English translation task show that our algorithm is at least 19 times faster in rule matching and is able to help to save 57% of overall translation time over previous methods when using large fragment translation rules.

1 Introduction

Recently linguistically-motivated syntax-based translation method has achieved great success in statistical machine translation (SMT) (Galley et al., 2004; Liu et al., 2006, 2007; Zhang et al., 2007, 2008a; Mi et al., 2008; Mi and Huang 2008; Zhang et al., 2009). It translates a source sentence to its target one in two steps by using structured translation rules. In the first step, which is called translation rule matching step, all the applicable[1] translation rules are extracted from the entire rule set by matching the source parse tree/forest. The second step is to decode the source sentence into its target one using the extracted translation rules. Both of the two steps are very time-consuming due to the exponential number of translation rules and the complex nature of machine translation as an NP-hard search problem (Knight, 1999). In the SMT research community, the second step has been well studied and many methods have been proposed to speed up the decoding process, such as node-based or span-based beam search with different pruning strategies (Liu et al., 2006; Zhang et al., 2008a, 2008b) and cube pruning (Huang and Chiang, 2007; Mi et al., 2008). However, the first step attracts less attention. The previous solution to this problem is to do exhaustive searching with heuristics on each tree/forest node or on each source span. This solution becomes computationally infeasible when it is applied to packed forests with loose pruning threshold or rule sets with large tree fragments of large rule height and width. This not only overloads the translation process but also compromises the translation performance since as shown in our experiments the large tree fragment rules are also very useful.

To solve the above issue, in this paper, we propose a hyper-tree-based fast algorithm for translation rule matching. Our solution includes two steps. In the first step, all the translation rules are re-organized using our proposed hyper-tree structure, which is a compact representation of the entire translation rule set, in order to make the common parts of translation rules shared as much as possible. This enables the common parts of different translation rules to be visited only once in rule matching. Please note that the first step can be easily done off-line very fast. As a result, it does not consume real translation time. In the second step, we design a recursive algorithm to traverse the hyper-tree structure and the input source forest in a top-down manner to do the rule matching between them. As we will show later, the hyper-tree structure and the recursive algorithm significantly improve the speed of the rule matching and the entire translation process compared with previous methods.

With the proposed algorithm, we are able to carry out experiments with very loose pruning

[1] Given a source structure (either a parse tree or a parse forest), a translation rule is applicable if and only if the left hand side of the translation rule exactly matches a tree fragment of the given source structure.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1037–1045,
Singapore, 6-7 August 2009.

thresholds and larger tree fragment rules efficiently. Experimental results on the NIST MT-2003 Chinese-English translation task shows that our algorithm is 19 times faster in rule matching and is able to save 57% of overall translation time over previous methods when using large fragment translation rules with height up to 5. It also shows that the larger rules with height of up to 5 significantly outperforms the rules with height of up to 3 by around 1 BLEU score.

The rest of this paper is organized as follows. Section 2 introduces the syntax-based translation system that we are working on. Section 3 reviews the previous work. Section 4 explains our solution while section 5 reports the experimental results. Section 6 concludes the paper.

2 Syntax-based Translation

This section briefly introduces the forest/tree-based tree-to-string translation model which serves as the translation platform in this paper.

2.1 Tree-to-string model

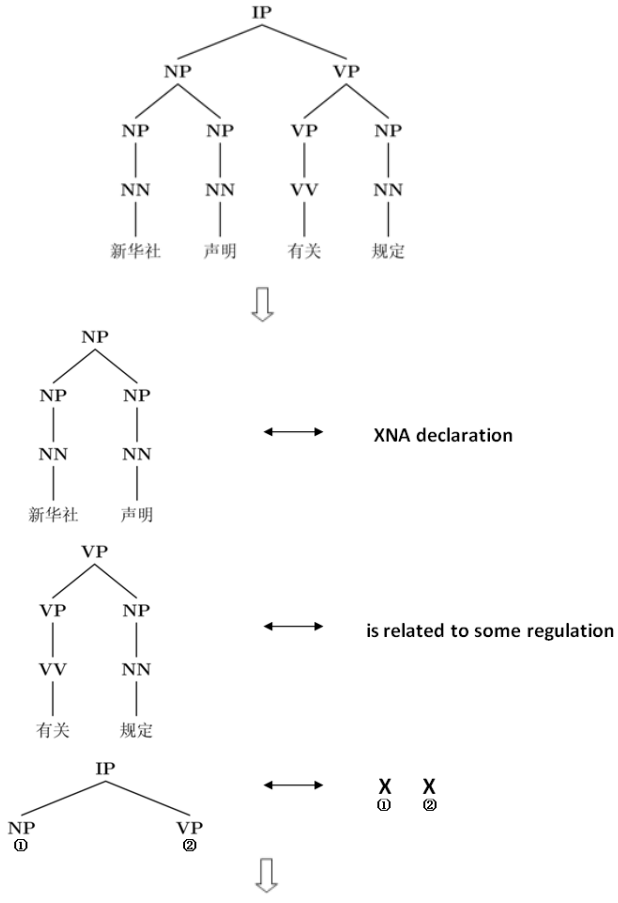

Figure 1. A tree-to-string translation process.

The tree-to-string model (Galley et al. 2004; Liu et al. 2006) views the translation as a structure mapping process, which first breaks the source syntax tree into many tree fragments and then maps each tree fragment into its corresponding target translation using translation rules, finally combines these target translations into a complete sentence. Fig. 1 illustrates this process. In real translation, the number of possible tree fragment segmentations for a given input tree is exponential in the number of tree nodes.

2.2 Forest-based translation

To overcome parse error for SMT, Mi and Huang (2008) propose forest-based translation by using a packed forest instead of a single syntax tree as the translation input. A packed forest (Tomita 1987; Klein and Manning, 2001; Huang and Chiang, 2005) is a compact representation of many possible parse trees of a sentence, which can be formally described as a triple $< V, E, S >$, where V is the set of non-terminal nodes, E is the set of hyper-edges and S is a sentence represented as an ordered word sequence. A hyper-edge in a packed forest is a group of edges in a tree which connects a father node to all its children nodes, representing a CFG-based parse rule. Fig. 2 is a packed forest incorporating two parse trees T1 and T2 of a sentence as shown in Fig. 3 and Fig. 4. Given a hyper-edge e, let h be its father node, then we say that e is attached to h.

A non-terminal node in a packed forest can be represented as "label [start, stop]", where "label" is its syntax category and "[start, stop]" is the range of words it covers. For example, the node in Fig. 5 pointed by the dark arrow is labelled as "NP[3,4]", where NP is its label and [3,4] means that it covers the span from the 3rd word to the 4th word. In forest-based translation, rule matching is much more complicated than the tree-based one.

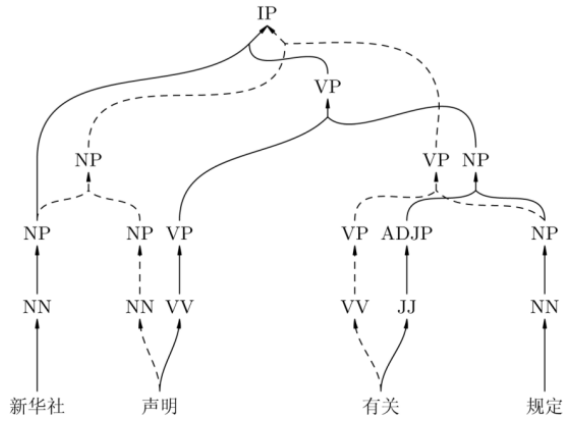

Figure 2. A packed forest

Zhang et al. (2009) reduce the tree sequence problem into tree problem by introducing virtual node and related forest conversion algorithms, so

the algorithm proposed in this paper is also applicable to the tree sequence-based models.

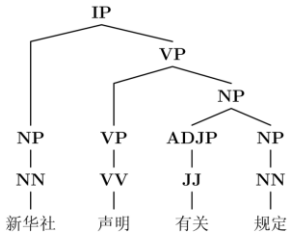

Figure 3. Tree 1 (T1)

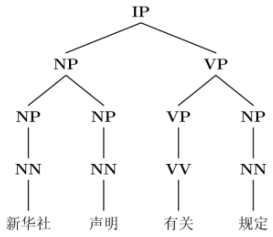

Figure 4. Tree 2 (T2)

3 Matching Methods in Previous Work

In this section, we discuss the two typical rule matching algorithms used in previous work.

3.1 Exhaustive search by tree fragments

This method generates all possible tree fragments rooted by each node in the source parse tree or forest, and then matches all the generated tree fragments against the source parts (left hand side) of translation rules to extract the useful rules (Zhang et al., 2008a).

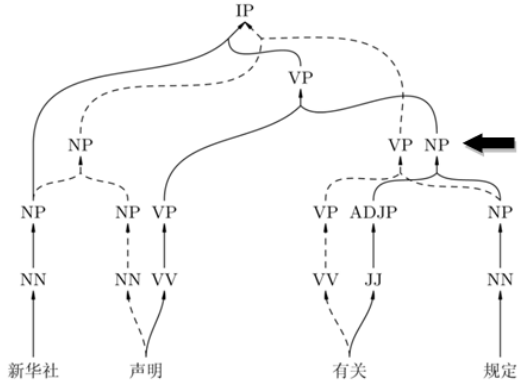

Figure 5. Node NP[3,4] in packed forest

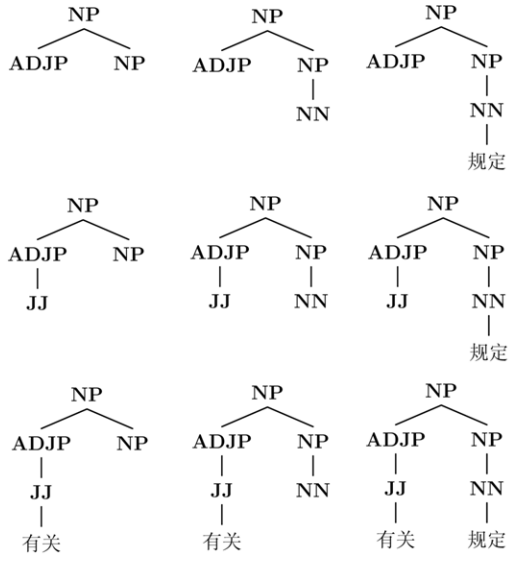

Figure 6. Candidate fragments on NP[3,4]

For example, if we want to extract useful rules for node NP[3,4] in Fig 5, we have to generate all the tree fragments rooted at node NP[3,4] as shown in Fig 6, and then query each fragment in the rule set. Let h be a node in the packed forest, $f(h)$ represents the number of possible tree fragments rooted at node h, then we have:

$$f(h) = \begin{cases} 0, & if\ h\ is\ a\ leaf\ node \\ \sum_{\substack{e\ is\ a\ hyper-edge \\ attached\ to\ h}} \prod_{\substack{c_i\ is\ the \\ i^{th}\ children \\ node\ in\ e}} (1 + f(c_i)), & otherwise \end{cases}$$

The above equation shows that the number of tree fragments is exponential to the span size, the height and the number of hyper-edges it covers. In a real system, one can use heuristics, e.g. the maximum number of nodes and the maximum height of fragment, to limit the number of possible fragments. However, these heuristics are very subjective and hard to optimize. In addition, they may filter out some "good" fragments.

3.2 Exhaustive search by rules

This method does not generate any source tree fragments. Instead, it does top-down recursive matching from each node one-by-one with each translation rule in the rule set (Mi and Huang 2008).

For example, given a translation rule with its left hand side as shown in Fig. 7, the rule matching between the given rule and the node IP[1,4] in Fig. 2 can be done as follows.

1. Decompose the left hand side of the translation rule as shown in Fig. 7 into a sequence of hyper-edges in top-down, left-to-right order as follows:

IP => NP VP; NP => NP NP; NP => NN;
NN => 声明

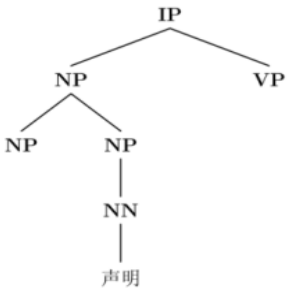

Figure 7. The left hand side of a rule

2. Pattern match these hyper-edges(rule) one-by-one in top-down left-to-right order from node IP[1,4]. If there is a continuous path in the forest matching all of these hyper-edges in order, then we can say that the rule is useful and matchable

with the tree fragment covered by the continuous path. The following illustrates the matching steps:

1. Match hyper-edge "IP => NP VP" with node IP[1,4]. There are two hyper-edges in the forest matching it: "IP[1,4] => NP[1,1] VP[2,4]" and "IP[1,4] => NP[1,2] VP [3,4]", which generates two candidate paths.

2. Since hyper-edge "NP => NP NP" fails to match NP[1,1], the path initiated with "IP[1,4] => NP[1,1] VP[2,4]" is pruned out.

3. Since there is a hyper-edge "NP[1,2] => NP[1,1] NP[2,2]" matching "NP => NP NP" on NP[1,2], then continue for further matching.

4. Since "NP=>NN" on NP[2,2] matches "NP[2,2] => NN[2,2]", then continue for further matching.

5. "NN=>声明" on NN[2,2] matches "NN[2,2] =>声明" and it is the last hyper-edge in the input rules. Finally, there is one continuous path successfully matching the left hand side of the input rule.

This method is able to avoid the exponential problem of the first method as described in the previous subsection. However, it has to do one-by-one pattern matching for each rule on each node. When the rule set is very large (indeed it is very large in the forest-based model even with a small training set), it becomes very slow, and even much slower than the first method.

4 The Proposed Hyper-tree-based Rule Matching Algorithm

In this section, we first explain the motivation why we re-organize the translation rule sets, and then elaborate how to re-organize the translation rules using our proposed hyper-tree structure. Finally we discuss the top-down rule matching algorithm between forest and hyper-tree.

4.1 Motivation

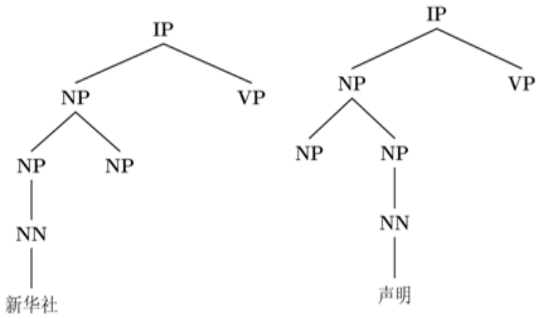

Figure 8. Two rules' left hand side

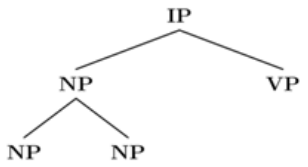

Figure 9. Common part of the two rules' left hand sides in Figure 8

Fig. 9 shows the common part of the left hand sides of two translation rules as shown in Fig. 8. In previous rule matching algorithm, the common parts are matched as many times as they appear in the rule set, which reduces the rule matching speed significantly. This motivates us to propose the hyper-tree structure and the rule matching algorithm to make the common parts shared by multiple translation rules to be visited only once in the entire rule matching process.

4.2 Hyper-node, hyper-path and hyper-tree

A hyper-tree is a compact representation of a group of tree translation rules with common parts shared. It consists of a set of hyper-nodes with edges connecting different hyper-nodes into a big tree. A hyper-tree is constructed from the translation rule sets in two steps:

1) Convert each tree translation rule into a hyper-path;
2) Construct the hyper-tree by incrementally adding each individual hyper-path into the hyper-tree.

A tree rule can be converted into a hyper-path without losing information. Fig. 10 demonstrates the conversion process:

1) We first fill the rule tree with virtual nodes to make all its leaves have the same depth to the root;
2) We then group all the nodes in the same tree level to form a single hyper-node, where we use a comma as a delimiter to separate the tree nodes with different father nodes;
3) A hyper-path is a set of hyper-nodes linked in a top-down manner.

The commas and virtual nodes ε are introduced to help to recover the original tree from the hyper-path. Given a tree node in a hyper-node, if there are n commas before it, then its father node is the $(n+1)^{th}$ tree node in the father hyper-node. If we could find father node for each node in hyper-nodes, then it is straightforward to recover the original tree from the hyper-path by just adding the edges between original father and children nodes except the virtual node ε.

After converting each tree rule into a hyper-path, we can organize the entire rule set into a big hyper-tree as shown in Figure 11. The concept of hyper-path and hyper-tree could be viewed as an extension of the "prefix merging" ideas for CFG rules (Klein and Manning 2001).

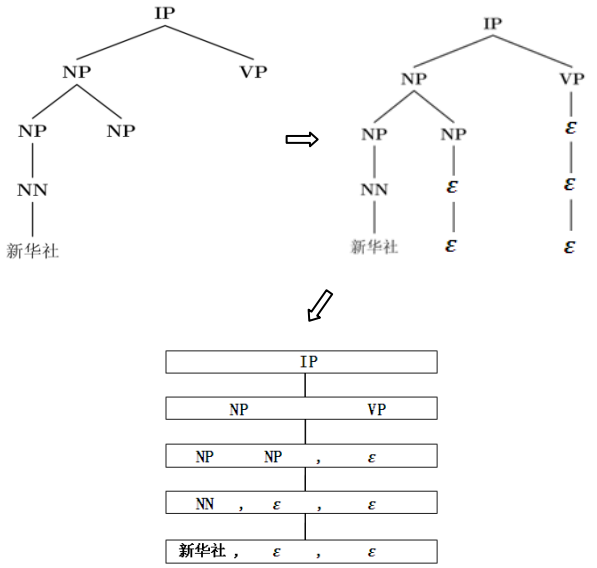

Figure 10. Convert tree to hyper-path

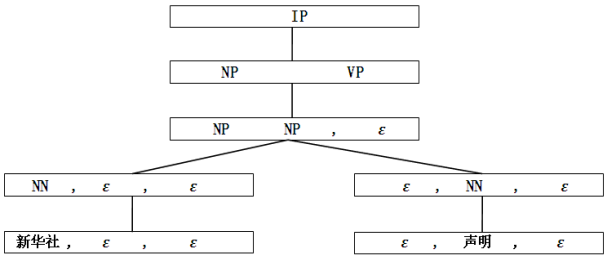

Figure 11. A hyper-tree example

Algorithm 1 shows how to organize the rule set into a big hyper-tree. The general process is that for each rule we convert it into a hyper-path and then add the hyper-path into a hyper-tree incrementally. However, there are many different hyper-trees generated given a big rule set. We then introduce a TOP label as the root node to link all the individual hyper-trees to a single big hyper-tree. Algorithm 2 shows the process of adding a hyper-path into a hyper-tree. Given a hyper-path, we do a top-down matching between the hyper-tree and the input hyper-path from root hyper-node until a leaf hyper-node is reached or there is no matching hyper-node at some level found. Then we add the remaining unmatchable part of the input hyper-path as the descendants of the last matchable hyper-node.

Please note that in Fig. 10 and Fig. 11, we ignore the target side (right hand side) of translation rules for easy discussion. Indeed, we can easily represent all the complete translation rules (not only left hand side) in Fig. 11 by simply adding the corresponding rule target sides into each hyper-node as done by line 5 of Algorithm 1.

Any hyper-path from the root to any hyper-node (not necessarily be a leaf of the hyper-tree) in a hyper-tree can represent a tree fragment. As a result, the hyper-tree in Fig. 11 can represent up to 6 candidate tree fragments. It is easy to understand that the maximum number of tree fragments that a hyper-tree can represent is equal to the number of hyper-nodes in it except the root. It is worth noting that a hyper-node in a hyper-tree without any target side rule attached means there is no translation rule corresponding to the tree fragment represented by the hyper-path from the root to the current hyper-node. The compact representation of the rule set by hyper-tree enables a fast algorithm to do translation rule matching.

Algorithm 1. *Compile rule set into hyper-tree*
Input: *rule set*
Output: *hyper-tree*

1. Initialize hyper-tree as a TOP node
2. **for** each rule in rule set **do**
3. Convert the left hand side tree to a hyper-path p
4. Add hyper-path p into hyper-tree
5. Add rule's right hand side to the leaf hyper-node of a hyper-path in the hyper-tree
6. **end for**

Algorithm 2. *Add hyper-path into hyper-tree*
Input: *hyper-path p and hyper-tree t*
Notation:
h: the height of hyper-path p
p(i) : the hyper-node of ith level (top-down) of p
TN: the hyper-node in hyper-tree
Output: *updated hyper-tree t*

1. Initialize TN as TOP
2. **for** i := 1 to h **do**
3. **if** there is a child c of TN has the same label as p(i) **then**
4. TN := c
5. **else**
6. Add a child c to TN, label c as p(i)
7. TN := c

4.3 Translation rule matching between forest and hyper-tree

Given the source parse forest and the translation rules represented in the hyper-tree structure, here we present a fast matching algorithm to extract so-called useful translation rules from the entire rule set in a top-down manner for each node of the forest.

As shown in Algorithm 3, the general process of the matching algorithm is as follows:

Algorithm 3. *Rule matching on one node*
Input: *hyper-tree T, forest F, and node n*
Notation:
FP: a pair <FNS, TN>, FNS is the frontier nodes of matched tree fragment,
TN is the hyper-tree node matching it
SFP: the queue of FP
Output: *Available rules on node n*

```
1.  if there is no child c of TOP having the same label as n
    then
2.      Return failure.
3.  else
4.      Initialize FP as <{n},c> and put it into SFP
5.      for each FP in SFP do
6.          SFP ← PropagateNextLevel(FP.FNS, FP.TN)
7.      for each FP in SFP do
8.          if the rule set attached to FP.TN is not empty
            then
9.              Add FP to result
```

Algorithm 4. *PropagateNextLevel*
Input: *Frontier node sequence FNS, hyper-tree node TN*
Notation:
CT: a child node of TN
the number of node sequence (separated by comma, see Fig 11) in CT is equal to the number of node in TN.
CT(i) : the ith node sequence in hyper-node CT
FNS(i): the ith node in FNS
TFNS: the temporary set of frontier node sequence
RFNS: the result set of frontier node sequence
FP: a pair of frontier node sequence and hyper-tree node
RFP: the result set of FP
Output: *RFP*

```
1.  for each child hyper-node CT of TN do
2.      for i:= 1 to the number of node sequence in CT do
3.          empty TFNS
4.          if CT(i) == ε then
5.              Add FNS(i) to TFNS.
6.          else
7.              for each hyper-edge e attached to FNS(i) do
8.                  if e.children match CT(i) then
9.                      Add e.children to TFNS
10.         if TFNS is empty then
11.             empty RFNS
12.             break
13.         else if i == 1 then
14.             RFNS := TFNS
15.         else
16.             RFNS := RFNS ⊗ TFNS
17.     for each FNS in RFNS do
18.         add <FNS, CT > into RFP
```

1) For each node *n* of the source forest if no child node of TOP in hyper-tree has the same label with it, it means that no rule matches any tree fragments rooted at the node *n* (i.e., no useful rules to be used for the node *n*) (line 1-2)

2) Otherwise, we match the sub-forest starting from the node *n* against a sub-hyper-tree starting from the matchable child node of TOP layer by layer in a top-down manner. There may be many possible tree fragments rooted at node *n* and each of them may have multiple useful translation rules. In our implementation, we maintain a data structure of FP = <FNS, TN> to record the currently matched tree fragment of forest and its corresponding hyper-tree node in the rule set, where FNS is the frontier node set of the current tree fragment and TN is the hyper-tree node. The data structure FP is used to help extract useful translation rules and is also used for further matching of larger tree fragments. Finally, all the FPs for the node *n* are kept in a queue. During the search, the queue size is dynamically increased. The matching algorithm terminates when all the FPs have been visited (line 5-6 and Algorithm 4).

3) In the final queue, each element (FP) of the queue contains the frontier node sequence of the matched tree fragment and its corresponding hyper-tree node. If the target side of a rule in the hyper-tree node is not empty, we just output the frontier nodes of the matched tree fragment, its root node *n* and all the useful translation rules for later translation process.

Algorithm 4 describes the detailed process of how to propagate the matching process down to the next level. <FNS, TN> is the current level frontier node sequence and hyper-tree node. Given a child hyper-node CT of TN (line 1), we try to find the group of next level frontier node sequence to match it (line 2-18). As shown in Fig 11, a hyper-node consists of a sequence of node sequence with comma as delimiter. For the i^{th} node sequence CT(i) in CT, If CT(i) is ε, that means FNS(i) is a leaf/frontier node in the matched tree fragment and thus no need to propagate to the next level (line 4-5). Otherwise, we try each hyper-edge e of FNS(i) to see whether its children match CT(i), and put the children of the matched hyper-edge into a temp set TFNS (line 7-9). If the temp set is empty, that means the current matching fails and no further expansion needs (line 10-12). Otherwise, we integrate current matched children into the final group of frontier node sequence (line 13-16) by Descartes Product (⊗). Finally, we construct all the <FNS, TN> pair for next level matching (line 17-18).

It would be interesting to study the time complexity of our Algorithm 3 and 4. Suppose the maximum number of children of each hyper-node in hyper-tree is N (line 1), the maximum number of node sequence in CT is M (line 2), the maximum number of hyper-edge in each node in packed forest is K (line 7), the maximum number of hyper-edge with same children representation in each node in packed forest is C (i.e. the maximum size of TFNS in line 16, and the maximum complexity of the Descartes Product in line 16

would be C^M), then the time complexity upper-bound of Algorithm 4 is $O(NM(K+C^M))$. For Algorithm 3, its time complexity is $O(RNM(K+C^M))$, where R is the maximum number of tree fragment matched in each node.

5 Experiment

5.1 Experimental settings

We carry out experiment on Chinese-English NIST evaluation tasks. We use FBIS corpus (250K sentence pairs) as training data with the source side parsed by a modified Charniak parser (Charniak 2000) which can output a packed forest. The Charniak Parser is trained on CTB5, tuned on 301-325 portion, with F1 score of 80.85% on 271-300 portion. We use GIZA++ (Och and Ney, 2003) to do *m-to-n* word-alignment and adopt heuristic "grow-diag-final-and" to do refinement. A 4-gram language model is trained on Gigaword 3 Xinhua portion by SRILM toolkit (Stolcke, 2002) with Kneser-Ney smoothing. We use NIST 2002 as development set and NIST 2003 as test set. The feature weights are tuned by the modified Koehn's MER (Och, 2003, Koehn, 2007) trainer. We use case-sensitive BLEU-4 (Papineni et al., 2002) to measure the quality of translation result. Zhang et al. 2004's implementation is used to do significant test.

Following (Mi and Huang 2008), we use viterbi algorithm to prune the forest. Instead of using a static pruning threshold (Mi and Huang 2008), we set the threshold as the distance of the probabilities of the n^{th} best tree and the 1^{st} best tree. It means the pruned forest is able to at least keep all the top n best trees. However, because of the sharing nature of the packed forest, it may still contain a large number of additional trees. Our statistic shows that when we set the threshold as the 100^{th} best tree, the average number of all possible trees in the forest is $1.2*10^5$ after pruning.

In our experiments, we compare our algorithm with the two traditional algorithms as discussed in section 3. For the "Exhaustive search by tree" algorithm, we use a bottom-up dynamic programming algorithm to generate all the candidate tree fragments rooted at each node. For the "Exhaustive search by rule" algorithm, we group all rules with the same left hand side in order to remove the duplicated matching for the same left hand side rules. All these settings aim for fair comparison.

5.2 Accuracy, speed vs. rule heights

We first compare the three algorithms' performance by setting the maximum rule height from 1 to 5. We set the forest pruning threshold to the 100^{th} best parse tree.

Table 1 compares the speed of the three algorithms. It clearly shows that the speed of both of the two traditional algorithms increases dramatically while the speed of our hyper-tree based algorithm is almost linear to the tree height. In the case of rule height of 5, the hyper-tree algorithm is at least 19 times (9.329/0.486) faster than the two traditional algorithms and saves 8.843(9.329 - 0.486) seconds in rule matching for each sentence on average, which contributes 57% (8.843/(9.329 + 6.21)) speed improvement to the overall translation.

H	Rule Matching			D
	Exhaustive by tree	Exhaustive by rule	Hyper-tree-based	
1	0.043	0.077	0.083	2.96
2	0.047	0.920	0.173	3.56
3	0.237	9.572	0.358	4.02
4	2.300	48.90	0.450	5.27
5	9.329	90.80	0.486	6.21

Table 1. Speed in seconds per sentence vs. rule height; "H" is rule height, "D" represents the decoding time after rule matching

Height	BLEU
1	0.1646
2	0.2498
3	0.2824
4	0.2874
5	**0.2925**
Moses	0.2625

Table 2. BLEU vs. rule height

Table 2 reports the BLEU score with different rule heights, where Moses, a state-of-the-art phrase-based SMT system, serves as the baseline system. It shows the BLEU score consistently improves as the rule height increases. In addition, one can see that the rules with maximum height of 5 are able to outperform the rules with maximum height of 3 by 1 BLEU score ($p<0.05$) and significantly outperforms Moses by 3 BLEU score ($p<0.01$). To our knowledge, this is the first time to report the performance of rules up to height of 5 for forest-based translation model.

We also study the distribution of the rules used in the 1-best translation output. The results are shown in Table 3; we could see something interesting that is as the rule height increases, the total number of rules with that height decreases, while the percentage of partial-lexicalized increases dramatically. And one thing needs to note is the percentage of partial-lexicalized rules with height of 1 is 0, since there is no partial-lexicalized rule with height of 1 in the rule set (the father node of a word is a pos tag node).

H	Total	Rule Type Percentage (%)		
		F	P	U
1	9814	76.58	0	23.42
2	5289	44.99	46.40	8.60
3	3925	18.39	77.25	4.35
4	1810	7.90	87.68	4.41
5	511	6.46	90.50	3.04

Table 3. statistics of rules used in the 1-best translation output, "F" means full-lexicalized, "P" means partial-lexicalized, "U" means unlexiclaizd.

5.3 Speed vs. forest pruning threshold

This section studies the impact of the forest pruning threshold on the rule matching speed when setting the maximum rule height to 5.

Threshold	Rule Matching		
	Exhaustive by tree	Exhaustive by rule	Hyper-tree-based
1	1.2	23.66	0.171
10	3.1	36.42	0.234
50	5.7	66.20	0.405
100	9.3	90.80	0.486
200	27.3	104.86	0.598
500	133.6	148.54	0.873

Table 4. Speed in seconds per sentence vs. forest pruning threshold

In Table 4, we can see that our hyper-tree based algorithm is the fastest among the three algorithms in all pruning threshold settings and even 150 times faster than both of the two traditional algorithms with threshold of 500th best. Table 5 shows the average number of parse trees embedded in a packed forest with different pruning thresholds per sentence. We can see that the number of trees increases exponentially when the pruning threshold increases linearly. When the threshold is 500th best, the average number of trees per sentence is $1.49*10^9$. However, even in this extreme case, the hyper-tree based algorithm is still capable of completing rule matching within 1 second.

Threshold	Number of Trees
1	1
10	32
50	5922
100	128860
200	$2.75*10^6$
500	$1.49*10^9$

Table 5. Average number of trees in packed forest with different pruning threshold.

5.4 Hyper-tree compression rate

As we describe in section 4.2, theoretically the number of tree fragments that a hyper-tree can represent is equal to the number of hyper-nodes in it. However, in real rule set, there is no guarantee that each tree fragment in the hyper-tree has corresponding translation rules. To gain insights into how effective the compact representation of the hyper-tree and how many hyper-nodes without translation rules, we define the compression rate as follows.

$$compression\ rate\ = \frac{the\ number\ tree\ fragments\ having\ trans\ rules}{the\ total\ number\ of\ tree\ fragments}$$

Table 6 reports the different statistics on the rule sets with different maximum rule heights ranging from 1 to 5. The reported statistics are the number of rules, the number of unique left hand side (since there may be more than one rules having the same left hand side), the number of hyper-nodes and the compression rate.

H	n_rules	n_LHS	n_nodes	c_rate
1	21588	10779	10779	100%
2	141632	51807	51903	99.8%
3	$1.73*10^6$	491268	494919	99.2%
4	$8.65*10^6$	2052731	2083296	98.5%
5	$1.89*10^7$	3966742	4043824	98.1%

Table 6. Statistics of rule set and hyper-tree. "H" is rule height, "n_rules" is the number of rules, "n_LHS" is the number of unique left hand side, "n_nodes" is the number of hyper-nodes in hyper-tree and "c_rate" is the compression rate.

Table 6 shows that in all the five cases, the compression rates of hyper-tree are all more than

98%. It means that almost all the tree fragments embedded in the hyper-tree have corresponding translation rules. As a result, we are able to use almost only one hyper-edge (i.e. only the frontier nodes of a tree fragment without any internal nodes) to represent all the rules with the same left hand side. This suggests that our hyper-tree is particularly effective in representing the tree translation rules compactly. It also shows that there are a lot of common parts among different translation rules.

All the experiments reported in this section convincingly demonstrate the effectiveness of our proposed hyper-tree representation of translation rules and the hyper-tree-based rule matching algorithm.

6 Conclusion

In this paper, we propose the concept of hyper-tree for compact rule representation and a hyper-tree-based fast algorithm for translation rule matching in a forest-based translation system. We compare our algorithm with two previous widely-used rule matching algorithms. Experimental results on the NIST Chinese-English MT 2003 evaluation data set show the rules with maximum rule height of 5 outperform those with height 3 by 1.0 BLEU and outperform MOSES by 3.0 BLEU. In the same test cases, our algorithm is at least 19 times faster than the two traditional algorithms, and contributes 57% speed improvement to the overall translation. We also show that in a more challenging setting (forest containing $1.49*10^9$ trees on average) our algorithm is 150 times faster than the two traditional algorithms. Finally, we show that the hyper-tree structure has more than 98% compression rate. It means the compact representation by the hyper-tree is very effective for translation rules.

Gazpacho and summer rash: lexical relationships from temporal patterns of web search queries

Enrique Alfonseca **Massimiliano Ciaramita** **Keith Hall**

ealfonseca@google.com, massi@google.com, kbhall@google.com

Abstract

In this paper we investigate temporal patterns of web search queries. We carry out several evaluations to analyze the properties of temporal profiles of queries, revealing promising semantic and pragmatic relationships between words. We focus on two applications: query suggestion and query categorization. The former shows a potential for time-series similarity measures to identify specific semantic relatedness between words, which results in state-of-the-art performance in query suggestion while providing complementary information to more traditional distributional similarity measures. The query categorization evaluation suggests that the temporal profile alone is not a strong indicator of broad topical categories.

1 Introduction

The temporal patterns of word occurrences in human communication carry an implicit measure of their relationship to real-world events and behavioral patterns. For example, when there is an event affecting a given entity (such as a natural disaster in a country), the entity name will turn up more frequently in human conversation, newswire articles and web documents; and people will search for it more often. Two entities that are closely related in the real world, such as the name of a country and a prominent region inside the country are likely to share common events and therefore be closely associated in human communication. Finally, two instances of the same class are also likely to share common usage patterns. For example, names of airlines or retail stores are more likely to be used by day rather than by night (Chien, 2005).

In this paper we explore the linguistic relationship between phrases that are judged to be similar based on their frequency time series correlation in search query logs. For every *phrase*[1] available in WordNet 3.0[2] (Miller, 1995), we have obtained its temporal signature from query logs, and calculated all their pairwise correlations. Next, we study the relationship in the top-ranked pairs with respect to their distribution in WordNet and a human-annotated labelling.

We also discuss possible applications of this data to solve open problems and present the results of two experiments: one where time series correlations turned out to be highly discriminative; and another where they were not particularly informative but shed some light on the nature of temporal semantics and topical categorization:

- *Query suggestion*, i.e. given a query, generate a ranked list of alternative queries in which the user may be interested.
- *Query categorization*, i.e. given a predefined set of categories, find the top categories to which the query can be assigned.

Finally, we illustrate with an example another application of time series in solving information extraction problems.

Although query logs are typically proprietary data, there are ongoing initiatives, like the Lemur toolbar[3], which make this kind of information available for research purposes. Other work (Bansal and Koudas, 2007b; Bansal and Koudas, 2007a) shows that temporal information can also be extracted from public data, such as blogs. More traditional types of text, such as news, are also typically associated with temporal labels; e.g., dates and timestamps.

This paper is structured in the following way:

[1] We use the term *phrase* to refer to any single word or multi-word expression that belongs to a synset in WordNet. Examples of phrases are *person*, *causal entity* or *william shakespeare*. We focused on the nouns hierarchy only.

Section 2 summarizes the related work. Section 3 describes the correlation analysis between all pairs of phrases from WordNet. Next, Section 4 describes the application to query suggestion, and Section 5 the application to labelling queries in topical categories. Section 7 summarizes the conclusions and outlines ideas for future research.

2 Related work

The study of query time series explores a particular instance of the so-called *wisdom of the crowds* effect. Within this area, we can distinguish two kinds of phenomena. Knowledge and resources assembled by people explicitly, either individually, such as the case of blogs, or in a collaborative way, as in forums or wikis. These resources are valuable for human-consumption and can also be exploited in order to learn computational resources (Medelyan et al., 2008; Weld et al., 2008; Zesch et al., 2008b; Zesch et al., 2008a). On the other hand, it is possible to acquire useful resources and knowledge from aggregating behavioral patterns of large groups of people, even in the absence of a conscious effort. There is extensive ongoing research on the use of web search usage patterns to develop knowledge resources. Some examples are clustering co-click patterns to learn semantically related queries (Beeferman and Berger, 2000), combining co-click patterns with hitting times (Mei et al., 2008), analyzing query revisions made by users when querying search engines (Jones et al., 2006), replacing query words with other words that have the highest pointwise mutual information (Terra and Clarke, 2004), or using the temporal distribution of words in documents to improve ranking of search results (Jones and Diaz, 2007).

Within this second category, an important area is dedicated to the study of time-related features of search queries. News aggregators use real-time frequencies of user queries to detect spikes and identify news shortly after the spikes occur (Murata, 2008). Web users' query patterns have also proved useful for building a real-time surveillance system that accurately estimates region-by-region influenza activity with a lag of one day (Ginsberg et al., 2009). Search engines specifically developed for real-time searches, like Twitter search, will most likely provide new use cases and scenarios for quickly detecting trends in user search query patterns.

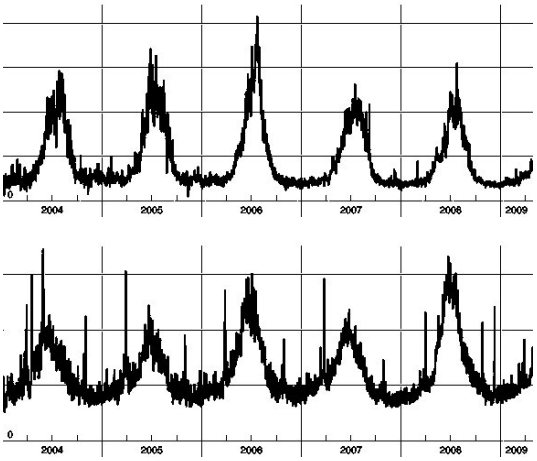

Figure 1: Time series obtained for the queries [gazpacho] and [summertime] (normalized scales).

Our study builds upon the work of Chien (2005), who observed that queries with highly-correlated temporal usage patterns are typically semantically related, and described a procedure for calculating the correlations efficiently. We have extended the analysis described in this work, by performing a more extensive evaluation of the kinds of semantic relationships that we can find among temporally-similar queries. We also propose, to our knowledge for the first time, areas of applications in solving well-established problems which shed some light on the nature of time-based semantic similarity. This work is also related to the analysis of temporal properties of information streams in data mining (Kleinberg, 2006) and information retrieval from time series databases (Agrawal et al., 1993).

3 Time-based similarities between phrases

Similarly to the method described in Chien (2005), we take a time interval, divide it into equally spaced subintervals, and represent each phrase of interest as the sequence of frequencies with which the phrase was observed in the subintervals. In our experiments, we have used as source data the set of fully anonymized query logs from the Google search engine between January 1st, 2004 and March 1st, 2009.[4].

These data have been aggregated on a daily basis so that we have the daily frequency of the

[4]Part of this data is publicly available from `http://www.google.com/trends`

queries of interest for over five years. The frequencies are then normalized with the total number of queries that happened on that day. The normalization is necessary to avoid daily and seasonal variations as there are typically more queries on weekdays than on weekends and fewer queries during holiday seasons than in the rest of the year. It also helps reducing the effect deriving from the fact that the population with Internet access is still monotonically growing, so we can expect that the number of queries will become higher and higher over time.

Given two phrases and their associated time series, the similarity metric used is the correlation coefficient between the two series (Chien, 2005). For illustration, Figure 1 shows the time series obtained for two sample queries, *gazpacho* and *summertime*, whose time series yield a correlation of 0.92. Similar high correlations can be observed with other queries related to phenomena that occur mainly in summer in the countries from which most queries come, like *summer rash*.

3.1 WordNet-based evaluation

In this section, we describe a study carried out with the purpose of discovering the traditional lexico-semantic relationships which hold between the queries that are most strongly related according to their temporal profiles.

For this evaluation, we have taken the nominal phrases appearing in WordNet 3.0. Given that users, when writing queries, typically do not pay attention to punctuation and case, we have normalized all phrases by lowercasing them and removing all punctuation. Next, we collected the time series for each phrase by computing the normalized daily frequency of each of them as exact queries in the query logs. The computation of the pairwise correlations was performed in parallel using the MapReduce infrastructure running over 2048 cores with 500 MB of RAM each. The total execution (including data shuffling and networking time) took approximately three hours.

Next, we represented the data as a complete graph where phrases are nodes and the edge between each pair of nodes is weighted by their time series correlation. Using a simple graph-cut we obtained clusters of related terms. A minimum weight threshold equal to 0.9 was applied;[5] thus, two phrases belong to the same cluster if there is a path between them only via edges with weight over 0.9.

The previous procedure produced a set of 604 clusters, with highly different sizes. The first observation is that 70% of the phrases in WordNet do not have a correlation over 0.9 with any other phrase, so they are placed alone in singleton clusters. There are several reasons for this. The clusters obtained are very specific: only phrases that have a very strong temporal association have temporal correlations exceeding the threshold. This is combined with the fact that we are using a very restricted vocabulary, namely the terms included in WordNet, which is many orders of magnitude smaller than the vocabulary of all possible queries from the users. Few phrase pairs in WordNet have a temporal association and popularity strong enough to be clustered together. Finally, many of the phrases in WordNet are rare, including scientific names of animals and plants, genuses or families, which are not commonly used. Therefore, the clusters extracted here correspond to very salient sets of phrases. If, instead of WordNet, we choose a vocabulary from known user queries (cf. Section 4), there would be many fewer singleton clusters, as the options of similar phrases to choose from would be much larger.

From the phrases that belong to clusters, 25% of the WordNet phrases do not have strong daily temporal profiles. The typical pattern for these terms is an almost flat time series, usually with small drops at summertime and Christmas (when seasonal leisure-related queries dominate). Therefore, these phrases were collected in just one cluster containing them all. Typical examples of the elements of this set are names of famous scientists and mathematicians (Gauss, Isaac Newton, Albert Einstein, Thomas Alva Edison, Hipprocrates, Gregor Mendel, ...), common terms (fertilization, famine, macroeconomics, genus, nationalism, ...), numbers and common first names, among other things. It is possible that using sub-day intervals might help to discriminate within this cluster.

The items in this big cluster contrast with periodical events, which display recurring patterns (e.g., queries related to elections or tax-returns), and names of famous people and other entities which appeared in the news in the past few years. All of these are associated with irregular, spiky time series. These constitute the final 5% of the

[5] This threshold is the same used by Chien (2005), and was confirmed after a manual inspection of a sample of the data

Type	Pairs	Examples
Synonyms	283	(angel cake, angel food cake), (thames, river thames), (armistice day, Nov 11)
Hyponym/hyperonyms	86	(howard hughes, aviator), (muhammad, prophet), (olga korbut, gymnast)
Siblings in hyponym taxonomy	611	(hiroshima, nagasaki), (junior school, primary school), (aids, welt)
Meronym/holonyms	53	(tutsi, rwanda), (july 4, july), (pyongyang, north korea)
Siblings in meronymy taxonomy	7	(everglades, everglades national park), (mississipi, orleans)
Other paths	471	(maundy thursday, maundy money), (tap water, water tap), (gren party, liberal)
Not structurally related	1009	(poppy, veterans day), (olympic games, gimnast), (belmont park, horse racing)

Table 1: Relationships between pairs of WordNet phrases belonging to the same cluster.

phrases belonging to small, highly focused, clusters.

Table 1 shows the relationships that hold between all pairs of phrases belonging to any of the smaller clusters. Out of 2520 pairs, 283 belong to the same synset, 697 are related via hyponymy links, 60 via meronymy links, and 471 by alternating hyponymy and meronymy links in the path. When the phrases were polysemous, the shortest path between any of their meaning was used. About 40% of the relations do not have a clear structural interpretation in WordNet.

The majority of pairs are related via more or less complex paths in the WordNet graph. Interestingly, even the structurally unrelated terms are characterized by transparent relations in terms of world knowledge, as it is the case between *poppy* and *veteran day*. Note as well that sometimes a WordNet term is used with a meaning not present in WordNet or in a different language, which may explain why *aids* has a very high correlation with *welt* (AIDS and welt are both hyponyms of *health problem*, but the correlation may be explained better by the AIDS World Day, *Welt Aids Tag* in German), and it also has a very high correlation with *sida*, defined in WordNet as a genus of tropical herbs, but which is in fact the translation of AIDS into Spanish. These observations motivated an additional manual labelling of the extracted pairs.

3.2 Hand labelled evaluation

As can be seen in Table 2, most of the terms that constitute a cluster are related to each other, although the kinds of semantic relationships that hold between them can vary significantly. Examples of the following kinds can be observed:

- **True synonyms**, as in the case of *november* and *nov*, or *architeuthis* and *giant squid*.
- **Variations of people names**, especially if a person's first name or surname is typically used to refer to that person, as in the case of *john lennon* and *lennon*, or *janis joplin* and *joplin*. Sometimes the variations include personal titles, as it is the case of *president carter* and *president nixon*, which are highly correlated with *jimmy carter* and *richard nixon*.
- **Geographically-related terms**, referring to locations which are located close to each other, as in the clusters {*korea, north korean, south korea, pyongyang, north korea*} and {*strasbourg, grenoble, toulouse, poitiers, lyon, lille, nantes, reims*}.
- **Synonyms of location names**, like *bahrain* and *bahrein*.
- **Derived words**, like *north korea* and *north korean*, or *lebanese* and *lebanon*.
- **Generic word optionalizations**, which happen when one word in a multi-word phrase is very correlated to the phrase, as in the case of *spanish inquisition* and *inquisition*, or *red bone marrow* and *red marrow*, where the most common interpretation for the shortened version of the phrase is the same as for the long version.
- **Word reordering**, where the two related phrases have the same words in a different order, as in the case of *maple sugar* and *sugar maple*, or *oil palm* and *palm oil*.
- **Morphological variants**: WordNet does not contain many morphological variants in the main dataset, but there are a few, like *station of the cross* and *stations of the cross*.
- **Acronyms**, like *federal emergency management agency* and *fema*.
- **Hyperonym-hyponym**, like *fern* and *plant*.
- **Sibling terms** in a taxonomy, as in the cluster {*lutheran, methodist, presbyterian, united methodist church, lutheran church,methodist church, presbyterian church,baptist, baptist church*}, which contains mostly names of Christian denominations.
- **Co-occurring events in time**, as is the case of *hitch* and *pacifier*, both titles of movies which were launched at almost the same

Table 3: Results of the manual annotation of 2-item clusters.

time. A particular example of this is when the two terms are part of a named entity, as in the case of *quantum* and *solace*, which have a similar correlation because they appear together in a movie title.

- **Topically-related terms**, as the cluster {*jesus christ, pilate, pontius pilate, passion of christ, passion, aramaic*}, or the cluster containing popes and the Vatican. A similar example, *execution* is highly correlated to *saddam hussein*, because his execution attracted more interest worldwide during this time period than any other execution. Interestingly, topical correlation emerges at very specific granularity.

For the manual analysis of the results, we randomly selected 332 clusters containing only two items (so that 664 phrases were considered in total). Each of these pairs has been classified in one of the previous categories. The results of this analysis are shown in Table 3.

4 Application to query suggestion

Query suggestion is a feature of search engines that helps users reformulate queries in order to better describe their information need with the purpose of reducing the time needed to find the desired information (Beeferman and Berger, 2000; Kraft and Zien, 2004; Sahami and Heilman, 2006; Cucerzan and White, 2007; Yih and Meek, 2008). In this section, we explore the application of a similarity metric based on time series correlations for finding related queries to suggest to the users.

As a test set, we have used the query suggestion dataset from (Alfonseca et al., 2009). It contains a set of 57 queries and an average of 22 candidate query suggestions for each of them. Each suggestion was rated by two human raters using the 5-point Likert scale defined in (Sahami and Heilman, 2006), from irrelevant to highly relevant. The task involves providing a ranking of the suggestions that most closely resembles the human scores. The evaluation is based on standard IR metrics: precision at 1, 3 and 5, and mean average precision. In order to compute the precision- and recall-based metrics, we infer a binary distinction from the ratings: related or not related. The inter-annotator agreement for this dataset given the binary classification as computed by Cohen's Kappa is 0.6171.

Method	P@1	P@3	P@5	mAP
Random	0.37	0.37	0.37	0.43
Web Kernel	0.51	0.47	0.42	0.51
Dist. simil.	0.72	0.63	0.60	0.64
Time series	0.74	0.63	0.53	0.67
Combination	0.79	0.68	0.60	0.69

Table 4: Results for the query suggestion task.

We used three baselines: the average values that would be produced by a random scorer of the candidate suggestions, Sahami and Heilman (2006)'s system (based on calculating similarities between the retrieved snippets), and a recent competitive ranker based on calculating standard distributional similarities (Alfonseca et al., 2009) between the original query and the suggestion. Please refer to the referenced work for details.

In order to produce the ranked lists of candidate suggestions for each query, due to the lack of training data, we have opted for the unsupervised procedure described in the previous section:

1. Collect the daily time series of each of the queries and the candidate suggestions.
2. Calculate the correlation between the original query and each of the candidate suggestions provided for it, and use it as the candidate's score.
3. For each query, rank its candidate suggestions in decreasing order of correlation.

Finally, taking into account that the source of similarity is very different to the one used for distributional similarity, we tested the hypothesis that

a combination of the two techniques would be beneficial to capture different features of the queries and suggestions. We have trained a linear mixture model combining both scores (time series and distributional similarities), using 10-fold cross validation.

The results are displayed in Table 4. For evaluating the results, whenever a system produced a tie between several suggestions, we generated 100 random orderings of the elements in the tie, and report the average scores.

Using distributional similarities and the temporal series turned out to be indistinguishable for the precision scores at 0.95 confidence, and both are significantly better than the similarity metric based on the web kernel. The combination produced an improvement across all metrics, although not statistically significant at p=0.05.

This is quite a positive finding as the time series method relies on stored information requiring only simple and highly optimized lookups.

5 Application to query categorization

The results from the manual evaluation in Section 3.2 support the conclusion that time series from query logs provide powerful signals for clustering at a fine-grained level, in some cases uncovering synonyms (may 1st, may day) and even causal relations (insulation, heating). A natural question is if temporal information is correlated with other types of categorizations. In this section we carry out a preliminary exploration of the relation between query time series and query categorization. To this extent we adapt the data from the KDD 2005 CUP (Li et al., 2005), which provides a set of queries classified into 67 broad topical categories. Since the data is rather sparse (678 queries) we applied Fourier analysis to "smooth" the time series.

5.1 The KDD CUP data

The KDD Cup 2005 [6] introduced a query categorization task and dataset consisting of 800,000 unlabeled queries for unsupervised training, and an evaluation set of 911 queries, 111 for development and 800 for the final evaluation. The systems submitted for this task can be quite complex and made full use of the large unlabeled set. Our goal here is not to provide a comparative evaluation, but only

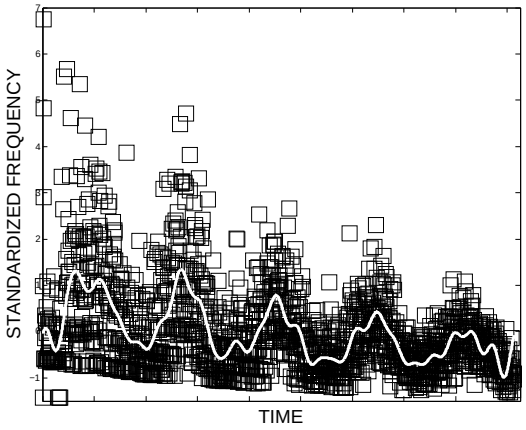

Figure 2: RDFT reconstruction for the query "brush cutters" using the first 25 Fourier coefficients. The squares represent the original time series datapoints, while the continuous line represents the reconstructed signal.

to use the labelled data[7] in a simplified manner to better understand the semantic properties of query time series. Each query in the dataset is assessed by three editors who can assign multiple topic labels from a set of 67 categories belonging to seven broad topics: Computers, Entertainment, Information, Living, Online Community, Shopping and Sports. We merged the KDD Cup development and test set, out of the 911 queries we were able to retrieve significant temporal information for 678 queries. We joined the sets of labels from each assessor for each query. On average, each query is assigned five labels.

5.2 DFT analysis

Assessing the similarity of data represented as time series has been addressed mostly my means of Fourier analysis; e.g., Agrawal et al. (1993) introduce a method for efficiently retrieving time series from databases based on Discrete Fourier Transform (DFT). Several other methods have been proposed, e.g., Discrete Wavelet Transform (DWT), however DFT provide a competitive benchmark approach (Wu et al., 2000).

We use DFT to generate the Fourier coefficients of the time series and Reverse DFT (RDFT) to reconstruct the original signal using only a subset of the coefficients. This analysis effectively compresses the time series producing a smoother approximate representation. DFT can be computed efficiently via Fast Fourier Transform (FFT), with

[6] http://www.sigkdd.org/kdd2005/kddcup.html

[7] The KDD Cup dataset is probably the only public query log providing topical categorization information.

Method	Accuracy	± std-err
Random	0.107	0.03
MostFrequent	0.490	0.07
DFT-c10	0.425	0.06
DFT-c50	0.456	0.05
DFT-c100	0.502	0.05
DFT-c200	0.456	0.04
DFT-c400	0.506	0.05
DFT-c600	0.481	0.06
DFT-c800	0.478	0.04
DFT-c1000	0.466	0.05

Table 5: Results of the KDD dataset exploration.

complexity $O(n \log n)$ where n is the length of the sequence. The approximate representation is useful not only to address sparsity but can also be used to efficiently estimate the similarity of two time series using only a small subset of coefficients as in (Agrawal et al., 1993). As an example, Figure 2 shows the original time series for the query "brush cutters" and its reconstructed signal using only the first 25 Fourier coefficients. The reconstructed signal captures the essence of the periodicity of the query and highlights the yearly peaks registered for the query in spring and summer.

5.3 Experiment and discussion

To explore the correlation between the structured temporal representation of queries provided by the time series and topical categorization we run the following experiment. Each KDD Cup query was reconstructed via RDFT using a variable number of coefficients. The set of 679 queries was partitioned in 10 sets and a 10-fold evaluation was performed. For each fold we trained a classifier on the remaining 9 folds. We used an average multi-class perceptron (Freund and Schapire, 1999) adapted to multi-label learning (Crammer and Singer, 2003). Each model was trained on a fixed number of 10 iterations. The accuracy of each model was evaluated as the fraction of test items for which the selected highest scoring class was in the gold standard set provided by the editors. As a lower bound we estimated the accuracy of randomly choosing a label for each test instance, and as a baseline we used the most frequent label. The latter is a powerful predictor: baselines based on class frequency outperform most of the systems that participated in the KDD Cup (Lin and Wu, 2009).

Table 5 reports the average accuracy over the 10 runs with relative standard errors. Each DFT-based model is characterized by the number of coefficients used for the reconstruction. Two main patterns are noticeable. First, none of the differences between the frequency-based baseline and the DFT models is significant, this seems to indicate that temporal structure alone is not a good discriminator of topic, at least of broad categories. In retrospect, this is somewhat predictable. The temporal dimension is a basic semantic component of lexical meaning and world knowledge which is not necessarily associated with any broad, and to some extent subjective, categorization. An inspection of the patterns found in each category shows in fact that similar patterns often emerge in different categories; e.g., "Halloween costume" and "cheesecake recipe" have a similar yearly periodical pattern with spikes in early winter, while monotonically decaying patterns are shared across all categories; e.g., between computer hardware and kids toys.

The second interesting finding is the trend of the DFT system results, higher at low-intermediate values, providing some initial promising evidence that DFT analysis generates useful compressed representations which could be indexed and applied efficiently. Notice that the sequences reconstructed using 1,000 coefficients reproduce almost identically the original signals.

6 Applications in information extraction

Time series from query logs are particularly relevant for phrases that refer to entities which are involved in recent events. Therefore, we expect them to be useful for solving other applications that require handling entities, such as named entity recognition and classification, relation extraction or disambiguation.

To illustrate this point, we mention an example of relation extraction between actors and movies: movies usually have spikes when they are released, and then the frequency again drops sharply. At the same times, when a movie is released, the search engine users have a renewed interest in their actors. Figure 3 displays the time series for the five most recent movies by Jim Carrey (as of march 2009), and the time series for Jim Carrey. As can be seen, the spikes are at exactly the same points in time. If we add up the series (a) through (e) into a single series and calculate the correlation with (f), it turns out to be very high (0.88).

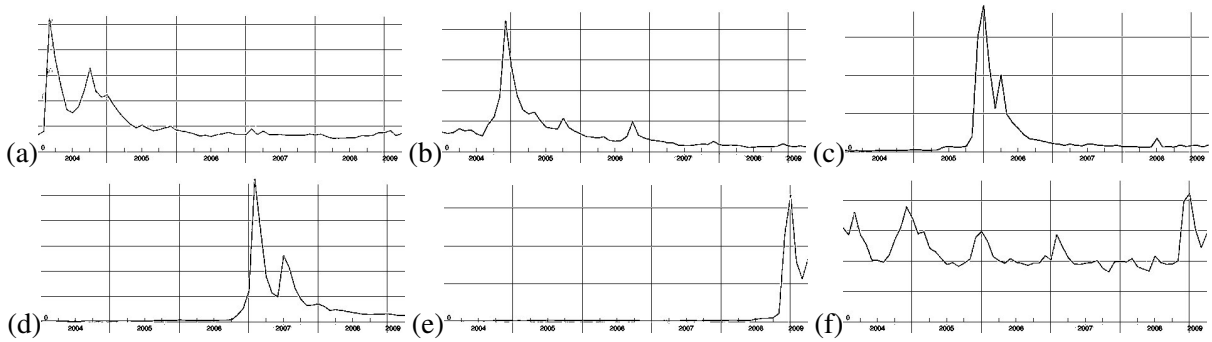

Figure 3: Time series obtained for the five most recent movies with Jim Carrey, and (f) time serie for the query [jim carrey] (normalized scales).

System	Precision	Recall	F-measure
Random	0.24	0.14	0.17
Time series	0.53	0.66	0.57

Table 6: Results for the query suggestion task.

To validate the hypothesis that this data should be useful for identifying related entities, we have performed a small experiment in the following way: by choosing five popular actors[8] and the cinema movies in which they appear since the year 2004, obtained from IMDB[9]. Using the time series, for each actor we choose the combination of movies such that, by adding up the time series of those movies, we maximise the correlation with the actor's time series. It has been implemented with a greedy beam search, with a beam size of 100. The results are shown in Table 6. The random baseline randomly associates the movies from the dataset with the five actors.

We do not believe this to be a perfect feature as, for example, actors may have a peak in the time series related to their personal lives, not necessarily to movies. However, the high correlations that can be obtained when the pairing between actors and movies is correct, and the improvement with respect a random baseline, indicates this is a feature which can probably be integrated with other relation extraction systems when handling relationships between entities that have big temporal dependencies.

7 Conclusions and future work

This paper explores the relationships between queries whose associated time series obtained from query logs are highly correlated. The use of time series in semantic similarity has been discussed by Chien (2005), but only a very preliminary evaluation was described, and, to our knowledge, they had never been applied and evaluated in solving existing problems. Our results indicate that, for a substantial percentage of phrases in a thesaurus, it is possible to find other highly-related phrases; and we have categorized the kind of semantic relationships that hold between them.

We have found that in a query suggestion task, somewhat surprisingly, results are comparable with other state-of-the-art techniques based on distributional similarities. Furthermore, information obtained from time series seems to be complementary with them, as a simple combination of similarity metrics produces an important increase in performance..

From an analysis on a query categorization task the initial evidence suggests that there is no strong correlation between broad topics and temporal profiles. This agrees with the intuition that time provides a fundamental semantic dimension possibly orthogonal to broad topical classification. This issue however deserves further investigation. Another issue which is worth a deeper investigation is the application of Fourier transform methods which offer tools for studying the periodic structure of the temporal sequences.

Abstract

A large body of recent research has been investigating the acquisition and application of applied inference knowledge. Such knowledge may be typically captured as *entailment rules*, applied over syntactic representations. Efficient inference with such knowledge then becomes a fundamental problem. Starting out from a formalism for entailment-rule application we present a novel packed data-structure and a corresponding algorithm for its scalable implementation. We proved the validity of the new algorithm and established its efficiency analytically and empirically.

1 Introduction

Applied semantic inference is concerned with deriving target meanings from texts. In the textual entailment framework, this is reduced to inferring a textual statement (the *hypothesis* h) from a source *text* (t). Traditional formal semantics approaches perform such inferences over logical forms derived from the text. By contrast, most practical NLP applications operate over shallower representations such as parse trees, possibly supplemented with limited semantic information about named entities, semantic roles etc.

Most commonly, inference over such representations is made by applying some kind of transformations or substitutions to the tree or graph representing the text. Such transformations may be generally viewed as *entailment (inference) rules*, which capture semantic knowledge about paraphrases, lexical relations such as synonyms and hyponyms, syntactic variations etc. Such knowledge is either composed manually, e.g. WordNet (Fellbaum, 1998), or learned automatically.

A large body of work has been dedicated to learning paraphrases and entailment rules, e.g. (Lin and Pantel, 2001; Shinyama et al., 2002; Szpektor et al., 2004; Bhagat and Ravichandran, 2008), identifying appropriate contexts for their application (Pantel et al., 2007) and utilizing them for inference (de Salvo Braz et al., 2005; Bar-Haim et al., 2007). Although current available rule bases are still quite noisy and incomplete, the progress made in recent years suggests that they may become increasingly valuable for text understanding applications. Overall, applied knowledge-based inference is a prominent line of research gaining much interest, with recent examples including the series of workshops on *Knowledge and Reasoning for Answering Questions (KRAQ)*[1] and the planned evaluation of knowledge resources in the forthcoming 5^{th} Recognizing Textual Entailment challenge (RTE-5)[2].

While many applied systems utilize semantic knowledge via such inference rules, their use is typically limited, application-specific, and quite heuristic. Formalizing these practices seems important for applied semantic inference research, analogously to the role of well-formalized models in parsing and machine translation. Bar-Haim et al. (2007) made a step in this direction by introducing a generic formalism for semantic inference over parse trees. Their formalism uses entailment rules as a unifying representation for various types of inference knowledge, allowing unified inference as well. In this formalism, rule application has a clear, intuitive interpretation as generating a new sentence parse (a *consequent*), semantically entailed by the source sentence. The inferred consequent may be subject to further rule applications

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1056–1065,
Singapore, 6-7 August 2009.

and so on. In their implementation, each consequent was generated explicitly as a separate tree.

Following this line of work, our long-term research goal is to investigate effective utilization of entailment rules for inference. While the formalism of Bar-Haim et al. provides a principled framework for modeling such inferences, its implementation using explicit generation of consequents raises severe efficiency issues, since the number of consequents may grow exponentially in the number of rule applications. Consider, for example, the sentence *"Children are fond of candies."*, and the following entailment rules: *'children→kids'*, *'candies→sweets'*, and *'X is fond of Y→X likes Y'*. The number of derivable sentences (including the source sentence) would be 2^3 as each rule can either be applied or not, independently. Indeed, we found that this exponential explosion leads to poor scalability in practice. Intuitively, we would like that each rule application would add just the entailed part (e.g. *kids*) to a packed sentence representation. Yet, we still want the resulting structure to represent a set of entailed sentences, rather than some mixture of sentence fragments whose semantics is unclear.

As discussed in section 5, previous work proposed only partial solutions to this problem. In this paper we present a novel data structure, termed *compact forest*, and a corresponding inference algorithm, which efficiently generate and represent all consequents while preserving the identity of each individual one (section 3). Our work is inspired by previous work on packed representations in other fields, such as parsing, generation and machine translation (section 5). As we follow a well-defined formalism, we could prove that all inference operations of Bar-Haim et al. are equivalently applied over the compact forest. We compare inference cost over compact forests to explicit consequent generation both theoretically (section 3.4), illustrating an exponential-to-linear complexity ratio, and empirically (section 4), showing improvement by orders of magnitude. These results suggest that our data-structure and algorithm are both valid and scalable, opening up the possibility to investigate large-scale entailment rule application within a well-formalized framework.

2 Inference Framework

This section briefly presents a (simplified) description of the tree transformations inference formalism of Bar-Haim et al. (2007). Given a source text, syntactically parsed, and a set of *entailment rules* representing tree transformations, the formalism defines the set of consequents derivable from the text using the rules. Each consequent is obtained through a sequence of rule applications, each generates an intermediate parse tree, similar to a proof process in logic.

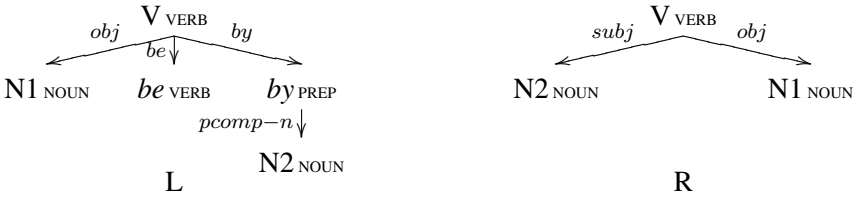
More specifically, sentences are represented as dependency trees, where nodes are annotated with lemma and part-of-speech, and edges are annotated with dependency relation. A rule '$L \rightarrow R$' is primarily composed of two *templates*, termed *left-hand-side* (L), and *right-hand-side* (R). Templates are dependency subtrees which may contain POS-tagged *variables*, matching any lemma. Figure 1(a) shows passive-to-active transformation rule, and (b) illustrates its application.

A rule application generates a derived tree d from a source tree s through the following steps:

L matching: First, a match of L in the source tree s is sought. In our example, the variable V is matched in the verb *see*, $N1$ is matched in *Mary* and $N2$ is matched in *John*.

R instantiation: Next, a copy of R is generated and its variables are instantiated according to their matching node in L. In addition, a rule may specify *alignments*, defined as a partial function from L nodes to R nodes. An alignment indicates that for each modifier m of the source node that is not part of the rule structure, the subtree rooted at m should also be copied as a modifier of the target node. In addition to defining alignments explicitly, each variable in L is implicitly aligned to its counterpart in R. In our example, the alignment between the V nodes implies that *yesterday* (modifying *see*) should be copied to the generated sentence, and similarly *beautiful* (modifying *Mary*) is copied for $N1$.

Derived tree generation: Let r be the instantiated R, along with its descendants copied from L through alignment, and l be the subtree matched by L. The formalism has two methods for generating the derived tree d: *substitution* and *introduction*, as specified by the rule type. *Substitution* rules specify modification of a subtree of s, leaving the rest of s unchanged. Thus, d is formed by copying s while replacing l (and the descendants



(a) Passive to active transformation (substitution rule)

Source: Beautiful Mary was seen by John yesterday.

Derived: John saw beautiful Mary yesterday.

(b) Application of passive to active transformation

Figure 1: An inference rule application. POS and relation labels are based on Minipar (Lin, 1998)

of l's nodes) with r. This is the case for the passive rule, as well as for lexical rules such as '*buy* → *purchase*'. By contrast, *introduction* rules are used to make inferences from a subtree of s, while the other parts of s are ignored and do not affect d. A typical example is inferring a proposition embedded as a relative clause in s. In this case, the derived tree d is simply taken to be r.

In addition to inference rules, the formalism includes *annotation rules* which add features to existing parse tree nodes. These rules have been used for identifying contexts that affect the polarity of predicates.

As shown by Bar-Haim et al., this concise, well defined formalism allows unified representation of diverse types of knowledge which are commonly used for applied semantic inference.

3 Efficient Inference over Compact Parse Forests

As shown in the introduction, explicit generation of consequents (henceforth *explicit inference*) leads to an exponential explosion of the number of generated trees. In this section we present our efficient implementation for this formalism. Our implementation is based on a novel data structure, termed *compact forest* (Section 3.1), which compactly represents a large set of trees. Each rule application generates explicitly only the nodes of the rule right-hand-side while the rest of the consequent tree is shared with the source, which also reduces the number of redundant rule applications. As we shall see, this novel representation is based primarily on *disjunction edges*, an extension of dependency edges that specify a set of alternative edges of multiple trees. Section 3.2 presents an efficient algorithm for inference over compact forests, followed by a discussion of its correctness and complexity (sections 3.3 and 3.4).

3.1 The Compact Forest Data Structure

A compact forest $\mathcal{F}$ represents a set of dependency trees. Figure 2 shows an example of a compact forest, containing both the source and derived sentences of Figure 1. We first define a more general data structure for directed graphs, and then narrow the definition to the case of trees.

A *Compact Directed Graph (cDG)* is a pair $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V}$ is a set of nodes and $\mathcal{E}$ is a set of **disjunction edges** *(d-edges)*. Let $\mathcal{D}$ be a set of dependency relations. A d-edge d is a triple (S_d, rel_d, T_d), where S_d and T_d are disjoint sets of source nodes and target nodes; $rel_d : S_d \rightarrow \mathcal{D}$ is a function specifying the dependency relation corresponding to each source node. Graphically, d-edges are shown as point nodes, with incoming edges from source nodes and outgoing edges to target nodes. For instance, let d be the bottom-most d-edge in Figure 3. Then $S_d = \{$*of, like*$\}$, $T_d = \{$*candy, sweet*$\}$, $rel(of) =$ *pcomp-n*, and $rel($*like*$) =$ *obj*.

A d-edge represents, for each $s_i \in S_d$, a set of

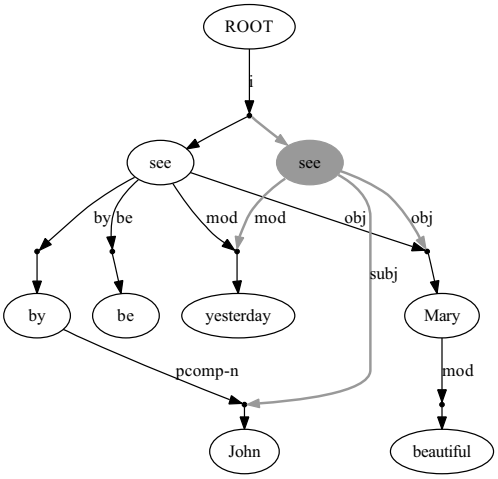


Figure 2: A compact forest containing both the source and derived sentences of Figure 1. Parts of speech are omitted.

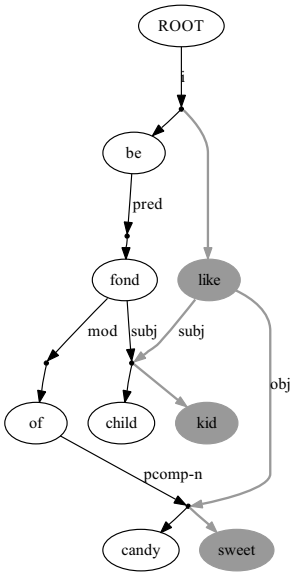

Figure 3: A compact forest representing the 2^3 sentences derivable from the sentence *"children are fond of candies"* using the following three rules: *'children→kids'*, *'candies→sweets'*, and *'X is fond of Y→X likes Y'*.

alternative directed edges $\{(s_i, t_j) : t_j \in T_d\}$, all of which are labeled with the same relation given by $rel_d(s_i)$. Each of these edges, termed *embedded edge (e-edge)*, would correspond to a different graph represented in $\mathcal{G}$. In the previous example, the e-edges are *like* $\xrightarrow{obj}$ *candy*, *like* $\xrightarrow{obj}$ *sweet*, *of* $\xrightarrow{pcomp-n}$ *candy* and *of* $\xrightarrow{pcomp-n}$ *sweet* (notice that the definition implies that all source nodes in S_d have the same set of alternative target nodes T_d). d is called an *outgoing d-edge* of a node v if $v \in S_d$ and an *incoming d-edge* of v if $v \in T_d$. A *Compact Directed Acyclic Graph (cDAG)* is a cDG that contains no cycles of e-edges.

A DAG G rooted in a node $v \in \mathcal{V}$ of a cDAG $\mathcal{G}$ is *embedded* in $\mathcal{G}$ if it can be derived as follows: we initialize G with v alone; then, we *expand* v by choosing exactly one target node $t \in T_d$ from each outgoing d-edge d of v, and adding t and the corresponding e-edge (v, t) to G. This expansion process is repeated recursively for each new node added to G.

Each such set of choices results in a different DAG with v as its only root. In Figure 2, we may choose to connect the root either to the left *see*, resulting in the source passive sentence, or to the right *see*, resulting in the derived active sentence.

A **Compact Forest** $\mathcal{F}$ is a cDAG with a single root r (i.e. r has no incoming d-edges) where all the embedded DAGs rooted in r are trees. This set of trees, termed *embedded trees*, comprise the set of trees represented by $\mathcal{F}$.

Figure 3 shows another example for a compact forest efficiently representing the 2^3 sentences resulting from three independently-applied rules.

3.2 The Inference Process

Next, we describe the algorithm implementing the inference process of Section 2 over the compact forest (henceforth, *compact inference*), illustrating it through Figures 1 and 2.

Forest initialization $\mathcal{F}$ is initialized with the set of dependency trees representing the *text* sentences, with their roots connected under the forest root as the target nodes of a single d-edge. Dependency edges are transformed trivially to d-edges with a single source and target. Annotation rules are applied at this stage to the initial $\mathcal{F}$. The black part of Figure 2 corresponds to the initial forest.

Rule application comprises the following steps:

L matching: L is matched in $\mathcal{F}$ if there exists an embedded tree t in $\mathcal{F}$ such that L is matched in t, as in Section 2. We denote by l the subtree of t in which L was matched. As in section 2, the match in our example is $(V, N1, N2)$=*(see, Mary, John)*. Notice that this definition does not allow l to be scattered over multiple embedded trees.

As the target nodes of a d-edge specify alternatives for the same position in the tree, their parts-of-speech are expected to be of substitutable types.

In this paper we further assume that all target nodes of the same d-edge have the same part-of-speech[3]. Consequently, variables that are leaves in L and may match a certain target node of a d-edge d are mapped to the whole set of target nodes T_d rather than to a single node. This yields a compact representation of multiple matches, and prevents redundant rule applications. For instance, given a compact representation of '{*Children/kids*} *are fond of* {*candies/sweeets*}' (cf. Figure 3), the rule *'X is fond of Y→X likes Y'* will be matched and applied only once, rather than four times (for each combination of matching X and Y).

Derived tree generation: A template r consisting of R while excluding variables that are leaves of both L and R (termed *dual leaf-variables*)[4] is generated and inserted into $\mathcal{F}$. In case of a substitution rule (as in our example), r is set as an alternative to l by adding r's root to T_d, where d is the incoming d-edge of l's root. In case of an introduction rule, it is set as an alternative to the other trees in the forest by adding r's root to the target node set of the forest root's outgoing d-edge. In our example, r is the gray node (still labeled with the variable V) , and it becomes an additional target node of the d-edge entering the original (left) *see*.

Variable instantiation: Each variable in r (i.e. a non-dual leaf) is instantiated according to its match in L (as in Section 2), e.g. V is instantiated with *see*. As specified above, if the variable is a leaf in L is not a dual leaf then it is matched in a set of nodes, and hence each of them should be instantiated in r. This is decomposed into a sequence of simpler operations: first, r is instantiated with a representative from the set, and then we apply (ad-hoc) lexical substitution rules for creating a new node for each other node in the set[5].

Alignment sharing: Modifiers of aligned nodes are shared (rather than copied) as follows. Given a node n_L in l aligned to a node n_R in r, and an outgoing d-edge d of n_L which is not part of l, we share d between n_L and n_R by adding n_R to S_d and setting $rel_d(n_R) = rel_d(n_L)$. This is illustrated by the sharing of *yesterday* in Figure 2. We also copy annotation features from n_L to n_R.

We note at this point that the instantiation of variables that are not dual leaves (e.g. V in our example) cannot be shared because they typically have different modifiers at the two sides of the rule. Yet, their modifiers which are not part of the rule are shared through the alignment operation (recall that common variables are always considered aligned). Dual leaf variables, on the other hand, might be shared, as described next, since the rule doesn't specify any modifiers for them.

Dual leaf variable sharing: This final step is performed analogously to alignment sharing. Suppose that a dual leaf variable X is matched in a node v in l whose incoming d-edge is d. Then we simply add the parent p of X in r to S_d and set $rel_d(p)$ to the relation between p and X (in R). Since v itself is shared, its modifiers become shared as well, implicitly implementing the alignment operation. The subtrees *beautiful Mary* and *John* are shared this way for variables $N1$ and $N2$.

Applying the rule in our example added only a single node and linked it to four d-edges, compared to duplicating the whole tree in explicit inference.

3.3 Correctness

In this section we present two theorems, which prove that the inference algorithm is a valid implementation of the inference formalism of Section 2. Due to space limitations, the proofs themselves are omitted, and instead we outline their general scheme.

We first argue that performing any sequence of rule applications over the set of initial trees results in a compact forest:

Theorem 1: *The compact inference process generates a compact forest.*

Proof scheme: We prove by induction on the number of rule applications. Initialization generates a single-rooted cDAG, whose embedded DAGs are all trees, as required. We then prove that if applying a rule on a compact forest creates a cycle or an embedded DAG that is not a tree, then such a cycle or a non-tree DAG already existed prior to rule application, in contradiction with the inductive assumption. A crucial observation for this proof is that for any path from a node u to a node v that passes through r, where u and v are

[3]This is the case in our current implementation, which is based on the coarse tag-set of Minipar (Lin, 1998).

[4]With the following exceptions: variables that are the only node in R (and hence are both the root and a leaf), and variables with additional alignments (other than the implicit alignment between their occurrences in L and R) are not considered dual-leaves.

[5]Notice that these nodes, in addition to the usual alignment with their source nodes in l, share the same daughters in r.

outside r, there is also an analogous path from u to v that passes through l instead, QED.

Next, we argue that the inference process over a compact forest is complete and sound, i.e., it generates the set of consequents derivable from a text according to the inference formalism.

Theorem 2: *Given a rule base $\mathcal{R}$ and a set of initial trees T, a tree t is embedded in a compact forest derivable from T by the compact inference process $\Leftrightarrow$ t is a consequent of T according to the inference formalism.*

Proof scheme: We first show completeness by induction on the number of explicit rule applications. Let t_{n+1} be a tree derived from a tree t_n using the rule r_n according to the inference formalism. The inductive assumption asserts that t_n is embedded in some derivable compact forest $\mathcal{F}$. It is easy to verify that applying r_n to $\mathcal{F}$ will yield a compact forest $\mathcal{F}'$ in which t_{n+1} is embedded.

Next, we show soundness by induction on the number of rule applications over the compact forest. Let t_{n+1} be a tree represented in some derived compact forest $\mathcal{F}_{n+1}$. $\mathcal{F}_{n+1}$ was derived from the compact forest $\mathcal{F}_n$, using the rule r_n. It can be shown that $\mathcal{F}_n$ represents a tree t_n, such that applying r_n on t_n will yield t_{n+1} according to the formalism. The inductive assumption asserts that t_n is a consequent in the inference formalism and therefore t_{n+1} is a consequent as well, QED.

These two theorems guarantee that the compact inference process is valid - i.e., it yields a compact forest that represents the set of consequents derivable from a given text by a given rule set.

3.4 Complexity

In this section we explain why compact inference exponentially reduces the time and space complexity in typical scenarios.

We consider a set of rule matches in a tree T *independent* if their matched left-hand-sides (excluding dual-leaf variables) do not overlap in T, and their application over T can be chained in any order. For example, the three rule matches presented in Figure 3 are independent.

Let us consider explicit inference first. Assume we start with a single tree T with k independent rules matched. Applying k rules will yield 2^k trees, since any subset of the rules might be applied to T. Therefore, the time and space complexity of applying k independent rule matches is $\Omega(2^k)$. Applying more rules on the newly derived consequents behaves in a similar manner.

	Compact	Explicit	Ratio
Time (msec)	61	24,184	396
Rule applications	12	123	10
Node count	69	5,901	86
Edge endpoints	141	11,552	82

Table 1: Compact vs. explicit inference, using generic rules. Results are averaged per text-hypothesis pair.

Next, we examine compact inference. Applying a rule using compact inference adds the right-hand-side of the rule and shares with it existing d-edges. Since that the size of the right-hand-side and the number of outgoing d-edges per node are practically bounded by low constants, applying k rules on a tree T yields a linear increase in the size of the forest. Thus, the resulting size is $O(|T|+k)$, as we can see from Figure 3.

The time complexity of rule application is composed of matching the rule in the forest and applying the matched rule. Applying a matched rule is linear in its size. Matching a rule of size r in a forest $\mathcal{F}$ takes $O(|\mathcal{F}|^r)$ time even when performing an exhaustive search for matches in the forest. Since r tends to be quite small and can be bounded by a low constant, this already gives polynomial time complexity. In practice, indexing the forest nodes, as well as the typical low connectivity of the forest, result in a very fast matching procedure, as illustrated in the empirical evaluation, described next.

4 Empirical Evaluation

This section reports empirical evaluation of the efficiency of compact inference, tested in the recognizing textual entailment setting using the RTE-3 and RTE-4 datasets (Giampiccolo et al., 2007; Giampiccolo et al., 2009). These datasets consist of *(text, hypothesis)* pairs, which need to be classified as *entailing/non entailing*. Our first experiment shows, using a small rule set, that compact inference outperforms explicit inference by orders of magnitude (Section 4.1). The second experiment shows that compact inference scales well to a full-blown RTE setting with several large-scale rule bases, where up to hundreds of rules are applied for a text (Section 4.2).

4.1 Compact vs. Explicit Inference

To compare explicit and compact inference we randomly sampled 100 pairs from the RTE-3 development set, and parsed the *text* in each pair using Minipar (Lin, 1998). We used a set of manually-composed entailment rules for inference over generic linguistic phenomena such as passive, conjunction, relative clause, apposition, possessives, and determiners, which contains a few dozens of rules. To make a fair comparison, we aimed to make the explicit inference implementation reasonably efficient, e.g. by preventing generation of the same tree by different permutations of the same rule applications. Both configurations perform rule application iteratively, until no new matches are found. In each iteration we first find all rule matches and then apply all matching rules. We compare run time, number of rule applications, and the overall generated size of nodes and edges, where edge size is represented by the sum of its endpoints.

The results are summarized in Table 1. As expected, the results show that compact inference is by orders of magnitude more efficient than explicit inference. To avoid memory overflow, inference was terminated after reaching 100,000 nodes. 3 out of the 100 pairs reached that limit with explicit inference, while the maximal node count for compact inference was only 268. The number of rule applications is reduced thanks to the sharing of common subtrees in the compact forest, by which a single rule application operates simultaneously over a large number of embedded trees. The results suggest that scaling to larger rule bases and longer inference chains would be feasible for compact inference, but prohibitive for explicit inference.

4.2 Application to an RTE System

Experimental setting The goal of the second experiment was to assess that compact inference scales well for broad entailment rule bases. In this experiment we used the Bar-Ilan RTE system (Bar-Haim et al., 2009). The system operates in two primary stages: ***Inference***, in which entailment rules are applied to the initial compact forest $\mathcal{F}$, aiming to bring it closer to the hypothesis $\mathcal{H}$, and ***Classification***, in which a set of features is extracted from the resulting $\mathcal{F}$ and from $\mathcal{H}$ and fed into an SVM classifier, which determines entailment.

The classification setting and its features are quite typical for the RTE literature. They include lexical and structural measures for the coverage of $\mathcal{H}$ by $\mathcal{F}$, where high coverage is assumed to correlate with entailment, as well as features aiming to detect inconsistencies between $\mathcal{F}$ and $\mathcal{H}$ such as incompatible arguments for the same predicate or incompatible verb polarity (see below). For a complete feature description, see (Bar-Haim et al., 2009).

Rule Bases In addition to the *generic rules* described in Section 4.1, the following large-scale sources for entailment rules were used: ***Wikipeda:*** We used the lexical rulebase of Shnarch et al. (2009), who extracted rules such as *'Janis Joplin → singer'* from Wikipedia based on both its metadata (e.g. links and redirects) and text definitions, using patterns such as '*X is a Y*'. ***WordNet:*** We extracted from WordNet (Fellbaum, 1998) lexical rules based on synonyms, hypernyms and derivation relations. ***DIRT:*** The DIRT algorithm (Lin and Pantel, 2001) learns from a corpus entailment rules between binary predicates, e.g. *'X is fond of Y→X likes Y'*. We used the version described in (Szpektor and Dagan, 2007), which learns canonical rule forms. ***Argument-Mapped WordNet (AmWN):*** A resource for entailment rules between verbal and nominal predicates (Szpektor and Dagan, 2009), including their argument mapping, based on WordNet and NomLexplus (Meyers et al., 2004), verified statistically through intersection with the unary-DIRT algorithm (Szpektor and Dagan, 2008). In total, these rule bases represent millions of rules. ***Polarity Annotation Rules:*** We compiled a small set of annotation rules for marking the polarity of predicates as *negative* or *unknown* due to verbal negation, modal verbs, conditionals etc. (Bar-Haim et al., 2009).

Search In this work we focus on efficient representation of the search space, leaving for future work the complementary problem of devising effective search heuristics over our representation. In the current experiment we implemented a simple search strategy, in the spirit of (de Salvo Braz et al., 2005): first, we applied three exhaustive iterations of generic rules. Since these rules have low fan-out (few possible right-hand-sides for a given left-hand-side) it is affordable to apply and chain them more freely. We then perform a single iteration of all other lexical and lexical-syntactic rules,

applying them only if their L part was matched in $\mathcal{F}$ and their R part was matched in $\mathcal{H}$.

The system was trained over the RTE-3 development set, and tested on both RTE-3 test set and RTE-4 (which includes only a test set).

Results Table 2 provides statistics on rule application using all rule bases, over the RTE-3 development set and the RTE-4 dataset[6]. Overall, the primary result is that the compact forest indeed accommodates well extensive rule application from large-scale rule bases. The resulting forest size is kept small, even in the maximal cases which were causing memory overflow for explicit inference.

The accuracies obtained in this experiment and the overall contribution of rule-based inference are shown in Table 3. The results on RTE-3 are quite competitive: compared to our 66.4%, only 3 teams out of the 26 who participated in RTE-3 scored higher than 67%, and three more systems scored between 66% and 67%. The results for RTE4 rank 9-10 out of 26, with only 6 teams scoring higher by more than 1%. Overall, these results validate that the setting of our experiment represents a state-of-the-art system.

Inference over the rule bases utilized in our experiment improved the accuracy on both test sets. The contribution was more prominent for the RTE-4 dataset. These results illustrate a typical contribution of current knowledge sources for current RTE systems. This contribution is likely to increase with current and near future research, on topics such as extending and improving knowledge resources, applying them only in semantically suitable contexts, improved classification features and broader search strategies. As for our current experiment, we may conclude that the goal of assessing the compact forest scalability in a state-of-the-art setting was achieved [7].

Finally, Tables 4 and 5 illustrate the usage and contribution of individual rule bases. Table 4 shows the distribution of rule applications over the various rule bases. Table 5 presents ablation study showing the marginal accuracy gain for each rule base. These results show that each of the rule bases is applicable for a large portion of the pairs, and contributes to the overall accuracy.

[6]Running time is omitted since most of it was dedicated to rule fetching, which was rather slow for our available implementation of some resources. The elapsed time was a few seconds per (t, h) pair.

[7]We note that common RTE research issues, such as improving accuracy, fall out of the scope of the current paper.

	RTE3-Dev		RTE4	
	Avg.	Max.	Avg.	Max.
Rule applications	14	275	15	110
Node count	71	606	80	357
Edge endpoints	155	1,741	173	1,062

5 Related Work

This section discusses related work on applying knowledge-based transformations within RTE systems, as well as on using packed representations in other NLP tasks.

RTE Systems Previous RTE systems usually restricted both the type of allowed transformations and the search space. Systems based on lexical (word-based or phrase-based) matching of h in t typically applied only lexical rules (without vari-

ables), where both sides of the rule are matched directly in t and h (Haghighi et al., 2005; MacCartney et al., 2008). The inference formalism we use is more expressive, allowing also syntactic and lexical-syntactic transformations as well as rule chaining.

Hickl (2008) derived from a given (t, h) pair a small set of *discourse commitments*, which are quite similar to the kind of consequents we derive by our syntactic and lexical-syntactic rules. The commitments were generated by several different tools and techniques, compared to our generic unified inference process, and commitment generation efficiency was not discussed.

Braz et al. (2005) presented a semantic inference framework which "augments" the text representation with only the right-hand-side of an applied rule, and in this respect is similar to ours. However, in their work, both rule application and the semantics of the resulting "augmented" structure were not fully specified. In particular, the distinction between individual consequents was lost in the augmented graph. By contrast, our compact inference is fully formalized and is provably equivalent to an expressive, well-defined formalism operating over individual trees, and each inferred consequent can be recovered from the compact forest.

Packed representations Packed representations in various NLP tasks share common principles, which also underly our compact forest: factoring out common substructures and representing choice as local disjunctions. Applying this general scheme to individual problems typically requires specific representations and algorithms, depending on the type of alternatives that should be represented and the specified operations for creating them. In our work, alternatives are created by rule application, where a newly derived subtree is set as an alternative to existing subtrees. Alternatives are specified locally using d-edges.

Packed chart representations for parse forests were introduced in classical parsing algorithms such as CYK and Earley (Jurafsky and Martin, 2008), and have been extended in later work for various purposes (Maxwell III and Kaplan, 1991; Kay, 1996). Alternatives in the parse chart stem from syntactic ambiguities, and are specified locally as the possible decompositions of each phrase into its sub-phrases.

Packed representations have been utilized also in transfer-based machine translation. Emele and Dorna (1998) translated packed source language representation to packed target language representation while avoiding unnecessary unpacking during transfer. Unlike our rule application, in their work transfer rules *preserve* ambiguity stemming from source language, rather than *generating* new alternatives. Mi et al.(2008) applied statistical machine translation to a source language parse forest, rather than to the 1-best parse. Their transfer rules are tree-to-string, contrary to our tree-to-tree rules, and chaining is not attempted (rules are applied in a single top-down pass over the source forest), and thus their representation and algorithms are quite different from ours.

6 Conclusion

This work addresses the efficiency of entailment and paraphrase rule application. We presented a novel compact data structure and a rule application algorithm for it, which are provably a valid implementation of a generic inference formalism. We illustrated inference efficiency both analytically and empirically. Beyond entailment inference, we suggest that the compact forest would also be useful in generation tasks (e.g. paraphrasing). Our efficient representation of the consequent search space opens the way to future investigation of the benefit of larger-scale rule chaining, and to the development of efficient search strategies required to support such inferences.

Discriminative Substring Decoding for Transliteration

Colin Cherry and **Hisami Suzuki**

Abstract

We present a discriminative substring decoder for transliteration. This decoder extends recent approaches for discriminative character transduction by allowing for a list of known target-language words, an important resource for transliteration. Our approach improves upon Sherif and Kondrak's (2007b) state-of-the-art decoder, creating a 28.5% relative improvement in transliteration accuracy on a Japanese katakana-to-English task. We also conduct a controlled comparison of two feature paradigms for discriminative training: indicators and hybrid generative features. Surprisingly, the generative hybrid outperforms its purely discriminative counterpart, despite losing access to rich source-context features. Finally, we show that machine transliterations have a positive impact on machine translation quality, improving human judgments by 0.5 on a 4-point scale.

1 Introduction

Transliteration occurs when a word is borrowed into a language with a different character set. The word is transcribed into the new character set in such a way as to maintain rough phonetic correspondence; for example, the English word *hip-hop* becomes ヒップホップ [*hippuhoppu*], when transliterated into Japanese. A task frequently of interest to the NLP community is back-transliteration, where one seeks the original word, given the borrowed form.

We investigate machine transliteration as a method to handle out-of-vocabulary items in a Japanese-to-English translation system. More often than not, this will correspond to back-transliteration. Our goal is to prevent the copying or deletion of Japanese words when they are missing from our statistical machine translation (SMT) system's translation tables. This can have a substantial impact on the quality of SMT output, transforming translations of questionable usefulness, such as:

> Avoid using a フリーメール account.[1]

into the far more informative:

> Avoid using a Freemail account.

Though the techniques we present here are language-independent, we focus this study on the task of Japanese katakana-to-English back-transliteration. Katakana is one of the four character types used in the Japanese writing system (along with hiragana, kanji and Roman alphabet), consisting of about 50 syllabic characters. It is used primarily to spell foreign loanwords (e.g., チョコレート [*chokoreeto*] — *chocolate*), and names (e.g., クリントン [*kurinton*] — *Clinton*). Therefore, katakana is a strong indicator that a Japanese word can be back-transliterated. However, katakana can also be used to spell scientific names of animals and plants (e.g., カモ [*kamo*] — *duck*), onomatopoeic expressions (e.g., バシャバシャ [*bashabasha*] — *splash*) and foreign origin words that are not transliterations (e.g., ホチキス [*hochikisu*] — *stapler*). These untransliterable cases constitute about 10% of the katakana words in our data.

We employ a discriminative substring decoder for machine transliteration. Following Sherif and Kondrak (2007b), the decoder operates on short source substrings, with each operation producing one or more target characters, as shown in Figure 1. However, where previous approaches employ generative modeling, we use structured perceptron training to discriminatively tune parameters according to 0-1 transliteration accuracy. This

Singapore, 6-7 August 2009.

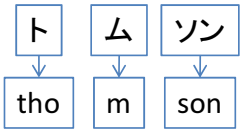

Figure 1: Example substring derivation

allows us to test novel methods for the use of target lexicons in discriminative character transduction, allowing our decoder to benefit from a list of known target words. Perhaps more significantly, our framework allows us to test two competing styles of features:

- sparse **indicators**, designed to capture the same channel and language modeling data collected by previous generative models, and
- components of existing generative models, used as real-valued features in a discriminatively weighted, **generative hybrid**.

Note that generative hybrids are the norm in SMT, where translation scores are provided by a discriminative combination of generative models (Och, 2003). Substring-based transliteration with a generative hybrid model is very similar to existing solutions for phrasal SMT (Koehn et al., 2003), operating on characters rather than words. Unlike out-of-the-box phrasal SMT solutions, our generative hybrid benefits from a target a lexicon. As we will show, this is the difference between a weak baseline and a strong competitor.

We demonstrate that despite recent successes in discriminative character transduction using indicator features (Jiampojamarn et al., 2008; Dreyer et al., 2008), our generative hybrid performs surprisingly well, producing our highest transliteration accuracies. Researchers frequently compare against a phrasal SMT baseline when evaluating a new transduction technique (Freitag and Khadivi, 2007; Dreyer et al., 2008); however, we are careful to vary only the features in our comparison. Confounding variables, such as alignment, decoder and training method, are held constant.

We also include a human evaluation of transliteration-augmented SMT output. Though human evaluations are too expensive to allow a comparison between transliteration systems, we are able to show that adding our transliterations to a production-level SMT engine results in a substantial improvement in translation quality.

2 Background

This work draws inspiration from previous work in transliteration, which we divide into similarity and transduction-based approaches. We also discuss recent successes in discriminative character transduction that have influenced this work.

2.1 Similarity-based transliteration

In similarity-based transliteration, a character-based, cross-lingual similarity metric is calculated (or bootstrapped) from known transliteration pairs. Given a source word s, its transliteration is the target word t most similar to s, where t is drawn from some pool of candidates. This approach may also be referred to as **transliteration discovery**.

Brill et al. (2001) describe a katakana-to-English approach with an EM-learned edit distance, which bootstraps from a small number of examples to learn transliteration pairs from query logs. Bilac and Tanaka (2005) harvest transliteration candidates from comparable bilingual corpora (conference abstracts in English and Japanese), and use distributional as well as phonetic similarity to choose among them. Sherif and Kondrak (2007a) also bootstrap a learned edit distance for Arabic named entities, with candidate pairs drawn from sentence or document-aligned parallel text. Klementiev and Roth (2006) bootstrap an SVM classifier trained to detect true transliteration-pairs. They draw candidates from comparable news text, using date information to provide further clues as to aligned named entities. Bergsma and Kondrak (2007) extend the classification approach with features derived from a character alignment. They train from bilingual dictionaries and word-aligned parallel text, selecting negative examples to target false-friends.

The work of Hermjakob et al. (2008) is particularly relevant to this paper, as they incorporate a similarity-based transliteration system into an Arabic-to-English SMT engine. They employ a hand-crafted cross-lingual similarity metric, and use capitalized n-grams from the Google n-gram corpus as candidates. With such a huge candidate list, a cross-lingual indexing scheme is designed for fast candidate look-up. Their work also addresses the question of when to transliterate (as opposed to translate), a realistic concern when deploying a transliteration component in SMT. This, however, is not of so much concern for katakana, as it is used primarily for loanwords.

2.2 Transduction-based transliteration

The approach presented in this paper is an instance of transduction-based transliteration, where the source word is transformed into a target word using a sequence of character-level operations. The parameters of the transduction process are learned from a collection of transliteration pairs. These systems do not require a list of candidates, but many incorporate a target lexicon, favoring target words that occur in the lexicon. This approach is also known as **transliteration generation**.

The majority of transliteration generation approaches are based on the noisy channel model, where a target t is generated according to $P(t|s) \propto P(s|t)P(t)$. This approach is typified by finite-state transliteration, where the various stages of the channel model are represented by finite state transducers and automata. Early systems employed a complex channel, passing through multiple phonetic representations (Knight and Graehl, 1998; Bilac and Tanaka, 2004), but later versions replaced characters directly (Al-Onaizan and Knight, 2002). Sherif and Kondrak (2007b) extend this approach with substring operations in the style of phrasal SMT, and show that doing so improves both accuracy as well as space and time efficiency. Note that it is possible to incorporate a target lexicon by making $P(t)$ a word unigram model with a character-based back-off.

Li et al. (2004) present an alternative to the noisy channel with their joint n-gram model, which calculates $P(s,t)$. This formulation allows operations to be conditioned on both source and target context. However, the inclusion of a candidate list is more difficult in this setting, as $P(t)$ is not given its own model.

Zelenko and Aone (2006) investigate a purely discriminative, alignment-free approach to transliteration generation. The target word is constructed one character at a time, with each new character triggering a suite of features, including indicators for near-by source and target characters, as well a generative target language model. Freitag and Khadivi (2007) propose a discriminative, latent edit distance for transliteration. In this case, training data need not be aligned in advance, but a latent alignment is produced during decoding. Again, the target word is constructed one character at a time, using edit operations that are scored according to source and target context features. Both approaches train using a structured perceptron, as we do here. However, these models represent a dramatic departure from the existing literature, while ours has clear analogs to the well-known noisy-channel paradigm, which allows for useful comparisons and insights into the advantages of discriminative training.

2.3 Discriminative character transduction

While our chosen application is transliteration, our decoder is influenced by recent successes in general-purpose discriminative transduction. Jiampojamarn et al. (2008) describe a discriminative letter-to-phoneme substring transducer, while Dreyer et al. (2008) describe a discriminative character transducer with a latent derivation structure for morphological transformations. Both models are extremely effective, but both rely exclusively on indicator features; they do not explore the use of knowledge-rich generative models. Our indicator system uses an extended version of the Jiampojamarn et al. (2008) feature set.

3 Methods

We adopt a discriminative substring decoder for our transliteration task. A structured perceptron (Collins, 2002) learns weights for our transliteration features, which are drawn from two broad classes: indicator and hybrid generative features.

3.1 Structured perceptron

The decoder's discriminative parameters are learned with structured perceptron training. Let a derivation d describe a substring operation sequence that transliterates a source word into a target word. Given an input training corpus of such derivations $D = d_1 \ldots d_n$, a vector feature function on derivations $\vec{F}(d)$, and an initial weight vector $\vec{w}$, the perceptron performs two steps for each training example $d_i \in D$:

- Decode: $\bar{d} = \text{argmax}_{d \in D(\text{src}(d_i))} \left(\vec{w} \cdot \vec{F}(d) \right)$
- Update: $\vec{w} = \vec{w} + \vec{F}(d_i) - \vec{F}(\bar{d})$

where $D(\text{src}(d))$ enumerates all possible derivations with the same source side as d. To improve generalization, the final feature vector is the average of all vectors found during learning (Collins, 2002). Accuracy on the development set is used to select the number of times we pass through all $d_i \in D$.

Given the above framework, we require training derivations D, feature vectors $\vec{F}$, and a decoder to

carry out the argmax over all d reachable from a particular source word. We describe each of these components in turn below.

3.2 Training derivations

Note that the above framework describes a max-derivation decoder trained on a corpus of gold-standard derivations, as opposed to a max-transliteration decoder trained directly on source-target pairs. By building the entire system on the derivation level, we side-step issues that can occur when perceptron training with hidden derivations (Liang et al., 2006), but we also introduce the need to transform our training source-target pairs into training derivations.

Training derivations can be learned unsupervised from source-target pairs using character alignment techniques. Previously, this has been done using an EM-learned edit distance (Ristad and Yianilos, 1998), or generalizations thereof (Brill and Moore, 2000; Jiampojamarn et al., 2007). We opt for an alternative alignment technique, similar to the word-aligner described by Zhang et al. (2008). This approach employs variational EM with sparse priors, along with hard length limits, to reduce the length of substrings operated upon. By doing so, we hope to learn only non-compositional transliteration units.

Our aligner produces only monotonic alignments, and does not allow either the source or target side of an operation to be empty. The same restrictions are imposed during decoding. In this way, each alignment found by variational EM is also an unambiguous derivation. We align our training corpus with a maximum substring length of three characters. The same derivations are used to train all of the transliteration systems tested in this paper.

3.3 Features

We employ two main types of features: indicators and hybrid generative models. Indicators detect binary events in a derivation, such as the presence of a particular operation. Hybrid generative features assign a real-valued probability to a derivation, based on statistics collected from training derivations. There are few generative features and each carries a substantial amount of information, while indicators are sparse and knowledge-poor.

We treat these two classes of features as distinct. We do so because researchers often use either one approach or the other.[2] Furthermore, it is not clear how to optimally employ training derivations when combining generative models and sparse indicators: generative models need large amounts of data to collect statistics and relatively little for perceptron training,[3] while sparse indicators require only a large perceptron training set.

We can further divide feature space according to the information required to calculate each feature. Both feature sets can be partitioned into the following subtypes:

- **Emission**: How accurate are the operations used by this derivation?
- **Transition**: Does the target string produced by this derivation look like a well-formed target character sequence?
- **Lexicon**: Does the target string contain known words from a target lexicon?

Indicator Features

Previous approaches to discriminative character transduction tend to employ only sparse indicators (Jiampojamarn et al., 2008; Dreyer et al., 2008). This is because sparsity is not a major concern in character-based domains, and sparse indicators are extremely flexible.

Our emission and transition indicator features follow Jiampojamarn et al. (2008). Emission indicators are centered around an operation, such as $[\vdash \rightarrow \textit{tho}]$. Minimally, an indicator exists for each operation. Many more **source context** features can be generated by conjoining an operation with source n-grams found within a fixed window of C characters to either side of the operation. These source context features have minimal computational cost, and they allow each operator to account for large, overlapping portions of the source, even when the substrings being operated upon are small. Meanwhile, transition indicators stand in for a character-based target language model. Indicators are built for each possible target n-gram, for $n = 1 \ldots K$, allowing the perceptron to construct a discriminative back-off model. Development experiments lead us to select $C = 3$ and $K = 5$.

[2] Generative hybrids are often accompanied by a small number of unsparse indicators, such as operation count.

[3] Perceptron training on the same data used for model construction can lead to overconfidence in model quality. One can address this problem by using a large number of modeling-training folds (Collins et al., 2005), but we do not do so here.

Indicator lexicon features are novel to this work. Given access to a target lexicon with type frequencies, we opt to create features that indicate the frequencies of generated target words according to coarse bins. Experiments on our development set lead to the selection of 5 frequency bins: [$<$ 2,000], [$<$ 200], [$<$ 20], [$<$ 2], [$<$ 1]. To keep the model linear, these features are cumulative; thus, generating a word with frequency 126 will result in both the $[< 2,000]$ and $[< 200]$ features firing. Note that a single transliteration can potentially generate multiple target words, and doing so can have a major impact on how often the lexicon features fire. Thus, we employ another feature that indicates the introduction of a new word. We expect these frequency indicators to be superior to a word-level unigram model, as they allow the designer to select notable frequencies. In particular, the bins we have selected do not give any advantage to extremely common words, as these are generally less likely to be transliterated.

Hybrid Generative Features

We begin with the three components of the generative noisy channel employed by Sherif and Kondrak (2007b). Their transliteration probability is:

$$P(t|s) \propto P_E(s|t) \cdot \max\left[P_T(t), P_L(t)\right] \quad (1)$$

Inspired by the linear models used in SMT (Och, 2003), we can discriminatively weight the components of this generative model, producing:

$$w_E \log P_E(s|t) + w_T \log P_T(t) + w_L \log P_L(t)$$

with weights w learned by perceptron training.

These three models conveniently align with our three feature subtypes. Emission information is provided by $P_E(s|t)$, which is estimated by maximum likelihood on the operations observed in our training derivations. Including source context is difficult in such a model. To compensate for this, all systems using $P_E(s|t)$ also use composed operations, which are constructed from operation sequences observed in the training set. This removes the length limit on substring operations.[4] $P_T(t)$ provides transition information through a character language model, estimated on the target side of the training derivations. In our implementation, we employ a KN-smoothed 7-gram model (Kneser and Ney, 1995). Finally, $P_L(t)$ is a unigram target word model, estimated from the same type frequencies used to build our lexicon indicators.

Since we have adopted a linear model, we are no longer constrained by the original generative story. Therefore, we are free to incorporate other SMT-inspired features: $P_{E'}(t|s)$, target character count, and operation count.[5]

Feature summary

The indicator and hybrid-generative feature sets each provide a discriminative version of the noisy channel model. In the case of transition and lexicon features, both systems have access to the exact same information, but encode that information differently. The lexicon encoding is the most dramatic difference, with the indicators using a small number of frequency bins, and the generative unigram model providing a single, real-valued feature that is proportional to frequency.

In the case of their emission features, the two systems actually encode different information. Both have access to the same training derivations, but the indicator system provides source context through n-gram indicators, while the generative system does so using composed operations.

3.4 Decoder

Our decoder builds upon machine translation's monotone phrasal decoding (Zens and Ney, 2004), or equivalently, the sequence tagging algorithm used in semi-Markov CRFs (Sarawagi and Cohen, 2004). This dynamic programming (DP) decoder extends the Viterbi algorithm for HMMs by operating on one or more source characters (a substring) at each step. A DP block stores the best scoring solution for a particular prefix. Each block is subdivided into cells, which maintain the context necessary to calculate target-side features. We employ a beam, keeping only the 40 highest-scoring cells for each block, which speeds up inference at the expense of optimality. We found that the beam had no major effect on perceptron training, nor on the system's final accuracy.

Previously, target lexicons have been used primarily in finite-state transliteration, as they are easily encoded as finite-state-acceptors (Al-Onaizan and Knight, 2002; Sherif and Kondrak,

[4] Derivations built by our character aligner use operations on substrings of maximum length 3. To enable perceptron training with composed operations, once $P_E(s|t)$ has been estimated by counting composed operations in the initial alignments, we re-align our training examples with those composed operations to maximize $P_E(s|t)$, creating new training derivations.

[5] Character and operation counts also fit in the indicator system, but did not improve performance in development.

2007b). It is possible to extend the DP decoder to also use a target lexicon. By encoding the lexicon as a trie, and adding the trie index to the context tracked by the DP cells, we can provide access to frequency estimates for words and word prefixes. This has the side-effect of creating a new cell for each target prefix; however, in the character domain, this remains computationally tractable.

4 Data

4.1 Wikipedia training and test data

Our katakana-to-English training data is derived from bilingually-linked Wikipedia titles. Any Japanese Wikipedia article with an entirely katakana title and a linked English article results in training pair. This results in 60K transliteration pairs; we removed 2K pairs for development, and 2K for held-out testing.

The remaining 56K training pairs are quite noisy. As mentioned earlier, roughly 10% of our examples are simply not transliterable, but approximate Wikipedia title translations are an even more substantial source of noise. For example, コンピュータゲーム [*konpyuutageemu*] — *computer game* is aligned with the English article *Computer and video games*. We found it beneficial, in terms of both speed and accuracy, to do some coarse alignment-based pruning. After alignment, the operations used by all derivations are counted. Any operation that is used fewer than three times is eliminated, along with any derivation using that operation. The goal is to eliminate loose transliteration pairs from our data, where a word or initial is included in one language but not the other. This results in 40K training pairs. Despite the noise in the Wikipedia data, there are clear advantages in using it for training transliteration models: it is available for any language pair, it reflects recent trends and events, and the amount of data increases daily. As we will see below, the model trained on this data performs well on a test set from a very different domain.

All systems use development set accuracy to select their meta-parameters, such as the number of perceptron iterations, the size of the source-context window, and the n-gram length used in character language modeling. The hybrid generative system further splits the training set, using 38K derivations for the calculation of its emission and transition models, and 2K derivations for perceptron training its model weights.

4.2 Machine translation test data

In order to see how effective our transliterator is on out-of-domain test data, we also created test data from a log of translation requests to a web-based, Japanese-to-English translation service.[6] Out of 5,000 randomly selected translation requests, there are 312 cases where katakana source words are out-of-vocabulary for the MT system, and therefore remain untranslated. We created a reference translation (not necessarily a transliteration) for these katakana words by manually selecting the corresponding English word(s) in the sentence-level reference translation, which was produced independently from this experiment. This test set is quite divergent from the Wikipedia titles: only 17 (5.5%) of its katakana words are found in the Wikipedia training data, and six of these did not agree on the English translation.

4.3 English lexicon

Our English lexicon is derived from two overlapping data sources: the English gigaword corpus (LDC2003T05; GW) and the language model training data for our SMT system, which contains selections from Europarl, gigaword, and web-harvested text. Both are lowercased. We combine the unigram frequency counts from the two sources by taking the max when they overlap. The resulting lexicon has 5M types, 2.5M of which have frequency 1.

5 Experiments

In this section, we summarize development experiments, and then conduct a comparison on our two transliteration test sets. We report 0-1 accuracy: a transliteration is only correct if it exactly matches the reference. For the comparison experiments, we also report 10-best accuracy, where a system is correct if it includes the correct transliteration somewhere in its 10-best list.

5.1 Baselines

We compare our systems against a re-implementation of Sherif and Kondrak's (2007b) noisy-channel substring decoder. This uses the same P_E, P_T and P_L models as our hybrid generative system, but employs a two-pass decoding scheme to find the max transliteration according to Equation 1. It represents a purely generative solution using otherwise identical architecture.

[6] http://www.microsofttranslator.com

Since our hybrid generative system implements a model that is very similar to those used in phrasal SMT, we also compare against a state-of-the-art phrasal SMT system (Moore and Quirk, 2007). This system is trained by applying the standard SMT pipeline to our Wikipedia title pairs, treating characters as words, using a 7-gram character-level language model, and disabling re-ordering. Unfortunately, the decoder's architecture does not allow the use of a word-level unigram model, reducing the usefulness of this baseline. Instead, we include the target lexicon as a second character-level language model. This baseline indicates the level of performance one can expect by applying phrasal SMT straight out of the box.

Comparing the two baselines qualitatively, both use a combination of generative models inspired by the noisy channel. Sherif and Kondrak employ a word-level unigram model without discriminatively weighting the models, while the Phrasal SMT approach uses weights derived from max-BLEU training without word-level unigrams. The obvious question of what happens when one does both will be answered by our hybrid generative system.

5.2 Development experiments

Table 1 shows development set accuracy for a number of systems and feature types, along with the model size of the corresponding systems, where size is measured in terms of the number of non-zero discriminatively-trained parameters. The accuracy of the Sherif and Kondrak baseline is shown as *SK07*. Despite its lack of discriminative training, word-level unigrams allow the *SK07* baseline to outperform *Phrasal SMT*. In future experiments, we compare only against *SK07*.

The indicator system was tested using only operation indicators, with source context, transition and lexicon indicators added incrementally. All feature types have a substantial impact, with the lexicon providing the boost needed to surpass the baseline. Note that the inclusion of the five frequency bins is sufficient to decrease the overall feature count of the system by 600K, as much fewer mistakes are made during training.

Development of the hybrid generative system used the *SK07* baseline as a starting point. The result of combining its three components into a flat linear model, with all weights set to 1, is shown in Table 1 as *Linear SK07*. This violation of conditional independence assumptions results in a drop in accuracy. However, the *+ perceptron* line shows that setting the three weights with perceptron training results in a huge boost in accuracy, nearly matching our indicator system. Adding features inspired by SMT, such as $P_{E'}(t|s)$, eliminates the gap between the two.

Table 1: Development accuracy and model size

System		Acc.	Size
Baseline	Phrasal SMT	30.7	8
	SK07	33.5	–
Indicator	Operations only	3.6	6.8K
	+ source context	23.9	2.8M
	+ transition	28.6	3.1M
	+ lexicon	**44.2**	2.5M
	+ gen. lexicon	44.1	3.0M
Generative	Linear SK07	31.7	–
	+ perceptron	42.4	3
	+ SMT features	44.1	6
	+ ind. lexicon	**44.3**	12

5.3 Development discussion

Considering their differences, the two systems' proximity in score is quite surprising. Given the character domain's lack of sparsity, and the large amount of available training data, we had expected the hybrid generative system to behave only as a strong baseline; instead, it matched the performance of the indicator system. However, this is not unprecedented: discriminatively weighted generative models have been shown to outperform purely discriminative competitors in various NLP classification tasks (Raina et al., 2004; Toutanova, 2006), and remain the standard approach in statistical translation modeling (Och, 2003).

Examining the development results on an example-by-example basis, we see that the two systems make mostly the same mistakes: for 87% of examples, either both systems are right, or both are wrong. The remainder represents a (relatively small) opportunity to improve through system or feature combination: an oracle that perfectly selects between the two scores 50.6.

One opportunity for straight-forward combination is the target lexicon. Because lexicon frequencies are drawn from an independent word list, and not the transliteration training derivations, there is no reason why both systems cannot use both lexicon representations. Unfortunately, doing so has

Table 2: Test set comparisons

	Wikipedia		MT	
System	Acc.	Top 10	Acc.	Top 10
SK07	33.5	57.9	38.8	57.0
Generative	**43.0**	**65.6**	42.9	**58.3**
Indicator	42.5	63.5	**43.6**	57.7

little impact, as is shown in each system's final row in Table 1. Adding the word unigram model to the indicator system results in slightly lower performance, and a much larger model. Adding the frequency bins to the generative system does improve performance slightly, but attempts to completely replace the generative system's word unigram model with frequency bins resulted in a substantial drop in accuracy.[7]

5.4 Test set comparisons

Table 2 shows the accuracies of the systems selected during development on our testing data. On the held-out Wikipedia examples, the trends observed during development remain the same, with the generative system expanding its lead. Moving to 10-best accuracies changes little, except for slightly narrowing the gap between SK07 and the discriminative systems.

The second column of Table 2 compares the systems on our MT test set. As discussed earlier, this data is quite different from the Wikipedia training set, and as a result, the systems' differences are less pronounced. 1-best accuracy still shows the discriminative systems having a definite advantage, but at the 10-best level, those distinctions are muted.

Compared with the previous work on katakana-to-English transliteration, these accuracies do not look particularly high: both Knight and Graehl (1998) and Bilac and Tanaka (2004) report accuracies above 60% for 1-best transliteration. We should emphasize that this is due to the difficulty of our test data, and that we have tested against a baseline that has been shown to outperform Knight and Graehl (1998). The test data was not filtered for noise, leaving untransliterable cases and loose translations intact. The accuracies reported above are under-estimates of real performance: many transliterations not matching the reference may still be useful to a human reader, such as differences in inflection (e.g., レチノイド [*rechinoido*] — *retinoids*, transliterated as *retinoid*), and spacing (e.g. シエラレオネ [*shierareone*]— *Sierra Leone*, transliterated as *sierraleone*).

[7] Lexicon replacement experiment is not shown in Table 1.

6 Integration with machine translation

We used the transliterations from our indicator system to augment a Japanese-to-English MT system.[8] This treelet-based SMT system (Quirk et al., 2005) is trained on about 4.6M parallel sentence pairs from diverse sources including bilingual books, dictionaries and web publications. Our goal is to measure the impact of machine transliterations on end-to-end translation quality.

6.1 Evaluation method

We use the MT-log translation pairs described in Section 4.2 as a sentence-level translation test set. For each katakana word left untranslated by the baseline SMT engine, we generated 10-best transliteration candidates and added the katakana-English pairs to the SMT system's translation table. Perceptron scores were exponentiated, then normalized, to create probabilities, which were given to the SMT system as $P(source|target)$;[9] all other translation features were set to $\log 1$.

We translated the test set with and without the augmented translation table. 120 sentences were randomly selected from the cases where the translations output by the two SMT systems differed, and were submitted for two types of human evaluation. In the **absolute evaluation**, each SMT output was assigned a score between 1 and 4 (1 = completely useless; 4 = perfect translation); in the **relative evaluation**, the evaluators were presented with a pair of SMT outputs, with and without the transliteration table, and were asked to judge if they preferred one translation over the other. In both evaluation settings, the machine-translated sentences were evaluated by two native speakers of English who have no knowledge of Japanese, with access to a reference translation.

6.2 Results

The evaluation results show that our transliterator does improve the quality of SMT. The BLEU

[8] The human evaluation was carried out before we discovered the effectiveness of the hybrid generative system, but recall that the performance of the two is similar.

[9] The perceptron scores are more naturally interpreted as $P(target|source)$, but the opposite direction is generally the highest-weighted feature in the SMT system's linear model.

Table 3: Relative translation evaluation

	evaluator 1 preference			
eval2pref	+translit	equal	baseline	sum
+translit	**95**	0	2	97
equal	19	**1**	2	22
baseline	1	0	**0**	1
sum	115	1	4	120

score on the entire test set improved only slightly, from 21.8 to 22.0. However, in the absolute human evaluation, the transliteration table increased the average human judgement from 1.5 to 2 out of a maximum score of 4. Table 3 shows the results of the relative evaluation along with the judges' sentence-level agreement. In 95 out of 120 cases, both annotators agreed that the augmented table produced a better translation than the baseline.

One might expect that any replacement of katakana would improve the perception of MT quality. This is not necessarily the case: it can be more confusing to have a drastically incorrect transliteration, such as transliterating アップローダ [*appurooda*] — *uploader* incorrectly as *applaud*. Fortunately, Table 3 shows that we make very few of these sorts of mistakes: the baseline is preferred only rarely. Also note that, according the MT 10-best accuracies in Table 2, we would have expected to improve at most 60% of cases, however, the human judgements indicate that our actual rate of improvement is closer to 80%, which demonstrates that even an imperfect transliteration is often useful.

7 Conclusion

We have presented a discriminative substring decoder for transliteration. Our decoder is based on recent approaches for discriminative character transduction, extended to provide access to a target lexicon. We have presented a comparison of indicator and hybrid generative features in a controlled setting, demonstrating that generative models perform surprisingly well when discriminatively weighted. We have also shown our discriminative models to be superior to a state-of-the-art generative system. Finally, we have demonstrated that machine transliteration is immediately useful to end-to-end SMT.

As mentioned earlier, by focusing on katakana, we bypass the problem of deciding when to transliterate rather than translate; next, we plan to combine our models with a classifier that makes such a decision, allowing us to integrate transliteration into SMT for other language pairs.

Abstract

The design of practical language applications by means of statistical approaches requires annotated data, which is one of the most critical constraint. This is particularly true for Spoken Dialog Systems since considerably domain-specific conceptual annotation is needed to obtain accurate Language Understanding models. Since data annotation is usually costly, methods to reduce the amount of data are needed. In this paper, we show that better feature representations serve the above purpose and that structure kernels provide the needed improved representation. Given the relatively high computational cost of kernel methods, we apply them to just re-rank the list of hypotheses provided by a fast generative model. Experiments with Support Vector Machines and different kernels on two different dialog corpora show that our re-ranking models can achieve better results than state-of-the-art approaches when small data is available.

1 Introduction

Spoken Dialog Systems carry out automatic speech recognition and shallow natural language understanding by heavily relying on statistical models. These in turn need annotated data describing the application domain. Such annotation is far the most expensive part of the system design. Therefore, methods reducing the amount of labeled data can speed up and lower the overall amount of work.

Among others, Spoken Language Understanding (SLU) is an important component of the systems above, which requires training data to translate a spoken sentence into its meaning representation based on semantic constituents. These are conceptual units instantiated by sequences of words.

In the last decade two major approaches have been proposed to automatically map words in concepts: (i) generative models, whose parameters refer to the joint probability of concepts and constituents; and (ii) discriminative models, which learn a classification function based on conditional probabilities of concepts given words.

A simple but effective generative model is the one based on Finite State Transducers. It performs SLU as a translation process from words to concepts using Finite State Transducers (FST). An example of discriminative model used for SLU is the one based on Support Vector Machines (SVMs) (Vapnik, 1995), as shown in (Raymond and Riccardi, 2007). In this approach, data is mapped into a vector space and SLU is performed as a classification problem using Maximal Margin Classifiers (Vapnik, 1995). A relatively more recent approach for SLU is based on Conditional Random Fields (CRF) (Lafferty et al., 2001). CRFs are undirected graphical and discriminative models. They use conditional probabilities to account for many feature dependencies without the need of explicitly representing such dependencies.

Generative models have the advantage to be more robust to overfitting on training data, while discriminative models are more robust to irrelevant features. Both approaches, used separately, have shown good accuracy (Raymond and Riccardi, 2007), but they have very different characteristics and the way they encode prior knowledge is very different, thus designing models that take into account characteristics of both approaches are particularly promising.

In this paper, we propose a method for SLU based on generative and discriminative models: the former uses FSTs to generate a list of SLU hypotheses, which are re-ranked by SVMs. To effectively design our re-ranker, we use all pos-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1076–1085,
Singapore, 6-7 August 2009.

sible word/concept subsequences with gaps of the spoken sentence as features (*i.e.* all possible n-grams). Gaps allow for encoding long distance dependencies between words in relatively small sequences. Since the space of such features is huge, we adopted kernel methods, i.e. sequence kernels (Shawe-Taylor and Cristianini, 2004) and tree kernels (Collins and Duffy, 2002; Moschitti, 2006a) to implicitly encode them along with other structural information in SVMs.

We experimented with different approaches for training the discriminative models and two different corpora: the french MEDIA corpus (Bonneau-Maynard et al., 2005) and a corpus made available by the European project LUNA[1] (Dinarelli et al., 2009b). In particular, the new contents with respect to our previous work (Dinarelli et al., 2009a) are:

- We designed a new sequential structure (SK2) and two new hierarchical tree structures (MULTILEVEL and FEATURES) for re-ranking models (see Section 4.2). The latter combined with two different tree kernels originate four new different models.
- We experimented with automatic speech transcriptions thus assessing the robustness to noise of our models.
- We compare our models against Conditional Random Field (CRF) approaches described in (Hahn et al., 2008), which are the current state-of-the-art in SLU. Learning curves clearly show that our models improve CRF, especially when small data sets are used.

The remainder of the paper is organized as follows: Section 2 introduces kernel methods for structured data, Section 3 describes the generative model producing the initial hypotheses whereas Section 4 presents the discriminative models for re-ranking them. The experiments and results are reported in Section 5 and the conclusions are drawn in Section 6.

2 Feature Engineering via Structure Kernels

Kernel methods are viable approaches to engineer features for text processing, *e.g.* (Collins and Duffy, 2002; Kudo and Matsumoto, 2003; Cumby and Roth, 2003; Cancedda et al., 2003; Culotta and Sorensen, 2004; Toutanova et al., 2004; Kudo et al., 2005; Moschitti, 2006a; Moschitti et al., 2007; Moschitti, 2008; Moschitti et al., 2008; Moschitti and Quarteroni, 2008). In the following, we describe structure kernels, which will be used to engineer features for our discriminative reranker.

2.1 String Kernels

The String Kernels that we consider count the number of substrings containing gaps shared by two sequences, *i.e.* some of the symbols of the original string are skipped. We adopted the efficient algorithm described in (Shawe-Taylor and Cristianini, 2004; Lodhi et al., 2000). More specifically, we used words and markers as symbols in a style similar to (Cancedda et al., 2003; Moschitti, 2008). For example, given the sentence: *How may I help you ?* sample substrings, extracted by the Sequence Kernel (SK), are: *How help you ?*, *How help ?*, *help you*, *may help you*, etc.

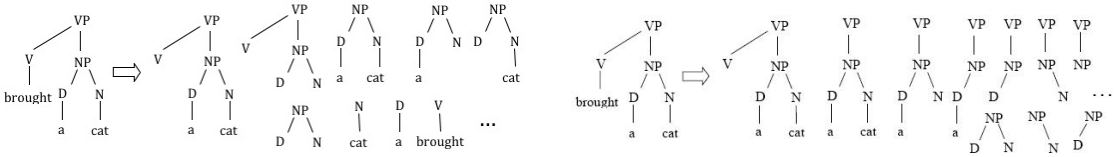
2.2 Tree kernels

Tree kernels represent trees in terms of their substructures (fragments). The kernel function detects if a tree subpart (common to both trees) belongs to the feature space that we intend to generate. For such purpose, the desired fragments need to be described. We consider two important characterizations: the syntactic tree (STF) and the partial tree (PTF) fragments.

2.2.1 Tree Fragment Types

An STF is a general subtree whose leaves can be non-terminal symbols (also called SubSet Tree (SST) in (Moschitti, 2006a)). For example, Figure 1(a) shows 10 STFs (out of 17) of the subtree rooted in `VP` (of the left tree). The STFs satisfy the constraint that grammatical rules cannot be broken. For example, `[VP [V NP]]` is an STF, which has two non-terminal symbols, `V` and `NP`, as leaves whereas `[VP [V]]` is not an STF. If we relax the constraint over the STFs, we obtain more general substructures called *partial trees fragments* (PTFs). These can be generated by the application of partial production rules of the grammar, consequently `[VP [V]]` and `[VP [NP]]` are valid PTFs. Figure 1(b) shows that the number of PTFs derived from the same tree as before is still higher (*i.e.* 30 PTs).

[1] Contract n. 33549



(a) Syntactic Tree fragments (STF)

(b) Partial Tree fragments (PTF)

Figure 1: Examples of different classes of tree fragments.

2.3 Counting Shared Subtrees

The main idea of tree kernels is to compute the number of common substructures between two trees T_1 and T_2 without explicitly considering the whole fragment space. To evaluate the above kernels between two T_1 and T_2, we need to define a set $\mathcal{F} = \{f_1, f_2, \ldots, f_{|\mathcal{F}|}\}$, *i.e.* a tree fragment space and an indicator function $I_i(n)$, equal to 1 if the target f_i is rooted at node n and equal to 0 otherwise. A tree-kernel function over T_1 and T_2 is $TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)$, where N_{T_1} and N_{T_2} are the sets of the T_1's and T_2's nodes, respectively and $\Delta(n_1, n_2) = \sum_{i=1}^{|\mathcal{F}|} I_i(n_1) I_i(n_2)$. The latter is equal to the number of common fragments rooted in the n_1 and n_2 nodes.

The algorithm for the efficient evaluation of Δ for the syntactic tree kernel (STK) has been widely discussed in (Collins and Duffy, 2002) whereas its fast evaluation is proposed in (Moschitti, 2006b), so we only describe the equations of the partial tree kernel (PTK).

2.4 The Partial Tree Kernel (PTK)

PTFs have been defined in (Moschitti, 2006a). Their computation is carried out by the following Δ function:

1. if the node labels of n_1 and n_2 are different then $\Delta(n_1, n_2) = 0$;
2. else $\Delta(n_1, n_2) =$
$1 + \sum_{\vec{I}_1, \vec{I}_2, l(\vec{I}_1) = l(\vec{I}_2)} \prod_{j=1}^{l(\vec{I}_1)} \Delta(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j}))$

where $\vec{I}_1 = \langle h_1, h_2, h_3, .. \rangle$ and $\vec{I}_2 = \langle k_1, k_2, k_3, .. \rangle$ are index sequences associated with the ordered child sequences c_{n_1} of n_1 and c_{n_2} of n_2, respectively, $\vec{I}_{1j}$ and $\vec{I}_{2j}$ point to the j-th child in the corresponding sequence, and, again, $l(\cdot)$ returns the sequence length, *i.e.* the number of children.

Furthermore, we add two decay factors: μ for the depth of the tree and λ for the length of the child subsequences with respect to the original sequence, *i.e.* we account for gaps. It follows that $\Delta(n_1, n_2) =$

$$\mu\Big(\lambda^2 + \sum_{\vec{I}_1, \vec{I}_2, l(\vec{I}_1) = l(\vec{I}_2)} \lambda^{d(\vec{I}_1) + d(\vec{I}_2)} \prod_{j=1}^{l(\vec{I}_1)} \Delta(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j}))\Big), \quad (1)$$

where $d(\vec{I}_1) = \vec{I}_{1l(\vec{I}_1)} - \vec{I}_{11}$ and $d(\vec{I}_2) = \vec{I}_{2l(\vec{I}_2)} - \vec{I}_{21}$. This way, we penalize both larger trees and child subsequences with gaps. Eq. 1 is more general than the Δ equation for STK. Indeed, if we only consider the contribution of the longest child sequence from node pairs that have the same children, we implement STK.

3 Generative Model: Stochastic Conceptual Language Model (SCLM)

The first step of our approach is to produce a list of SLU hypotheses using a Stochastic Conceptual Language Model. This is the same described in (Raymond and Riccardi, 2007) with the only difference that we train the language model using the SRILM toolkit (Stolcke, 2002) and we then convert it into a Stochastic Finite State Transducer (SFST). Such method allows us to use a wide group of language models, backed-off or interpolated with many kind of smoothing techniques (Chen and Goodman, 1998).

To exemplify our SCLM let us consider the following input italian sentence taken from the LUNA corpus along with its English translation:

Ho un problema col monitor.
(I have a problem with my screen).

A possible semantic annotation is:

null{*ho*} ***PROBLEM***{*un problema*} ***HARDWARE***{*col monitor*},

where ***PROBLEM*** and ***HARDWARE*** are two domain concepts and ***null*** is the label used for words not meaningful for the task. To associate word sequences with concepts, we use *begin*

(*B*) and *inside* (*I*) markers after each word of a sequence, *e.g.*:

null$\{ho\}$ ***PROBLEM-B***$\{un\}$ ***PROBLEM-I***$\{problema\}$ ***HARDWARE-B***$\{col\}$ ***HARDWARE-I***$\{monitor\}$

This annotation is automatically performed by a model based on a combination of three transducers:

$$\lambda_{SLU} = \lambda_W \circ \lambda_{W2C} \circ \lambda_{SLM},$$

where λ_W is the transducer representation of the input sentence, λ_{W2C} is the transducer mapping words to concepts and λ_{SLM} is the Stochastic Conceptual Language Model trained with SRILM toolkit and converted in FST. The SCLM represents joint probability of word and concept sequences by using the joint probability:

$$P(W, C) = \prod_{i=1}^{k} P(w_i, c_i | h_i),$$

where $W = w_1..w_k$, $C = c_1..c_k$ and $h_i = w_{i-1}c_{i-1}..w_1c_1$.

4 Discriminative re-ranking

Our discriminative re-ranking is based on SVMs trained with pairs of conceptually annotated sentences produced by the FST-based generative model described in the previous section. An SVM learn to classify which annotation has an error rate lower than the others so that it can be used to sort the *m*-best annotations based on their correctness. While for SVMs details we remaind to the wide literature available, for example (Vapnik, 1995) or (Shawe-Taylor and Cristianini, 2004), in this section we focus on hypotheses generation and on the kernels used to implement our re-ranking model.

4.1 Generation of m-best concept labeling

Using the FST-based model described in Section 3, we can generate the list of *m* best hypotheses ranked by the joint probability of the Stochastic Conceptual Language Model (SCLM). The Re-ranking model proposed in this paper re-ranks such list.

After an analysis of the *m*-best hypothesis list, we noticed that many times the first hypothesis ranked by SCLM is not the most accurate, *i.e.* the error rate evaluated with its Levenshtein distance from the manual annotation is not the lowest among the *m* hypotheses. This means that re-ranking hypotheses could improve the SLU accuracy. Intuitively, to achieve satisfactory results, different features from those used by SCLM should be considered to exploit in a different way the information encoded in the training data.

4.2 Structural features for re-ranking

The kernels described in previous sections provide a powerful technology for exploiting features of structured data. These kernels were originally designed for data annotated with syntactic parse trees. In Spoken Language Understanding the data available are text sentences with their semantic annotation based on basic semantic constituents. This kind of data has a rather flat structure with respect to syntactic parse trees. Thus, to exploit the power of kernels, a careful design of the structures used to represent data must be carried out, where the goal is to build tree-like annotation from the semantic annotation. For this purpose, we note that the latter is made upon sentence chunks, which implicitly define syntactic structures as long as the annotation is consistent in the corpus.

We took into account the characteristics of the presented kernels and the structure of semantic annotated data. As a result we designed the tree structures shown in figures 2(a), 2(b) and 3 for STK and PTK and sequential structures for SK defined in the following (where all the structures refer to the same example presented in Section 3, *i.e. Ho un problema col monitor*). The structures used with SK are:

($SK1$) ***NULL*** *ho* ***PROBLEM-B*** *un* ***PROBLEM-I*** *problema* ***HARDWARE-B*** *col* ***HARDWARE-I*** *monitor*

($SK2$) ***NULL*** *ho* ***PROBLEM B*** *un* ***PROBLEM I*** *problema* ***HARDWARE B*** *col* ***HARDWARE I*** *monitor*,

For simplicity, from now on, the two structures will be referred as *SK1* and *SK2* (String Kernel 1 and 2). They differer in the use of chunk markers *B* and *I*. In *SK1*, markers are part of the concept, thus they increase the number of semantic tags in the data whereas in *SK2* markers are put apart as separated words so that they can mark effectively the beginning and the end of a concept, but for the same reason they can add noise in the sentence. Notice that the order of words and concepts is meaningful since each word is preceded by its corresponding concepts.

The structures shown in Figure 2(a), 2(b) and 3

have been designed for STK and PTK. They provide trees with increasing structure complexity as described in the following.

The first structure (FLAT) is a simple tree providing direct dependency between words and chunked concepts. From it, STK and PTK can extract relevant features (tree fragments).

The second structure (MULTILEVEL) has one more level of nodes and yields the same separation of concepts and markers shown in *SK1*. Notice that the same separation can be carried out putting the markers *B* and *I* as features at the same level of the words. This would increase exponentially (in the number of leaves) the number of subtrees taken into account by the STK computation. Since STK doesn't separate children, as described in Section 2.3, the structure we chose is lighter but also more rigid.

The third structure (FEATURES) is a more complex structure. It allows to use a wide number of features (like Word categories, POS tags, morpho-syntactic features), which are commonly used in this kind of task. As described above, the use of features exponentially increases the number of subtrees taken into account by kernel computations but they also increase the robustness of the model. In this work we only used Word Categories as features. They are domain independent, e.g. *"Months"*, *"Dates"*, *"Number"* etc. or POS tags, which are useful to generalize target words. Note also that the features in common between two trees must appear in the same child-position, hence we sort them based on their indices, *e.g.'F0'* for words and *'F1'* for word categories.

4.3 Re-ranking models using sequences

The FST generates the *m* most likely concept annotations. These are used to build annotation pairs, $\langle s^i, s^j \rangle$, which are positive instances if s^i has a lower concept annotation error than s^j, with respect to the manual annotation. Thus, a trained binary classifier can decide if s^i is more accurate than s^j. Each candidate annotation s^i is described by a word sequence with its concept annotation. Considering the example in the previous section, a pair of annotations $\langle s^i, s^j \rangle$ could be

s^i: ***NULL*** *ho* ***PROBLEM-B*** *un* ***PROBLEM-I*** *problema* ***HARDWARE-B*** *col* ***HARDWARE-I*** *monitor*

s^j: ***NULL*** *ho* ***ACTION-B*** *un* ***ACTION-I*** *problema* ***HARDWARE-B*** *col* ***HARDWARE-B*** *monitor*

where **NULL**, **ACTION** and **HARDWARE** are the assigned concepts. The second annotation is less accurate than the first since *problema* is erroneously annotated as ***ACTION*** and *"col monitor"* is split in two different concepts.

Given the above data, the sequence kernel is used to evaluate the number of common *n*-grams between s^i and s^j. Since the string kernel skips some elements of the target sequences, the counted *n*-grams include: concept sequences, word sequences and any subsequence of words and concepts at any distance in the sentence.

Such counts are used in our re-ranking function as follows: let e_k be the pair $\langle s_k^1, s_k^2 \rangle$ we evaluate the kernel:

$$\begin{aligned} K_R(e_1, e_2) &= SK(s_1^1, s_2^1) + SK(s_1^2, s_2^2) \\ &- SK(s_1^1, s_2^2) - SK(s_1^2, s_2^1) \end{aligned} \quad (2)$$

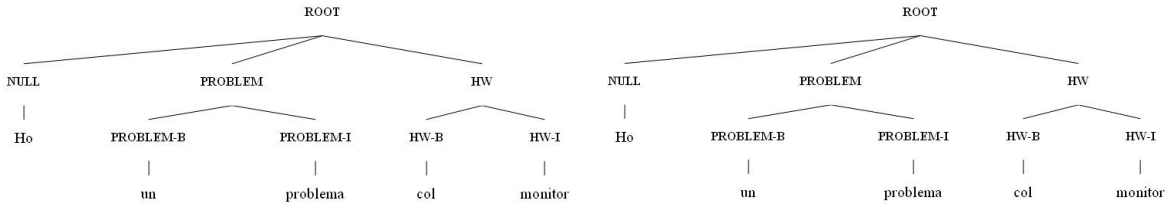
This schema, consisting in summing four different kernels, has been already applied in (Collins and Duffy, 2002; Shen et al., 2003) for syntactic parsing re-ranking, where the basic kernel was a tree kernel instead of SK. It was also used also in (Shen et al., 2004) to re-rank different candidates of the same hypothesis for machine translation. Notice that our goal is different from the one tackled in such paper and, in general, it is more difficult: we try to learn which is the best annotation of a given input sentence, while in (Shen et al., 2004), they learn to distinguish between *"good"* and *"bad"* translations of a sentence. Even if our goal is more difficult, our approach is very effective, as shown in (Dinarelli et al., 2009a). It is more appropriate since in parse re-ranking there is only one best hypothesis, while in machine translation a sentence can have more than one correct translations.

Additionally, in (Moschitti et al., 2006; Moschitti et al., 2008) a tree kernel was applied to semantic trees similar to the one introduced in the next section to re-rank Semantic Role Labeling annotations.

4.4 Re-ranking models using trees

Since the aim of concept annotation re-ranking is to exploit innovative and effective source of information, we can use, in addition to sequence kernels, the power of tree kernels to generate correlation between concepts and word structures.

Figures 2(a), 2(b) and 3 describe the structural association between the concept and the word



(a) *FLAT* Tree (b) *MULTILEVEL* Tree

level. This kind of trees allows us to engineer new kernels and consequently new features (Moschitti et al., 2008), *e.g.* their subparts extracted by STK or PTK, like the tree fragments in figures 1(a) and 1(b). These can be used in SVMs to learn the classification of words in concepts.

More specifically, in our approach, we use tree fragments to establish the order of correctness between two alternative annotations. Therefore, given two trees associated with two annotations, a re-ranker based on tree kernel can be built in the same way of the sequence-based kernel by substituting SK in Eq. 2 with STK or PTK. The major advantage of using trees is the hierarchical dependencies between its nodes, allowing for the use of richer n-grams with back-off models.

5 Experiments

In this section, we describe the corpora, parameters, models and results of our experiments on re-ranking for SLU. Our baseline is constituted by the error rate of systems solely based on either FST or SVMs. The re-ranking models are built on the FST output, which in turn is applied to both manual or automatic transcriptions.

5.1 Corpora

We used two different speech corpora:

The LUNA corpus, produced in the homonymous European project, is the first Italian dataset of spontaneous speech on spoken dialogs. It is based on help-desk conversations in a domain of software/hardware repairing (Dinarelli et al., 2009b). The data is organized in transcriptions and annotations of speech based on a new multi-level protocol. Although data acquisition is still in progress, 250 dialogs have been already acquired with a WOZ approach and other 180 Human-Human (HH) dialogs have been annotated. In this work, we only use WOZ dialogs, whose statistics are reported in Table 1.

The corpus MEDIA was collected within the French project MEDIA-EVALDA (Bonneau-Maynard et al., 2005) for development and evaluation of spoken understanding models and linguistic studies. The corpus is composed of 1257 dialogs (from 250 different speakers) acquired with a Wizard of Oz (WOZ) approach in the context of hotel room reservations and tourist information.

Statistics on transcribed and conceptually annotated data are reported in Table 2.

5.2 Experimental setup

Given the small size of LUNA corpus, we did not carried out any parameterization thus we used default or a priori parameters. We experimented with LUNA and three different re-rankers obtained with the combination of SVMs with STK, PTK and SK, described in Section 4. The initial annotation to be re-ranked is the list of the ten best hypotheses output by an FST model.

We point out that, on the large Media dataset the processing time is considerably high[2] so we could not run all the models.

We trained all the SCLMs used in our experiments with the SRILM toolkit (Stolcke, 2002) and we used an interpolated model for probability estimation with the Kneser-Ney discount (Chen and Goodman, 1998). We then converted the model in an FST again with SRILM toolkit.

The model used to obtain the SVM baseline for concept classification was trained using YamCHA (Kudo and Matsumoto, 2001). As re-ranking models based on structure kernels and SVMs, we used the SVM-Light-TK toolkit (available at disi.unitn.it/moschitti). For λ (see Section 3), cost-factor and trade-off parameters, we used, 0.4, 1 and 1, respectively (*i.e.* the default parameters). The number m of hypotheses was always set to 10.

The CRF model we compare with was trained with the CRF++ tool, available at http://crfpp.sourceforge.net/. The model is equivalent to the one described in (Hahn et al., 2008). As features, we used word and morpho-syntactic categories in a window of [-2, +2] with respect to the current token, plus bigrams of concept tags (see (Hahn et al., 2008) and the CRF++ web site for more details).

Such model is very effective for SLU. In (Hahn et al., 2008), it is compared with other four models (Stochastic Finite State Transducers, Support Vector Machines, Machine Translation, Positional-Based Log-linear model) and it is by far the best on MEDIA. Additionally, in (Raymond and Riccardi, 2007), a similar CRF model was compared with FST and SVMs on ATIS and on a different version of MEDIA, showing again to be very effective.

[2]The number of parameters of the models and the number of training approaches make the exhaustive experimentation very expensive in terms of processing time, which would be roughly between 2 and 3 months of a typical workstation.

Structure	STK	PTK	SK

Table 3: CER of SVMs using STK, PTK and SK on LUNA (manual transcriptions). The Baselines, FST and SVMs alone, show a CER of **23.2%** and **26.3%**, respectively.

Model	MEDIA (CER)	LUNA (CER)
FST	13.7%	23.2%
CRF	11.5%	20.4%
SVM-RR (PTK)	12.1%	18.4%

Table 4: Results of SLU experiments on MEDIA and LUNA test set (manual transcriptions).

We ran SLU experiments on manual and automatic transcriptions. The latter are produced by a speech recognizer with a WER of 41.0% and 31.4% on the LUNA and the MEDIA test sets, respectively.

5.3 Training approaches

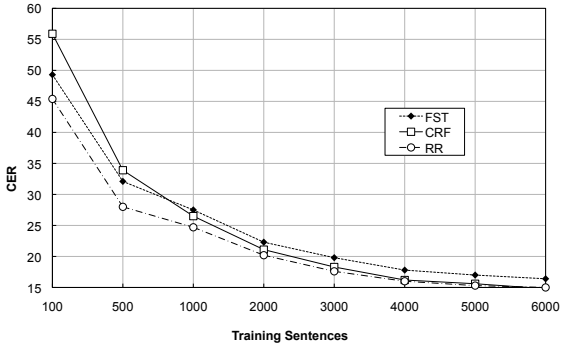
The FST model generates the *10*-best annotations, *i.e.* the data used to train the re-ranker based on SVMs. Different training approaches can be carried out based on the use of the data. We divided the training set in two parts. We train FSTs on part 1 and generate the *10*-best hypotheses using part 2, thus providing the first chunk of re-ranking data. Then, we re-apply these steps inverting part 1 with part 2 to provide the second data chunk. Finally, we train the re-ranker on the merged data.

For classification, we generate the *10*-best hypotheses of the whole test set using the FST trained on all training data.

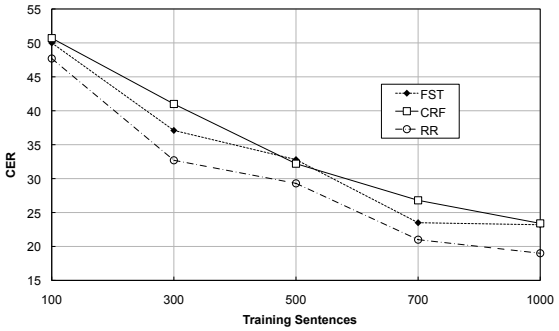
5.4 Re-ranking results

In Tables 3, 4 and 5 and Figures 4(a) and 4(b) we report the results of our experiments, expressed in terms of concept error rate (CER). CER is a standard measure based on the Levensthein alignment of sentences and it is computed as the ratio between inserted, deleted and confused concepts and the number of concepts in the reference sentence.

Table 3 shows the results on the LUNA corpus using the different training approaches, kernels and structures described in this paper. The



(a) Learning Curve on MEDIA corpus using the RR model based on SVMs and STK



(b) Learning Curve on LUNA corpus using the RR model based on SVMs and SK

Figure 4: Learning curves on MEDIA and LUNA corpora using FST, CRF and RR on the FST hypotheses

Model	MEDIA (CER)	LUNA (CER)
FST	28.6%	42.7%
CRF	24.0%	41.8%
SVM-RR (PTK)	25.0%	38.9%

Table 5: Results of SLU experiments on MEDIA and LUNA test set (automatic transcriptions with a WER 31.4% on MEDIA and 41% on LUNA)

dash symbol means that the structure cannot be applied to the corresponding kernel. We note that our re-rankers significantly improve our baselines, *i.e.* 23.2% CER for FST and 26.3% CER for SVM concept classifiers. For example, SVM re-ranker using SK, in the best case, improves FST concept classifier of 23.2-16.2 = 7 points.

Note also that the structures designed for trees yield quite different results depending on which kernel is used. We can see in Table 3 that the best result using STK is obtained with the simplest structure (FLAT), while with PTK the best result is achieved with the most complex structure (FEATURES). This is due to the fact that STK does not split the children of each node, as explained in Section 2.2, and so structures like *MULTILEVEL* and *FEATURES* are too rigid and prevent the STK to be effective.

For lack of space we do not report all the results using different kernels and structures on MEDIA, but we underline that as MEDIA is a more complex task (34 concepts in LUNA, 80 in MEDIA), the more complex structures are more effective to capture word-concept dependencies and the best results were obtained using the *FEATURES* tree.

Table 4 shows the results of the SLU experiments on the MEDIA and LUNA test sets using the manual transcriptions of spoken sentences and a re-ranker based on PTK and the *FEATURES* structure (already reported in the previous table). We used PTK since it is enough efficient to carry out the computation on the much larger Media corpus although as previously shown it is less accurate than SK.

We note that on a big corpus like MEDIA, the baseline models (FST and CRF) can be accurately learned thus less errors can be "corrected". As a consequence, our re-ranking approach does not improve CRF but it still improves the FSTs baseline of 1.6% points (11.7% of relative improvement).

The same behavior is reproduced for the SLU experiments on automatic transcriptions, shown in Table 5. We note that, on the LUNA corpus, CRFs are more accurate than FSTs (0.9% points), but they are significantly improved by the re-ranking model (2.9% points), which also improves the FSTs baseline by 3.8% points. On the MEDIA corpus, the re-ranking model is again very accurate improving the FSTs baseline of 3.6% points (12.6% relative improvement) on attribute annotation, but the most accurate model is again CRF (1% points better than the re-ranking model).

5.5 Discussion

The different behavior of the re-ranking model in the LUNA and MEDIA corpora is due partially to the task complexity, but it is mainly due to the fact that CRFs have been deeply studied and experimented (see (Hahn et al., 2008)) on MEDIA. Thus CRF parameters and features have been largely optimized. We believe that the re-ranking model can be relevantly improved by carrying out parameter optimization and new structural feature de-

sign.

Moreover, our re-ranking models achieve the highest accuracy for automatic concept annotation when small data sets are available. To show this, we report in Figure 4(a) and 4(b) the learning curves according to an increasing number of training sentences on the MEDIA and LUNA corpora, respectively. To draw the first plot, we used a re-ranker based on STK (and the FLAT tree), which is less accurate than the other kernels but also the most efficient in terms of training time. In the second plot, we report the re-ranker accuracy using SK applied to *SK1* structure.

In these figures, the FST baseline performance is compared with our re-ranking (RR) and a Conditional Random Field (CRF) model. The above curves clearly shows that for small datasets our RR model is better than CRF whereas when the data increases, CRF accuracy approaches the one of the RR.

Regarding the use of kernels two main findings can be derived:

- Kernels producing a high number of features, *e.g.* SK, produce accuracy higher than kernels less rich in terms of features, *i.e.* STK. In particular STK is improved by 18.5-16.2=2.3 points (Table 3). This is an interesting result since it shows that (a) a kernel producing more features also produces better re-ranking models and (b) kernel methods give a remarkable help in feature design.

- Although the training data is small, the re-rankers based on kernels appear to be very effective. This may also alleviate the burden of annotating large amount of data.

6 Conclusions

In this paper, we propose discriminative re-ranking of concept annotation to jointly exploit generative and discriminative models. We improve the FST-based generative approach, which is a state-of-the-art model in LUNA, by 7 points, where the more limited availability of annotated data leaves a larger room for improvement. Our re-ranking model also improves FST and CRF on MEDIA when small data sets are used.

Kernel methods show that combinations of feature vectors, sequence kernels and other structural kernels, *e.g.* on shallow or deep syntactic parse trees, appear to be a promising future research line[3]. Finally, the experimentation with automatic speech transcriptions revealed that to test the robustness of our models to transcription errors.

In the future we would like to extend this research by focusing on advanced shallow semantic approaches such as predicate argument structures, *e.g.* (Giuglea and Moschitti, 2004; Moschitti and Cosmin, 2004; Moschitti et al., 2008). Additionally, term similarity kernels, *e.g.* (Basili et al., 2005; Bloehdorn et al., 2006), will be likely improve our models, especially when combined syntactic and semantic kernels are used, i.e. (Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b).

Abstract

There have been increasing needs for task specific rankings in web search such as rankings for specific query segments like long queries, time-sensitive queries, navigational queries, etc; or rankings for specific domains/contents like answers, blogs, news, etc. In the spirit of "divide-and-conquer", task specific ranking may have potential advantages over generic ranking since different tasks have task-specific features, data distributions, as well as feature-grade correlations. A critical problem for the task-specific ranking is training data insufficiency, which may be solved by using the data extracted from click log. This paper empirically studies how to appropriately exploit click data to improve rank function learning in task-specific ranking. The main contributions are 1) the exploration on the utilities of two promising approaches for click pair extraction; 2) the analysis of the role played by the noise information which inevitably appears in click data extraction; 3) the appropriate strategy for combining training data and click data; 4) the comparison of click data which are consistent and inconsistent with baseline function.

1 Introduction

Learning-to-rank approaches (Liu, 2008) have been widely applied in commercial search engines, in which ranking models are learned using labeled documents. Significant efforts have been made in attempt to learn a generic ranking model which can appropriately rank documents for all queries . However, web users' query intentions are extremely heterogeneous, which makes it difficult for a generic ranking model to achieve best ranking results for all queries. For this reason, there have been increasing needs for task specific rankings in web search such as rankings for specific query segments like long queries, time-sensitive queries, navigational queries, etc; or rankings for specific domains/contents like answers, blogs, news, etc. Therefore, a specific ranking task usually correspond to a category of queries; when the search engine determines that a query is belonging to this category, it will call the ranking function dedicated to this ranking task. The motivation of this divide-and-conquer strategy is that, task specific ranking may have potential advantages over generic ranking since different tasks have task-specific features, data distributions, as well as feature-grade correlations.

Such a dedicated ranking model can be trained using the labeled data belonging to this query category (which is called dedicated training data). However, the amount of training data dedicated to a specific ranking task is usually insufficient because human labeling is expensive and time-consuming, not to mention there are multiple ranking tasks that need to be taken care of. To deal with the training data insufficiency problem for task-specific ranking, we propose to extract click-through data and incorporate it with dedicated training data to learn a dedicated model.

In order to incorporate click data to improve the ranking for a dedicate query category, it is critical to fully exploit click information. We empirically explore the related approaches for the appropriate click data exploitation in task-specific rank function learning. Figure 1 illustrates the procedures and critical components to be studied.

1) Click data mining: the purpose is to extract informative and reliable users' preference information from click log. We employ two promising approaches: one is heuristic rule approach, the other is sequential supervised learning approach.

2) Sample selection and combination: with labeled training data and unlabeled click data, how

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1086–1095,
Singapore, 6-7 August 2009.

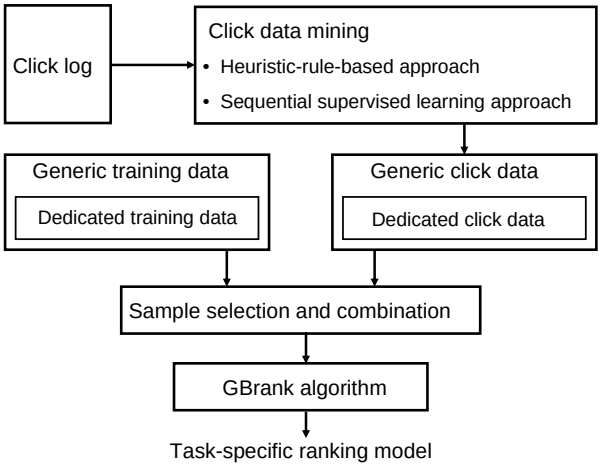

Figure 1: Framework of incorporating click-through data with training data to improve dedicated model for task-specific ranking.

to select and combine them so that the samples have the best utility for learning? As the data distribution for a specific ranking task is different from the generic data distribution, it is natural to select those labeled training samples and unlabeled click preference pairs which belong to this query category, so that the data distributions of training set and testing set are consistent for this category. On the other hand, we should keep in mind that: a) non-dedicated data, i.e, the data that does not belong the specific category, might also have similar distribution as the dedicated data. Such distribution similarity makes non-dedicated data also useful for task-specific rank function learning, especially for the scenario that dedicated training samples is insufficient. b) The quality of dedicated click data may be not as reliable as human labeled training data. In other words, there are some extracted click preference pairs that are inconsistent with human labeling while we regard human labeling as correct labeling.

3) Rank function learning algorithm: we use GBrank (Zheng et al., 2007) algorithm for rank function learning, which has proved to be one of the most effective up-to-date learning-to-rank algorithms; furthermore, GBrank algorithm also takes preference pairs as inputs, which will be illustrated with more details in the paper.

2 Related work

Learning to rank has been a promising research area which continuously improves web search relevance (Burges et al., 2005) (Zha et al., 2006) (Cao et al., 2007) (Freund et al., 1998) (Friedman, 2001) (Joachims, 2002) (Wang and Zhai, 2007) (Zheng et al., 2007). The ranking problem is usually formulated as learning a ranking function from preference data. The basic idea is to minimize the number of contradicted pairs in the training data, and different algorithm cast the preference learning problem from different point of view, for example, RankSVM (Joachims, 2002) uses support vector machines; RankBoost (Freund et al., 1998) applies the idea of boosting from weak learners; GBrank (Zheng et al., 2007) uses gradient boosting with decision tree; RankNet (Burges et al., 2005) uses gradient boosting with neural net-work. In (Zha et al., 2006), query difference is taken into consideration for learning effective retrieval function, which leads to a multi-task learning problem using risk minimization framework.

There are a few related works to apply multiple ranking models for different query categories. However, none of them takes click-through information into consideration. In (Kang and Kim, 2003), queries are categorized into 3 types, informational, navigational and transactional, and different models are applied on each query category.

a KNN method is proposed to employ different ranking models to handle different types of queries (Geng et al., 2008). The KNN method is unsupervised, and it targets to improve the overall ranking instead of the rank-ing for a certain query category. In addition, the KNN method requires all feature vector to be the same.

Quite a few research papers explore how to obtain useful information from click-through data, which could benefit search relevance (Carterette et al., 2008) (Fox et al., 2005) (Radlinski and Joachims, 2007) (Wang and Zhai, 2007). The information can be expressed as pair-wise preferences (Chapelle and Zhang, 2009) (Ji et al., 2009) (Radlinski et al., 2008), or represented as rank features (Agichtein et al., 2006). Task-specific ranking relies on the accuracy of query classification. Query classification or query intention identification has been extensively studied in (Beitzel et al., 2007) (Lee et al., 2005) (Li et al., 2008) (Rose and Levinson, 2004). How to combine editorial data and click data is well discussed in (Chen et al., 2008) (Zheng et al., 2007). In addition, how to use click data to improve ranking are also exploited in personalized or preference-based search (Coyle

Table 1: Statistics of click occurrences for heuristic rule approach.

imp	impression, number of occurrence of the tuple
cc	number of occurrence of the tuple where two documents both get clicked
ncc	number of occurrence of the tuple where url_1 is not clicked but url_2 is clicked
cnc	number of occurrence of the tuple where url_1 is clicked but url_2 is not clicked
$ncnc$	number of occurrence of the tuple where url_1 and url_2 are not clicked

and Smyth, 2007) (Glance, 2001) (R. Jin, 2008).

3 Technical approach

This section presents the related approaches in Figure 1. In Section 4, we will make deeper analysis based on experimental results.

3.1 Click data mining

We use two approaches for click data mining, whose outputs are preference pairs. A *preference pair* is defined as a tuple $\{< x_q, y_q > | x_q \succ y_q\}$, which means for the query q, the document x_q is more relevant than y_q. We need to extract informative and reliable preference pairs which can be used to improve rank function learning.

3.1.1 Heuristic rule approach

We use heuristic rules to extract skip-above pairs and skip-next pairs, which are similar to Strategy 1 (click $>$ skip above) and Strategy 5 (click $>$ no-click next) proposed in (Joachims et al., 2005). To reduce the misleading effect of an individual click behavior, click information from different query sessions is aggregated before applying heuristic rules. For a tuple $(q, \text{url}_1, \text{url}_2, \text{pos}_1, \text{pos}_2)$ where q is query, url_1 and url_2 are urls representing two documents, pos_1 and pos_2 are ranking positions for the two documents with $\text{pos}_1 \prec \text{pos}_2$ meaning url_1 has higher rank than url_2, the statistics for this tuple are listed in Table 1.

Skip-above pair extraction: if ncc is much larger than cnc, and $\frac{cc}{imp}$, $\frac{ncnc}{imp}$ is much smaller than 1, that means, when url_1 is ranked higher than url_2 in query q, most users click url_2 but not click url_1. In this case, we extract a skip-above pair, i.e., url_2 is more relevant than url_1. In order to have highly accurate skip-above pairs, a set of thresholds are applied to only extract the pairs that have high impression and ncc is larger enough than cnc.

Skip-next pair extraction: if $\text{pos}_1 = \text{pos}_2 - 1$, cnc is much larger than ncc, and $\frac{cc}{imp}$, $\frac{ncnc}{imp}$ is much smaller than 1, that means, in most of cases when url_2 is ranked just below url_1 in query q, most users click url_1 but not click url_2. In this case, we regard this tuple as a skip-next pair.

Table 2: Skip-above pairs count vs. human judgements (e.g., the element in the third row and second column means we have 40 skip-above pairs with "excellent" url_1 and "perfect" url_2). P: perfect; E: excellent; G: good; F: fair; B: bad.

	P	E	G	F	B
P	13	13	12	4	0
E	40	44	16	2	2
G	27	53	103	29	8
F	10	15	43	27	5
B	4	4	11	20	14

Table 3: Skip-next pairs vs. human judgements (e.g., the element in the third row and second column means we have 10 skip-next pairs with "excellent" url_1 and "perfect" url_2). P: perfect; E: excellent; G: good; F: fair; B: bad.

	P	E	G	F	B
P	126	343	225	100	35
E	10	71	84	37	12
G	6	9	116	56	21
F	1	5	17	29	14
B	1	1	1	2	5

To test the accuracy of preference pairs, we ask editors to judge some randomly selected pairs from skip-above pairs and skip-next pairs. Editors label each query-url pair using five grades according to relevance: perfect, excellent, good, fair, bad. Table 2 shows skip-above pair distribution. The diagonal elements have high values, which are for tied pairs labeled by editors but determined as skip-above pairs from heuristic rules. Higher values appear in the left-bottom triangle than in the right-top triangle, because there are more skip-above preferences agreed with editors than disagreed with editors. Summing up the tied pairs, agreed and disagreed pairs, 44% skip-above preference judgments agree with editors, 18% skip-above preference judgments disagree with editors,

and there are 38% skip-above pairs judged as tie pairs by editors.

Table 3 shows skip-next pair distribution. Summing up the tied pairs, agreed and disagreed pairs, 70% skip-next preference judgments agree with editors, 4% skip-next preference judgments disagree with editors, and 26% skip-next pairs judged as tie pairs by editors.

Therefore, skip-next pairs have much higher accuracy than skip-above. That is because in a search engine that already has a good ranking function, it is much easier to find a correct skip-next pairs which are consistent with the search engine than to find a correct skip-above pairs which are contradictory to the search engine. Skip-above and skip-next preferences provide us two kinds of users's feedbacks which are complementary: skip-above preferences provide us the feedback that the user's vote is contradictory to the current ranking, which implies the current relative ranking should be reversed; skip-next preferences shows that the user's vote is consistent with the current ranking, which implies the current relative ranking should be maintained with high confidence provided by users' vote.

3.1.2 Sequential supervised learning

The click modeling by sequential supervised learning (SSL) was proposed in (Ji et al., 2009), in which user's sequential click information is exploited to extract relevance information from click-logs. This approach is reliable because 1) the sequential click information embedded in an aggregation of user clicks provides substantial relevance information of the documents displayed in the search results, and 2) the SSL is supervised learning (i.e., human judgments are provided with relevance labels for the training).

The SSL is formulated in the framework of global ranking (Qin et al., 2008). Let $\mathbf{x}^{(q)} = \{x_1^{(q)}, x_2^{(q)}, \ldots, x_n^{(q)}\}$ represent the documents retrieved with a query q, and $\mathbf{y}^{(q)} = \{y_1^{(q)}, y_2^{(q)}, \ldots, y_n^{(q)}\}$ represent the relevance labels assigned to the documents. Here n is the number of documents retrieved with q. Without loss of generality, we assume that n is fixed and invariant with respect to different queries. The SSL determines to find a function F in the form of $\mathbf{y}^{(q)} = F(\mathbf{x}^{(q)})$ that takes all the documents as its inputs, exploiting both local and global information among the documents, and predict the relevance labels of all the document *jointly*. This is distinct to most of learning to rank methods that optimize a ranking model defined on a single document, i.e., in the form of $y_i^{(q)} = f(x_i^{(q)})$, $\forall\, i = 1, 2, \ldots, n$. This formulation of the SSL is important in extracting relevance information from user click data since users' click decisions among different documents displayed in a search session tend to rely not only on the relevance judgment of a single document, but also on the *relative* relevance comparison among the documents displayed; and the global ranking framework is well-formulated to exploit both local and global information from an aggregation of user clicks.

The SSL aggregates all the user sessions for the same query into a tuple <query, n-document list, and an aggregation of user clicks>. Figure 2 illustrates the process of feature extraction from an aggregated session, where $\mathbf{x}^{(q)} = \{x_1^{(q)}, x_2^{(q)}, \ldots, x_n^{(q)}\}$ denotes a sequence of feature vectors extracted from the aggregated session, with $x_i^{(q)}$ representing the feature vector extracted for document i. Specifically, to form feature vector $x_i^{(q)}$, first a feature vector $x_{i,j}^{(q)}$ is extracted from each user j's click information, and $j \in \{1, 2, \ldots\}$, then $x_i^{(q)}$ is formed by averaging over $x_{i,j}^{(q)}$, $\forall j \in \{1, 2, \ldots\}$, i.e., $x_i^{(q)}$ is actually an aggregated feature vector for document i. Table 4 lists all the features used in the SSL modeling. Note that some features are statistics independent of temporal information of the clicks, such as "Position" and "Frequency", while other features reply on their surrounding documents and the click sequences. We use 90,000 query-url pairs to train the SSL model, and 10,000 query-url pairs for best model selection.

With the sequential click modeling discussed above, several sequential supervised algorithms, including the conditional random fields (CRF) (Lafferty et al., 2001), the sliding window method and the recurrent sliding window method (Dietterich, 2002), are explored to find a global ranking function F. We omit the details but refer one to (Ji et al., 2009). The emphasis here is on the importance to adapt these algorithms to the ranking problem.

After training, the SSL model can be used to predict the relevance labels of all the documents in a new aggregated session, and thus pair-wise preference data can be extracted, with the score difference representing the confidence of preference

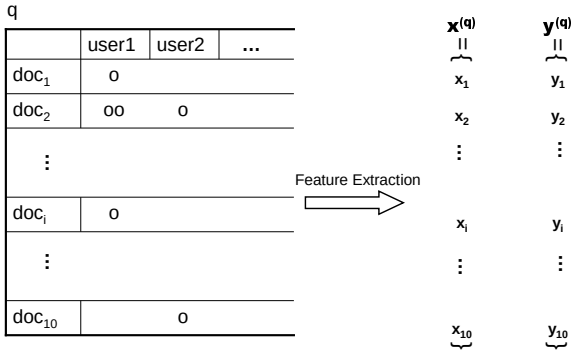

Figure 2: An illustration of feature extraction for an aggregated session for SSL approach. $\mathbf{x}^{(q)}$ denotes an extracted sequence of feature vectors, and $\mathbf{y}^{(q)}$ denotes the corresponding label sequence that is assigned by human judges for training.

Table 4: Click features used in SSL model.

Position	Position of the document in the result list
ClickRank	Rank of 1st click of doc. in click seq.
Frequency	Average number of clicks for this doc.
FrequencyRank	Rank in the list sorted by num. of clicks
IsNextClicked	1 if next position is clicked, 0 otherwise
IsPreClicked	1 if previous position is clicked, 0 otherwise
IsAboveClicked	1 if there is a click above, 0 otherwise
IsBelowClicked	1 if there is a click below, 0 otherwise
ClickDuration	Time spent on the document

prediction. For the reason of convenience, we also call the preference pairs contradicting with production ranking as skip-above pairs and those consistent with production ranking as skip-next pairs, so that we can analyze these two types of preference pairs respectively.

3.2 Modeling algorithm

The basic idea of GBrank (Zheng et al., 2007) is that if the ordering of a preference pair by the ranking function is contradictory to this preference, we need to modify the ranking function along the direction by swapping this prefence pair. Preferences pairs could be generated from labeled data, or could be extracted from click data. For each preference pair $< x, y >$ in the available preference set $S = \{< x_i, y_i > | x_i \succ y_i, i = 1, 2, ..., N\}$, x should be ranked higher than y. In GBrank algorithm, the problem of learning ranking functions is to compute a ranking function h , so that h matches the set of preference, i.e, $h(x_i) \geq h(y_i)$, if $x \succ y$, $i = 1, 2, ..., N$ as many as possible. The following loss function is used to measure the risk of a given ranking function h.

$$R(h) = \frac{1}{2}\sum_{i=1}^{N}(\max\{0, h(y_i) - h(x_i) + \tau\})^2, \quad (1)$$

where τ is the margin between the two documents in the pair. To minimize the loss function, $h(x)$ has to be larger than $h(y)$ with the margin τ, which can be chosen as constant value, or as dynamic values varying with pairs. When pair-wise judgments are extracted from editors' labels with different grades, pair-wise judgments can include grade difference, which can further be used as margin τ. The GBrank algorithm is illustrated in Algorithm 1, and two parameters need to be determined: the shrinkage factor η and the number of iteration.

Algorithm 1 GBrank algorithm.

Start with an initial guess h_0, for $m = 1, 2, ...$

1. Construct a training set: for each $< x_i, y_i > \in S$, derive $(x_i, \max\{0, h_{m-1}(y_i) - h_{m_1}(x_i) + \tau\})$, and
$(y_i, -\max\{0, h_{m-1}(y_i) - h_{m_1}(x_i) + \tau\})$.
2. Fit h_m by using a base regressor with the above training set.
3. $h_m = h_{m-1} + \eta s_m h_m(x)$, where s_m is found by line search to minimize the object function, η is shrinkage factor.

3.3 Sample selection and combination

We use a straightforward approach to learn ranking model from the combined data, which is illustrated in Algorithm 2.

Algorithm 2 Learn ranking model by combining editorial data and click preference pairs.

Input:
- Editorial absolute judgement data.
- Preference pairs from click data.

1. Extract preference pairs from labeled data with absolute judgement.
2. Select and combine preference pairs from click data and labeled data.
3. Learn GBrank model from the combined preference pairs.

Absolute judgement on labeled data contains (query, url) pairs with absolute grade values labeled by human. In Step 1, for each query with

n_q query-url pairs with corresponding grades, $\{<$ query, $\text{url}_i, \text{grade}_i > | i = 1, 2, \ldots, n_q\}$, its preference pairs are extracted as

$\{<$ query, $\text{url}_i, \text{url}_j, \text{grade}_i - \text{grade}_j > | i, j = 1, 2, \ldots, n_q, i \neq j\}$.

When combining human-labeled pairs and click preference pairs, we can give use different relative weights for these two data sources. The loss function becomes

$$R(h) = \frac{w}{N_l} \sum_{i \in \textbf{Labeled}} (\max\{0, h(y_i) - h(x_i) + \tau\})^2 \quad \frac{1-w}{N_c} \sum_{i \in \textbf{Click}} (\max\{0, h(y_i) - h(x_i) + \tau\})^2, \quad (2)$$

where w is used to control the relative weights between labeled training data and click data, N_l is the number of training data pairs, and N_c is the number of click pairs. The margin τ can be determined as grade difference for editor pairs, and be a constant parameter for click pairs.

Step 2 is critical for the efficacy of the approach. A few factors need to be considered:

1) data distribution: for the application of task-specific ranking, our purpose is to improve ranking for the queries belonging to this category. An important observation is that the relevance patterns for the ranking within a specific category may have some unique characteristics, which are different from generic relevance ranking. Thus, it is reasonable to consider only using dedicated labeled training data and dedicated click preference data for training. The reality is that dedicated training data is usually insufficient, while it is possible that non-dedicated data can also help the learning.

2) click pair quality: it is inevitable there exist some incorrect pairs in the click preference pairs. Such incorrect pairs may mislead the learning. So overall, can the click preference pairs still help the learning for task-specific ranking? By our study, skip-above pairs usually contain more incorrect pairs compared with skip-above pairs. Does this mean skip-next pairs are always more helpful in improving learning than skip-above pairs?

3) click pair utility: use labeled training data as baseline, how much complimentary information can click pairs bring? This is determined by the methodology of click data mining approach.

While it is possible to achieve some learning improvement for task-specific ranking by using click pairs by a plausible method, we attempt to empirically explore the above interweaving factors for deeper understanding, in order to apply the most appropriate strategy to exploit click data on real-world applications of task-specific ranking.

4 Experiments

4.1 Data set

Query category: in the experiments, we use long query ranking as an example of task-specific ranking, because it is commonly known that long query ranking has some unique relevance patterns compared with generic ranking. We define the long queries as the queries containing at least three tokens. The techniques and analysis proposed in this paper can be applied to other ranking tasks, such as rankings for specific query segments like time-sensitive queries, navigational queries, or rankings for specific domains/contents like answers, blogs, news, as long as the tasks have their own characteristics of data distributions and discriminant rank features.

Labeled training data: we do experiments based on a data set for a commercial search engine, for which there are 16,797 query-url pairs (with 1,123 different queries) that have been labeled by editors. The proportion of long queries is about 35% of all queries. The data distribution of such long queries may be different from general data distribution, as it will be validated in the experiments below.

The human labeled data is randomly split into two sets: training set (8,831 query-url pairs, 589 queries), and testing set (7,966 query-url pairs, 534 queries). The training set will be combined with click preference pairs for rank function learning, and the testing set will be used to evaluate the efficacy of the ranking function. In the training set, there are 3,842 long query-url pairs (229 queries). At testing stage, the learned rank functions are applied only to the long queries in the testing data, as our concern in this paper is how to improve task-specific ranking, i.e., long query ranking in the experiment. In the testing data, there are 3,210 query-url pairs (193 queries) are long query data, which will be used to test rank functions.

Click preference pairs: using the two approaches of heuristic rule approach and sequential supervised approach, we extract click prefence pairs from the click log of the search engine. Each approach yields both skip-next and skip-above pairs, which are sorted by confidence descending order respectively.

Table 5: Use click data by heuristic rule approach (Data Selection: "N": not use; "D": use dedicated data; "G": use generic data. Data Source: "T": training data; "C": click data)

(a) skip-next pairs

	NT	DT	GT
NC	n/a	0.7736	0.7813
DC	0.7822	0.7906 (1.2%)	0.7997(2.4%)
GC	0.7834	0.7908 (1.2%)	0.7950 (1.7%)

(b) skip-above pairs

	NT	DT	GT
NC	n/a	0.7736	0.7813
DC	0.6649	0.7676 (-1.6%)	0.7748 (-0.8%)
GC	0.6792	0.7656 (-2.0%)	0.7989 (2.2%)

Table 6: Use click data by SSL approach (Data Selection: "N": not use; "D": use dedicated data; "G": use generic data. Data Source: "T": training data; "C": click data)

(a) skip-next pairs

	NT	DT	GT
NC	n/a	0.7736	0.7813
DC	0.7752	0.7933 (1.5%)	0.7936 (1.5%)
GC	0.7624	0.7844 (0.4%)	0.7914 (1.2%)

(b) skip-above pairs

	NT	DT	GT
NC	n/a	0.7736	0.7813
DC	0.6756	0.7636 (-2.2%)	0.7784 (-0.3%)
GC	0.6860	0.7717 (-1.2%)	0.7774 (-0.5%)

4.2 Setup and measurements

We try different sample selection and combination strategies to train rank functions using GBrank algorithm. For the labeled training data, we either use generic data or dedicated data. For the click preference pairs, we also try these two options. Furthermore, as more click preference pairs may bring more useful information to help the learning while on the other hand, the more incorrect pairs may be given so that they mislead the learning, we try different amounts of these prefence pairs: 5,000, 10,000, 30,000, 50,000, 70,000 and 100,000 pairs.

We use NDCG to evaluate ranking model, which is defined as

$$\text{NDCG}_n = Z_n \sum_{i=1}^{n} \frac{2^{r(i)}-1}{\log(i+1)}$$

where i is the position in the document list, $r(i)$ is the score of Document i, and Z_n is a normalization factor, which is used to make the NDCG of ideal list be 1.

4.3 Results

Table 5 and 6 show the NDCG_5 results by using heuristic rule approach and SSL approach respectively. We do not present NDCG_1 results due to space limitation, but NDCG_1 results have the similar trends as NDCG_5.

Baseline by training data: there are two baseline functions by using training data sets 1) use dedicated training data (DT), NDCG_5 on the testing set by the rank function is 0.7736; 2) use generic training data (GT), NDCG_5 is 0.7813. It is reasonable that using generic training data is better than only using dedicated training data, because the distributions of non-dedicated data and dedicated data share some similarity. As the dedicated training data is insufficient, the adoption of the extra non-dedicated data helps the learning. We compare learning results with Baseline 2) (use generic training data, the slot of NC + GT in the tables), which is the higher baseline.

Baseline by click data: we then study the utilities of click preference pairs by using them alone for training without using labeled training data. In Table 5 and 6, each of the NDCG_5 results using click preference pairs is the highest NDCG_5 value over the cases of using different amounts of pairs (5000, 10,000, 30,000, 50,000, 70,000 and 100,000 pairs). The results regarding the pairs amounts are illustrated in Figure 3, which will help us to analyze the results more deeply.

If we only use click preference pairs for training (the two table slots DC+NT and GC+NT, corresponding to using dedicated click preference pairs and generic click pairs respectively), the best case is using skip-next pairs extracted by heuristic rule approach (Table 5 (a)). It is not surprising that skip-next pairs outperform skip-above pairs because there are significantly lower percentage of incorrect pairs in skip-next pairs compared with skip-above pairs. It is a little bit surprising that the case of DC+NT has no dominant advantage over GC+NT as we expected. For example, in Table 5 (a), the NDCG_5 values (0.7822 and 0.7834) are very close to each other. However, in Figure 3, we find that with the same amount of pairs, when we use 30,000 or fewer pairs, using dedi-

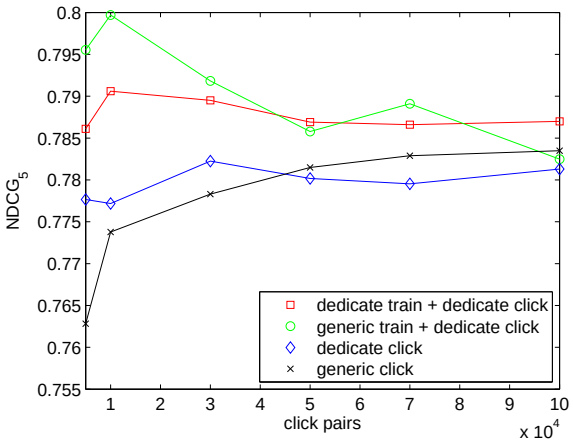

Figure 3: Incorporate different amounts of skip-next pairs by heuristic rule approach with generic training data.

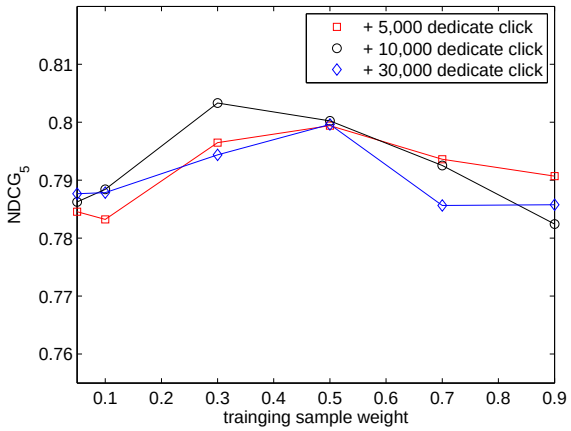

Figure 4: The effects of using different combining weights. Skip-next pairs by heuristic rule approach are combined with generic training data.

cated click pairs alone is always better than using generic click pairs alone. With more click pairs being used ($> 30,000$), the noise rates become higher in the pairs, which makes the distribution factor less important.

Combine training data and click data: we compare the four table slots, DC+DT, GC+DT, DC+GT, GC+GT, in Table 5 and 6, and there are quite a few interesting observations:

1) *Skip-next vs. skip-above*: overall, incorporating skip-next pairs with training data is better than incorporating skip-above pairs, due to the reason that there are more incorrect pairs in skip-above pairs, which may mislead the learning. The only exception is the slot GC+GT in Table 5 (b), whose NDCG_5 improvement is as high as 2.2%. We further track this result, and find that this is the case by using only 5,000 generic skip-above pairs. The noise rate of these 5,000 pairs is low because they have the highest pair extraction confidence values. At the same time, these 5,000 pairs may provide good complementary signals to the generic training data, so that the learning result is good. However, in general, skip-next pairs have better utilities than skip-above pairs.

2) *Dedicated training data vs. generic training data*: using generic training data is generally better than only using dedicated training data. If training data is insufficient, the extra non-dedicated data provides useful information for relevance pattern learning, and the distribution dissimilarity between dedicated data and non-dedicated data is not the most important factor.

3) *Dedicated click data vs. generic click data*: using dedicated click data is more effective than using generic click data. From Figure 3, we observe that when 30,000 or fewer pairs are incorporated into training data, using dedicate click pairs is always better than using generic click pairs.

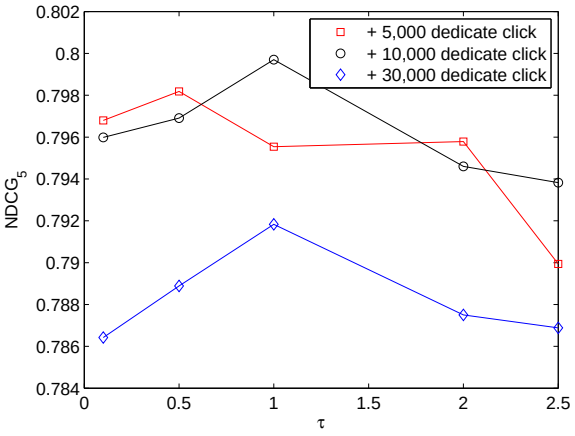

Figure 5: The effects of using different margin values for click preference pairs. Skip-next pairs by heuristic rule approach are incorporated with generic training data.

4) *Heuristic rule approach vs. SSL approach*: the preference pairs extracted by heuristic rule approach have better utilities than those extracted by SSL approach.

5) *GBrank parameters for combining training data and click pairs*: the relative weight w for combining training data and click pairs in (2) may also affect rank function learning. Figure 4 shows the effects of using different combining weights,

for which skip-next pairs by heuristic rule approach are combined with generic training data. We observe that neither over-weighting training data or over-weighting click pairs yields good results while the two data sources are best exploited at certain weight values when there is good balance between them. Another concern is the appropriate margin value τ for the click pairs in (2). Figure 5 shows that $\tau = 1$ consistently yields good learning results, which suggests us that click pair provides good information at $\tau = 1$.

4.4 Discussions

we have defactorized the related approaches for exploiting click data to improve task-specific rank learning. The utility of click preference pairs depends on the following factors:

1) Data distribution: if click pairs have good quality, we should use dedicated click pairs instead of generic click pairs, so that the samples for training have similar distribution to the task of task-specific ranking.

2) The amount of dedicated training data: the more dedicated training data, the more reliable the task-specific rank function is; thus, the less room for learning improvement using click data. For the case in the experiment that dedicated training is insufficient, the non-dedicated training data can also help the learning as non-dedicated training data share relevance pattern similarity with the dedicated data distribution.

3) The quality of click pairs: if we can extract large amount of high-quality click pairs, the learning improvement will be significant. For example, as shown in Figure 3, at the early stage with fewer click pairs (5,000 and 10,000 pairs) being combined with training data, the learning improvement is best. With more click pairs are used, the noise rate in the click pairs becomes higher so that the learning misleading factor is more important than information complementary factor. Thus, it is important to improve the reliability of the click pairs.

4) The utility of click pairs: by our study, the quality of click pairs extracted by SSL approach is comparable to those extracted by heuristic rule approach. The possible reason that heuristic-rule-based click pairs can bring more benefit is that these pairs provide more complementary information compared with SSL approach. As the methodologies of these two click data extraction approaches are totally different, in future we will explore the concrete reason that causes such utility difference.

5 Conclusions

By empirically exploring the related factors in utilizing click-through data to improve dedicated model learning for task-specific ranking, we have better understood the principles of using click preference pairs appropriately, which is important for the real-world applications in commercial search engines as using click data can significantly save human labeling costs and makes rank function learning more efficient. In the case that dedicated training data is limited, while non-dedicated training data is helpful, using dedicated skip-next pairs is the most effective way to further improve the learning. Heuristic rule approach provides more useful click pairs compared with sequential supervised learning approach. The quality of click pairs is critical for the efficacy of the approach. Therefore, an interesting topic is how to further reduce the inconsistency between skip-above pairs and human labeling so that such data may also be useful for task-specific ranking.

Abstract

Recently system combination has been shown to be an effective way to improve translation quality over single machine translation systems. In this paper, we present a simple and effective method to systematically derive an ensemble of SMT systems from one baseline linear SMT model for use in system combination. Each system in the resulting ensemble is based on a feature set derived from the features of the baseline model (typically a subset of it). We will discuss the principles to determine the feature sets for derived systems, and present in detail the system combination model used in our work. Evaluation is performed on the data sets for NIST 2004 and NIST 2005 Chinese-to-English machine translation tasks. Experimental results show that our method can bring significant improvements to baseline systems with state-of-the-art performance.

1 Introduction

Research on Statistical Machine Translation (SMT) has shown substantial progress in recent years. Since the success of phrase-based methods (Och and Ney, 2004; Koehn, 2004), models based on formal syntax (Chiang, 2005) or linguistic syntax (Liu et al., 2006; Marcu et al., 2006) have also achieved state-of-the-art performance. As a result of the increasing numbers of available machine translation systems, studies on system combination have been drawing more and more attention in SMT research.

There have been many successful attempts to combine outputs from multiple machine translation systems to further improve translation quality. A system combination model usually takes *n*-best translations of single systems as input, and depending on the combination strategy, different methods can be used. Sentence-level combination methods directly select hypotheses from original outputs of single SMT systems (Sim et al., 2007; Hildebrand and Vogel, 2008), while phrase-level or word–level combination methods are more complicated and could produce new translations different from any translations in the input (Bangalore et al., 2001; Jayaraman and Lavie, 2005; Matusov et al., 2006; Sim et al., 2007).

Among all the factors contributing to the success of system combination, there is no doubt that the availability of multiple machine translation systems is an indispensable premise. Although various approaches to SMT system combination have been explored, including enhanced combination model structure (Rosti et al., 2007), better word alignment between translations (Ayan et al., 2008; He et al., 2008) and improved confusion network construction (Rosti et al., 2008), most previous work simply used the ensemble of SMT systems based on different models and paradigms at hand and did not tackle the issue of how to obtain the ensemble in a principled way. To our knowledge the only work discussed this problem is Macherey and Och (2007), in which they experimented with building different SMT systems by varying one or more sub-models (i.e. translation model or distortion model) of an existing SMT system, and observed that changes in early-stage model training introduced most diversities in translation outputs.

In this paper, we address the problem of building an ensemble of diversified machine translation systems from a single translation engine for system combination. In particular, we propose a novel *Feature Subspace* method for the ensemble construction based on any baseline SMT model which can be formulated as a standard linear function. Each system within the ensemble is based on a group of features directly derived from the baseline model with minimal efforts (which is typically a subset of the features used in the baseline model), and the resulting system is optimized in the derived feature space accordingly.

We evaluated our method on the test sets for NIST 2004 and NIST 2005 Chinese-to-English

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1096–1104,
Singapore, 6-7 August 2009.

machine translation tasks using two baseline SMT systems with state-of-the-art performance. Experimental results show that the feature subspace method can bring significant improvements to both baseline systems.

The rest of the paper is organized as follows. The motivation of our work is described on Section 2. In Section 3, we first give a detailed description about feature subspace method, including the principle to select subspaces from all possible options, and then an *n*-gram consensus – based sentence-level system combination method is presented. Experimental results are given in Section 4. Section 5 discusses some related issues and concludes the paper.

2 Motivation

Our motivations for this work can be described in the following two aspects.

The first aspect is related to the cost of building single systems for system combination. In previous work, the SMT systems used in combination differ mostly in two ways. One is the underlying models adopted by individual systems. For example, using an ensemble of systems respectively based on phrase-based models, hierarchical models or even syntax-based models is a common practice. The other is the methods used for feature function estimation such as using different word alignment models, language models or distortion models. For the first solution, building a new SMT system with different methodology is by no means an easy task even for an experienced SMT researcher, because it requires not only considerable effects to develop but also plenty of time to accumulate enough experiences to fine tune the system. For the second alternative, usually it requires time-consuming retraining for word alignment or language models. Also some of the feature tweaking in this solution is system or language specific, thus for any new systems or language pairs, human engineering has to be involved. For example, using different word segmentation methods for Chinese can generate different word alignment results, and based on which a new SMT system can be built. Although this may be useful to combination of Chinese-to-English translation, it is not applicable to most of other language pairs. Therefore it will be very helpful if there is a light-weight method that enables the SMT system ensemble to be systematically constructed based on an existing SMT system.

Source sentence	中国 最大 规模 的 海水 淡化 工程 落户 舟山
Ref translation	China's largest sea water desalinization project settles in Zhoushan
Default translation	China 's largest desalination project in Zhoushan
FS_{-PEF} translation	China 's largest sea water desalination project in Zhoushan

Table 1: An example of translations generated from the same decoder but with different feature settings.

	Chinese	English	$p(e\|f)$
1	海水 淡化	desalination	0.4000
2	海水	sea water	0.1748
3	淡化	desalination	0.0923

Table 2: Parameters of related phrases for examples in Table 1.

The second aspect motivating our work comes from the subspace learning method in machine learning literature (Ho, 1998), in which an ensemble of classifiers are trained on subspaces of the full feature space, and final classification results are based on the vote of all classifiers in the ensemble. Lopez and Resnik (2006) also showed that feature engineering could be used to overcome deficiencies of poor alignment. To illustrate the usefulness of feature subspace in the SMT task, we start with the example shown in Table 1. In the example, the Chinese source sentence is translated with two settings of a hierarchical phrase-based system (Chiang, 2005). In the default setting all the features are used as usual in the decoder, and we find that the translation of the Chinese word 海水 (sea water) is missing in the output. This can be explained with the data shown in Table 2. Because of noises and word alignment errors in the parallel training data, the inaccurate translation phrase 海水 淡化 ⇒ $desalination$ is assigned with a high value of the phrase translation probability feature $p(e|f)$. Although the correct translation can also be composed by two phrases 海水 ⇒ $sea\ water$ and 淡化 ⇒ $desalination$, its overall translation score cannot beat the incorrect one because the combined phrase translation probability of these two phrases are much smaller than $p(desalination|$海水 淡化$)$. However, if we intentionally remove the $p(e|f)$ feature from the model, the preferred translation can be generated as shown in the result of FS_{-PEF} because in

this way the bad estimation of $p(e|f)$ for this phrase is avoided.

This example gives us the hint that building decoders based on subspaces of a standard model could help with working around some negative impacts of inaccurate estimations of feature values for some input sentences. The subspace-based systems are expected to work similarly to statistical classifiers trained on subspaces of a full feature space – though the overall accuracy of baseline system might be better than any individual systems, for a specific sentence some individual systems could generate better translations. It is expected that employing an ensemble of subspace-based systems and making use of consensus between them will outperform the baseline system.

3 Feature Subspace Method for SMT System Ensemble Construction

In this section, we will present in detail the method for systematically deriving SMT systems from a standard linear SMT model based on feature subspaces for system combination.

3.1 SMT System Ensemble Generation

Nowadays most of the state-of-the-art SMT systems are based on linear models as proposed in Och and Ney (2002). Let $h_m(f,e)$ be a feature function, and λ_m be its weight, an SMT model D can be formally written as:

$$e^* = \arg\max_e \sum_m \lambda_m h_m(f,e) \quad (1)$$

Noticing that Equation (1) is a general formulation independent of any specific features, technically for any subset of features used in D, a new SMT system can be constructed based on it, which we call a *sub-system*.

Next we will use Ω to denote the full feature space defined by the entire set of features used in D, and $s \subseteq \Omega$ is a feature subset that belongs to $\rho(\Omega)$, the power set of Ω. The derived sub-system based on subset $s \subseteq \Omega$ is denoted by d_s. Although in theory we can use all the sub-systems derived from every feature subset in $\rho(\Omega)$, it is still desirable to use only some of them in practice. The reasons for this are two-fold. First, the number of possible sub-systems ($2^{|\Omega|}$) is exponential to the size of Ω. Even when the number of features in Ω is relatively small, i.e. 10, there will be up to 1024 sub-systems in total, which is a large number for combination task. Larger feature sets will make the system combination practically infeasible. Second, not every sub-system could contribute to the system combination. For example, feature subsets only containing very small number of features will lead to sub-systems with very poor performance; and the language model feature is too important to be ignored for a sub-system to achieve reasonably good performance.

In our work, we only consider feature subspaces with only one difference from the features in Ω. For each non- language model feature h_i, a sub-system d_i is built by removing h_i from Ω. Allowing for the importance of the language model (LM) feature to an SMT model, we do not remove any LM feature from any sub-system. Instead, we try to weaken the strength of a LM feature by lowering its *n*-gram order. For example, if a 4-gram language model is used in the baseline system D, then a trigram model can be used in one sub-system, and a bigram model can be used in another. In this way more than one sub-system can be derived based on one LM feature. When varying a language model feature, the *one-feature difference* principle is still kept: if we lower the order of a language model feature, no other features are removed or changed.

The remaining issue of using weakened LM features is that the resulting ensemble is no longer strictly based on subspace of Ω. However, this theoretical imperfection can be remedied by introducing Ω', a super-space of Ω to include all lower-order LM features. In this way, an augmented baseline system D' can be built based on Ω', and the baseline system D itself can also be viewed as a sub-system of D'. We will show in the experimental section that D' actually performs even slightly better than the original baseline system D, but results of sub-system combination are significantly better that both D and D'.

After the sub-system ensemble is constructed, each sub-system tunes its feature weights independently to optimize the evaluation metrics on the development set.

Let $\mathcal{D} = \{d_1, \ldots, d_n\}$ be the set of sub-systems obtained by either removing one non-LM feature or changing the order of a LM feature, and $\mathcal{H}_i$ be the *n*-best list produced by d_i. Then $\mathcal{H}(\mathcal{D})$, the *translation candidate pool* to the system combination model can be written as:

$$\mathcal{H}(\mathcal{D}) = \bigcup_i \mathcal{H}_i \quad (2)$$

The advantage of this method is that it allows us to systematically build an ensemble of SMT systems at a very low cost. From the decoding

perspective, all the sub-systems share a common decoder, with minimal extensions to the baseline systems to support the use of specified subset of feature functions to compute the overall score for translation hypotheses. From the model training perspective, all the non-LM feature functions can be estimated once for all sub-systems. The only exception is the language model feature, which may be of different values across multiple sub-systems. However, since lower-order models have already been contained in higher-order model for the purpose of smoothing in almost all statistical language model implementations, there is also no extra training cost.

3.2 System Combination Scheme

In our work, we use a sentence-level system combination model to select best translation hypothesis from the candidate pool $\mathcal{H}(\mathcal{D})$. This method can also be viewed to be a hypotheses re-ranking model since we only use the existing translations instead of performing decoding over a confusion network as done in the word-level combination method (Rosti et al., 2007).

The score function in our combination model is formulated as follows:

$$e^* = \underset{e \in \mathcal{H}(\mathcal{D})}{argmax} \lambda_{LM} h_{LM}(e) + \lambda_l L + \psi(e, \mathcal{H}(\mathcal{D})) \tag{3}$$

where $h_{LM}(e)$ is the language model score for e, L is the length of e, and $\psi(e, \mathcal{H}(\mathcal{D}))$ is a translation consensus –based scoring function. The computation of $\psi(e, \mathcal{H}(\mathcal{D}))$ is further decomposed into weighted linear combination of a set of *n*-gram consensus –based features, which are defined in terms of the order of *n*-gram to be matched between current candidate and other translation in $\mathcal{H}(\mathcal{D})$.

Given a translation candidate e, the *n*-gram agreement feature between e and other translations in the candidate pool is defined as:

$$h_n^+(e, \mathcal{H}(\mathcal{D})) = \sum_{e' \in \mathcal{H}(\mathcal{D}), e' \neq e} G_n(e, e') \tag{4}$$

where the function $G_n(e, e')$ counts the occurrences of *n*-grams of e in e':

$$G_n(e, e') = \sum_{i=1}^{|e|-n+1} \delta(e_i^{i+n-1}, e') \tag{5}$$

Here $\delta(\cdot,\cdot)$ is the indicator function - $\delta(e_i^{i+n-1}, e')$ is 1 when the *n*-gram e_i^{i+n-1} appears in e', otherwise it is 0.

In order to give the combination model an opportunity to penalize long but inaccurate translations, we also introduce a set of *n*-gram disagreement features in the combination model:

$$h_n^-(e, \mathcal{H}(\mathcal{D})) = \sum_{e' \in \mathcal{H}(\mathcal{D}), e' \neq e} (|e| - n + 1 - G_n(e, e')) \tag{6}$$

Because each order of *n*-gram match introduces two features, the total number of features in the combination model will be $2m + 2$ if m orders of *n*-gram are to be matched in computing $\psi(e, \mathcal{H}(\mathcal{D}))$. Since we also adopt a linear scoring function in Equation (3), the feature weights of our combination model can also be tuned on a development data set to optimize the specified evaluation metrics using the standard Minimum Error Rate Training (MERT) algorithm (Och 2003).

Our method is similar to the work proposed by Hildebrand and Vogel (2008). However, except the language model and translation length, we only use intra-hypothesis *n*-gram agreement features as Hildebrand and Vogel did and use additional intra-hypothesis *n*-gram disagreement features as Li et al. (2009) did in their co-decoding method.

4 Experiments

4.1 Data

Experiments were conducted on the NIST evaluation sets of 2004 (MT04) and 2005 (MT05) for Chinese-to-English translation tasks. Both corpora provide 4 reference translations per source sentence. Parameters were tuned with MERT algorithm (Och, 2003) on the NIST evaluation set of 2003 (MT03) for both the baseline systems and the system combination model. Translation performance was measured in terms of case-insensitive NIST version of BLEU score which computes the brevity penalty using the shortest reference translation for each segment, and all the results will be reported in percentage numbers. Statistical significance is computed using the bootstrap re-sampling method proposed by Koehn (2004). Statistics of the data sets are summarized in Table 3.

Data set	#Sentences	#Words
MT03 (dev)	919	23,782
MT04 (test)	1,788	47,762
MT05 (test)	1,082	29,258

Table 3: Data set statistics.

We use the parallel data available for the NIST 2008 constrained track of Chinese-to-English machine translation task as bilingual training data, which contains 5.1M sentence pairs, 128M Chinese words and 147M English words after pre-processing. GIZA++ toolkit (Och and Ney, 2003) is used to perform word alignment in both directions with default settings, and the intersect-diag-grow method is used to generate symmetric word alignment refinement. The language model used for all systems is a 5-gram model trained with the English part of bilingual data and Xinhua portion of LDC English Gigaword corpus version 3. In experiments, multiple language model features with the order ranging from 2 to 5 can be easily obtained from the 5-gram one without retraining.

4.2 System Description

Theoretically our method is applicable to all linear model –based SMT systems. In our experiments, two in-house developed systems are used to validate our method. The first one (**SYS1**) is a system based on the hierarchical phrase-based model as proposed in (Chiang, 2005). Phrasal rules are extracted from all bilingual sentence pairs, while hierarchical rules with variables are extracted from selected data sets including LDC2003E14, LDC2003E07, LDC2005T06 and LDC2005T10, which contain around 350,000 sentence pairs, 8.8M Chinese words and 10.3M English words. The second one (**SYS2**) is a re-implementation of a phrase-based decoder with lexicalized reordering model based on maximum entropy principle proposed by Xiong et al. (2006). All bilingual data are used to extract phrases up to length 3 on the source side.

In following experiments, we only consider removing common features shared by both baseline systems for feature subspace generation. Rule penalty feature and lexicalized reordering feature, which are particular to SYS1 and SYS2, are not used. We list the features in consideration as follows:

- ***PEF*** and ***PFE***: phrase translation probabilities $p(e|f)$ and $p(f|e)$
- ***PEFLEX*** and ***PFELEX***: lexical weights $p_{lex}(e|f)$ and $p_{lex}(f|e)$
- ***PP***: phrase penalty
- ***WP***: word penalty
- ***BLP***: bi-lexicon pair counting how many entries of a conventional lexicon co-occurring in a given translation pair
- ***LM-n***: language model with order *n*

Based on the principle described in Section 3.1, we generate a number of feature subspaces for each baseline system as follows:

- *For non-LM features* (*PEF, PFE, PEFLEX, PFELEX, PP*, *WP* and *BLP*), we remove one of them from the full feature space each time. Thus 7 feature subspaces are generated, which are denoted as FS_{-PEF}, FS_{-PFE}, $FS_{-PEFLEX}$, $FS_{-PFELEX}$, FS_{-PP}, FS_{-WP} and FS_{-BLP} respectively. The 5-gram LM feature is used in each of them.
- *For LM features* (*LM-n*), we change the order from 2 to 5 with all the other non-LM features present. Thus 4 LM-related feature subspaces are generated, which are denoted as FS_{LM-2}, FS_{LM-3}, FS_{LM-4} and FS_{LM-5} respectively. FS_{LM-5} is essentially the full feature space of baseline system.

For each baseline system, we construct a total of 11 sub-systems by using above feature subspaces. The baseline system is also contained within them because of using FS_{LM-5}. We call all sub-systems are *non-baseline sub-systems* except the one derived by using FS_{LM-5}.

By default, the beam size of 60 is used for all systems in our experiments. The size of *n*-best list is set to 20 for each sub-system, and for baseline systems, this size is set to 220, which equals to the size of the combined *n*-best list generated by total 11 sub-systems. The order of *n*-gram agreement and disagreement features used in sentence-level combination model ranges from unigram to 4-gram.

4.3 Evaluation of Oracle Translations

We first evaluate the oracle performance on the *n*-best lists of baseline systems and on the combined *n*-best lists of sub-systems generated from each baseline system.

The oracle translations are obtained by using the metric of sentence-level BLEU score (Ye et al., 2007). Table 4 shows the evaluation results, in which ***Baseline*** stands for baseline system with a 5-gram LM feature, and ***FS*** stands for 11 sub-systems derived from the baseline system.

		SYS1	SYS2
		BLEU/TER	BLEU/TER
MT04	*Baseline*	49.68/0.6411	49.50/0.6349
	FS	**51.05/0.6089**	**50.53/0.6056**
MT05	*Baseline*	48.89/0.5946	48.37/0.5944
	FS	**50.69/0.5695**	**49.81/0.5684**

Table 4: Oracle BLEU and TER scores on baseline systems and their generated sub-systems.

For both SYS1 and SYS2, feature subspace method achieves higher oracle BLEU and lower TER scores on both MT04 and MT05 test sets, which gives the feature subspace method more potential to achieve higher performance than the baseline systems.

We then investigate the ratio of translation candidates in the combined *n*-best lists of non-baseline sub-systems that are not included in the baseline's *n*-best list. Table 5 shows the statistics.

	MT04	MT05
SYS1	69.71%	69.69%
SYS2	59.07%	58.54%

Table 5: Ratio of unique translation candidates from non-baseline sub-systems.

From Table 5 we can see that only less than half of the translation candidates of sub-systems overlap with those the of baseline systems. This result, together with the oracle BLEU and TER score estimation, helps eliminate the concern that no diversities or better translation candidates can be obtained by using sub-systems.

4.4 Feature Subspace Method on Single SMT System

Next we validate the effect of feature subspace method on single SMT systems.

Figure 1 shows the evaluation results of different systems on the MT05 test set. From the figure we can see that the overall accuracy of baseline systems is better than any of their derived sub-systems, and except the sub-system derived by using FS_{LM-2}, the performance of all the systems are fairly similar.

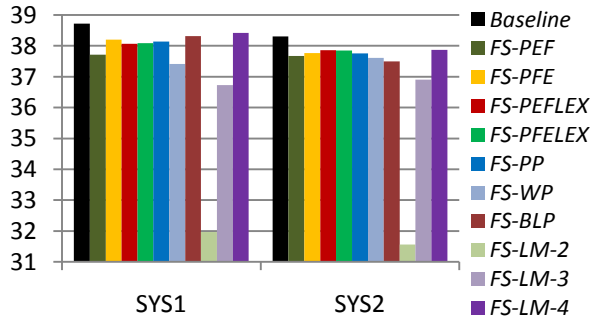

Figure 1: Performances of different systems.

We then evaluate the system combination method proposed in Section 3.2 with all the sub-systems for each baseline system. Table 6 shows the results on both MT04 and MT05 data sets, in which ***FS-Comb*** denotes the system combination using 11 sub-systems.

From Table 6 we can see that by using *FS-Comb* we obtain about 1.1~1.3 points of BLEU gains over baseline systems. We also include in Table 6 the results for ***Baseline+mLM***, which stands for the augmented baseline system as described in Section 3.1 using a bunch of LM features from bigram to 5-gram. It can be seen that both augmented baseline systems outperform their corresponding baseline systems slightly but consistently on both data sets.

		MT04	MT05
SYS1	*Baseline*	39.07	38.72
	Baseline+mLM	39.34+	39.14+
	FS-Comb	**40.43**++	**39.79**++
SYS2	*Baseline*	38.84	38.30
	Baseline+mLM	38.95*	38.63+
	FS-Comb	**39.92**++	**39.49**++

Table 6: Translation results of *Baseline*, *Baseline+mLM* and *FS-Comb* (+: significant better than baseline system with $p < 0.05$; ++: significant better than baseline system with $p < 0.01$; *: no significant improvement).

We also investigate the results when we incrementally add the *n*-best list of each sub-system into a candidate pool to see the effects when different numbers of sub-systems are used in combination. In order to decide the sequence of sub-systems to add, we first evaluate the performance of pair-wise combinations between each sub-system and its baseline system on the development set. That is, for each sub-system, we combine its *n*-best list with the *n*-best list of its baseline system and perform system combination for MT03 data set. Then we rank the sub-systems by the pair-wise combination performance from high to low, and use this ranking as the sequence to add *n*-best lists of sub-systems. Each time when a new *n*-best list is added, the combination performance based on the enlarged candidate pool is evaluated. Figure 2 shows the results on both MT04 and MT05 test sets, in which ***SYS1-fs*** and ***SYS2-fs*** denote the sub-systems derived from SYS1 and SYS2 respectively, and X-axis is the number of sub-systems used for combination each time and Y-axis is the BLEU score. From the figure we can see that although in some cases the performance slightly drops when a new sub-system is added, generally using more sub-systems always leads to better results.

Next we examine the performance of baseline systems when different beam sizes are used in decoding. The results on MT05 test set are shown in Figure3, where X-axis is the beam size. In Figure 3, ***SYS1+mLM*** and ***SYS2+mLM*** denote augmented baseline systems of SYS1 and SYS2 with multiple LM features.

From Figure 3 we can see that augmented baseline systems (with multiple LM features) outperform the baseline systems (with only one LM feature) for all beam sizes ranging from 20 to 220. In this experiment we did not observe any significant performance improvements when using larger beam sizes than the default setting, but using more sub-systems in combination almost always bring improvements.

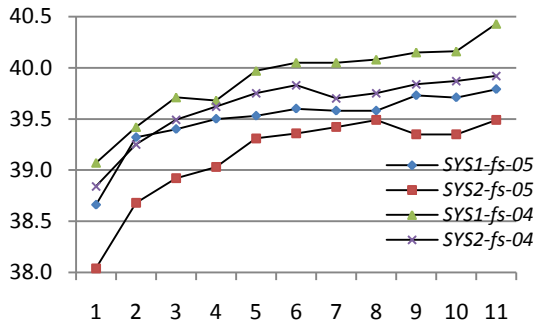

Figure 2: Performances on different numbers of sub-systems.

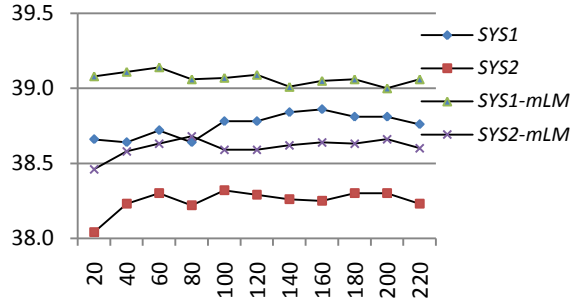

Figure 3: Performances on different beam sizes.

	MT04	MT05
SYS1-fs	44.63%	46.12%
SYS2-fs	47.54%	44.73%

Table 7: Ratio of final translations coming from non-baseline sub-systems.

Finally, we investigate the ratio of final translations coming from the *n*-best lists of non-baseline sub-systems only. Table 7 shows the results on both MT04 and MT05 test sets, which indicate that almost half of the final translations are contributed by the non-baseline sub-systems.

4.5 The Impact of *n*-best List Size

In order to find the optimal size of *n*-best list for combination, we compare the combination results of using list sizes from 10-best up to 500-best for each sub-system.

In this experiment, system combination was performed on the combined *n*-best list from total 11 sub-systems with different list size each time. Figure 4 shows the results on the MT03 dev set and the MT04 and MT05 test sets for both SYS1 and SYS2. X-axis is the *n*-best list size of each sub-system.

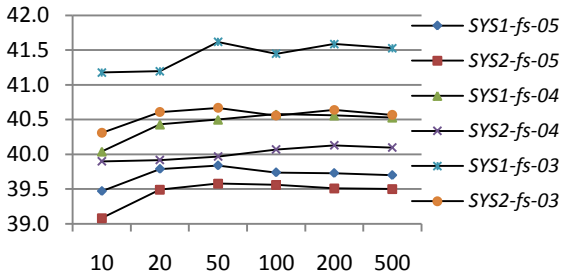

Figure 4: Performances on different *n*-best sizes.

We can see from the figure that for all data sets the optimal *n*-best list size is around 50, but the improvements are not significant over the results when 20-best translations are used. The reason for the small optimal *n*-best list size could be that the low-rank hypotheses might introduce more noises into the combined translation candidate pool for sentence-level combination (Hasan et al., 2007; Hildebrand and Vogel, 2008).

4.6 Feature Subspace Method on Multiple SMT Systems

In the last experiment, we investigate the effect of feature subspace method when multiple SMT systems are used in system combination.

Evaluation results are reported in Table 8. The system combination method described in Section 3.2 is used to combine outputs from two baseline systems (with only one 5-gram LM feature) and sub-systems generated from both baseline systems (22 in total), with their results denoted as ***Baseline Comb* (*both*)** and ***FS Comb* (*both*)** respectively. We also include the combination results of sub-systems based on one baseline system for reference in the table.

On both MT04 and MT05 test sets, the results of system combination based on sub-systems are significantly better than those of baseline systems, which show that our method can also help with system combination when more than one system are used. We can also see that using multiple systems based on different SMT models and using our subspace based method can help each other: the best performance can only be achieved when both are employed.

	MT04	MT05
Baseline Comb (*both*)	39.98	39.43
FS-Comb (SYS1)	40.43	39.79
FS-Comb (SYS2)	39.92	39.49
FS Comb (*both*)	**40.96**	**40.38**

Table 8: Performances of sentence-level combination on multiple SMT systems.

5 Conclusion

In this paper, we have presented a novel and effective *Feature Subspace* method for the construction of an ensemble of machine translation systems based on a baseline SMT model which can be formulated as a standard linear function. Each system within the ensemble is based on a subset of features derived from the baseline model, and the resulting ensemble can be used in system combination to improve translation quality. Experimental results on NIST Chinese-to-English translation tasks show that our method can bring significant improvements to two baseline systems with state-of-the-art performance, and it is expected that our method can be employed to improve any linear model -based SMT systems. There is still much room for improvements in the current work. For example, we still use a simple one-feature difference principle for feature subspace generation. In the future, we will explore more possibilities for feature subspaces selection and experiment with our method in a word-level system combination model.

Abstract

Current system combination methods usually use confusion networks to find consensus translations among different systems. Requiring one-to-one mappings between the words in candidate translations, confusion networks have difficulty in handling more general situations in which several words are connected to another several words. Instead, we propose a lattice-based system combination model that allows for such phrase alignments and uses *lattice*s to encode all candidate translations. Experiments show that our approach achieves significant improvements over the state-of-the-art baseline system on Chinese-to-English translation test sets.

1 Introduction

System combination aims to find consensus translations among different machine translation systems. It has been proven that such consensus translations are usually better than the output of individual systems (Frederking and Nirenburg, 1994).

In recent several years, the system combination methods based on confusion networks developed rapidly (Bangalore et al., 2001; Matusov et al., 2006; Sim et al., 2007; Rosti et al., 2007a; Rosti et al., 2007b; Rosti et al., 2008; He et al., 2008), which show state-of-the-art performance in benchmarks. A confusion network consists of a sequence of sets of candidate words. Each candidate word is associated with a score. The optimal consensus translation can be obtained by selecting one word from each set to maximizing the overall score.

To construct a confusion network, one first need to choose one of the hypotheses (i.e., candidate translations) as the backbone (also called "skeleton" in the literature) and then decide the word alignments of other hypotheses to the backbone. Hypothesis alignment plays a crucial role in confusion-network-based system combination because it has a direct effect on selecting consensus translations.

However, a confusion network is restricted in such a way that only 1-to-1 mappings are allowed in hypothesis alignment. This is not the fact even for word alignments between the same languages. It is more common that several words are connected to another several words. For example, "be capable of" and "be able to" have the same meaning. Although confusion-network-based approaches resort to inserting null words to alleviate this problem, they face the risk of producing degenerate translations such as "be capable to" and "be able of".

In this paper, we propose a new system combination method based on lattices. As a more general form of confusion network, a lattice is capable of describing arbitrary mappings in hypothesis alignment. In a lattice, each edge is associated with a sequence of words rather than a single word. Therefore, we select phrases instead of words in each candidate set and minimize the chance to produce unexpected translations such as "be capable to". We compared our approach with the state-of-the-art confusion-network-based system (He et al., 2008) and achieved a significant absolute improvement of 1.23 BLEU points on the NIST 2005 Chinese-to-English test set and 0.93 BLEU point on the NIST 2008 Chinese-to-English test set.

Figure 1: Comparison of a confusion network and a lattice.

2 Background

2.1 Confusion Network and Lattice

We use an example shown in Figure 1 to illustrate our idea. Suppose that there are three hypotheses:

He feels like apples
He prefer apples
He is fond of apples

We choose the first sentence as the backbone. Then, we perform hypothesis alignment to build a confusion network, as shown in Figure 1(a). Note that although "*feels like*" has the same meaning with "*is fond of*", a confusion network only allows for one-to-one mappings. In the confusion network shown in Figure 1(c), several null words ε are inserted to ensure that each hypothesis has the same length. As each edge in the confusion network only has a single word, it is possible to produce inappropriate translations such as "*He is like of apples*".

In contrast, we allow many-to-many mappings in the hypothesis alignment shown in Figure 2(b). For example, "*like*" is aligned to three words: "*is*", "*fond*", and "*of*". Then, we use a lattice shown in Figure 1(d) to represent all possible candidate translations. Note that the phrase "*is fond of*" is attached to an edge. Now, it is unlikely to obtain a translation like "*He is like of apples*".

A lattice $G = \langle V, E \rangle$ is a directed acyclic graph, formally a weighted finite state automation (FSA), where V is the set of nodes and E is the set of edges. The nodes in a lattice are usually labeled according to an appropriate numbering to reflect how to produce a translation. Each edge in a lattice is attached with a sequence of words as well as the associated probability.

As lattice is a more general form of confusion network (Dyer et al., 2008), we expect that replacing confusion networks with lattices will further improve system combination.

2.2 IHMM-based Alignment Method

Since the candidate hypotheses are aligned using Indirect-HMM-based (IHMM-based) alignment method (He et al., 2008) in both direction, we briefly review the IHMM-based alignment method first. Take the direction that the hypothesis is aligned to the backbone as an example. The conditional probability that the hypothesis is generated by the backbone is given by

$$p({e'_1}^J|e_1^I) = \sum_{a_1^J} \prod_{j=1}^{J} [p(a_j|a_{j-1}, I) p(e'_j|e_{a_j})] l \quad (1)$$

Where $e_1^I = (e_1, ..., e_I)$ is the backbone, ${e'}_1^J = (e'_1, ..., e'_J)$ is a hypothesis aligned to e_1^I, and $a_1^J = (a_1, .., a_J)$ is the alignment that specifies the position of backbone word that each hypothesis word is aligned to.

The translation probability $p(e'_j|e_i)$ is a linear interpolation of semantic similarity $p_{sem}(e'_j|e_i)$ and surface similarity $p_{sur}(e'_j|e_i)$ and α is the interpolation factor:

$$p(e'_j|e_i) = \alpha \cdot p_{sem}(e'_j|e_i) + (1-\alpha) \cdot p_{sur}(e'_j|e_i) \quad (2)$$

The semantic similarity model is derived by using the source word sequence as a hidden layer, so the bilingual dictionary is necessary. The semantic sim-

ilarity model is given by

$$p_{sem}(e'_j|e_i) = \sum_{k=0}^{K} p(f_k|e_i)p(e'_j|f_k, e_i) \approx \sum_{k=0}^{K} p(f_k|e_i)p(e'_j|f_k) \quad (3)$$

The surface similarity model is estimated by calculating the literal matching rate:

$$p_{sur}(e'_j|e_i) = \exp\{\rho \cdot [s(e'_j, e_i) - 1]\} \quad (4)$$

where $s(e'_j, e_i)$ is given by

$$s(e'_j, e_i) = \frac{M(e'_j, e_i)}{\max(|e'_j|, |e_i|)} \quad (5)$$

where $M(e'_j, e_i)$ is the length of the longest matched prefix (LMP) and ρ is a smoothing factor that specifies the mapping.

The distortion probability $p(a_j = i|a_{j-1} = i', I)$ is estimated by only considering the jump distance:

$$p(i|i', I) = \frac{c(i - i')}{\sum_{i=1}^{I} c(l - i')} \quad (6)$$

The distortion parameters $c(d)$ are grouped into 11 buckets, $c(\leq -4)$, $c(-3)$, ..., $c(0)$, ..., $c(5)$, $c(\geq 6)$. Since the alignments are in the same language, the distortion model favor monotonic alignments and penalize non-monotonic alignments. It is given in a intuitive way

$$c(d) = (1 + |d - 1|)^{-K}, d = -4, ..., 6 \quad (7)$$

where K is tuned on held-out data.

Also the probability p_0 of jumping to a $null$ word state is tuned on held-out data. So the overall distortion model becomes

$$p(i|i', I) = \begin{cases} p_0 & \text{if i = null state} \\ (1 - p_0) \cdot p(i|i', I) & \text{otherwise} \end{cases}$$

3 Lattice-based System Combination Model

Lattice-based system combination involves the following steps:

(1) Collect the hypotheses from the candidate systems.

(2) Choose the backbone from the hypotheses. This is performed using a sentence-level Minimum Bayes Risk (MBR) method. The hypothesis with the minimum cost of edits against all hypotheses is selected. The backbone is significant for it influences not only the word order, but also the following alignments. The backbone is selected as follows:

$$E_B = \underset{E' \in \mathbf{E}}{\operatorname{argmin}} \sum_{E \in \mathbf{E}} TER(E', E) \quad (8)$$

(3) Get the alignments of the backbone and hypothesis pairs. First, each pair is aligned in both directions using the IHMM-based alignment method. In the IHMM alignment model, bilingual dictionaries in both directions are indispensable. Then, we apply a grow-diag-final algorithm which is widely used in bilingual phrase extraction (Koehn et al., 2003) to monolingual alignments. The bidirectional alignments are combined to one resorting to the grow-diag-final algorithm, allowing n-to-n mappings.

(4)Normalize the alignment pairs. The word order of the backbone determines the word order of consensus outputs, so the word order of hypotheses must be consistent with that of the backbone. All words of a hypotheses are reordered according to the alignment to the backbone. For a word aligned to $null$, an actual $null$ word may be inserted to the proper position. The *alignment unit*s are extracted first and then the hypothesis words in each unit are shifted as a whole.

(5) Construct the lattice in the light of phrase pairs extracted on the normalized alignment pairs. The expression ability of the lattice depends on the phrase pairs.

(6) Decode the lattice using a model similar to the log-linear model.

The confusion-network-based system combination model goes in a similar way. The first two steps are the same as the lattice-based model. The difference is that the hypothesis pairs are aligned just in one direction due to the expression limit of the confusion network. As a result, the normalized alignments only contain 1-to-1 mappings (Actual $null$ words are also needed in the case of null alignment). In the following, we will give more details about the steps which are different in the two models.

4 Lattice Construction

Unlike a confusion network that operates words only, a lattice allows for phrase pairs. So phrase pairs must be extracted before constructing a lattice. A major difficulty in extracting phrase pairs is that the word order of hypotheses is not consistent with that of the backbone. As a result, hypothesis words belonging to a phrase pair may be discontinuous. Before phrase pairs are extracted, the hypothesis words should be normalized to make sure the words in a phrase pair is continuous. We call a phrase pair before normalization a *alignment unit*.

The problem mentioned above is shown in Figure 2. In Figure 2 (a), although ($e'_1e'_3$, e_2) should be a phrase pair, but "e'_1" and "e'_3" are discontinuous, so the phrase pair can not be extracted. Only after the words of the hypothesis are reordered according to the corresponding words in the backbone as shown in Figure 2 (b), "e'_1" and "e'_3" become continuous and the phrase pair ($e'_1e'_3$, e_2) can be extracted. The procedure of reordering is called *alignment normalization*

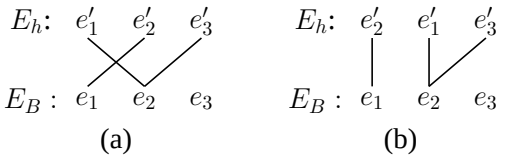

Figure 2: An example of alignment units

4.1 Alignment Normalization

After the final alignments are generated in the grow-diag-final algorithm, *minimum alignment unit*s are extracted. The hypothesis words of an alignment unit are packed as a whole in shift operations.

See the example in Figure 2 (a) first. All minimum alignment units are as follows: (e'_2, e_1), ($e'_1e'_3$, e_2) and (ε, e_3). ($e'_1e'_2e'_3$, e_1e_2) is an alignment unit, but not a minimum alignment unit.

Let $\bar{a}_i = (\bar{e}'_i, \bar{e}_i)$ denote a minimum alignment unit, and assume that the word string $\bar{e}'_i$ covers words e'_{i_1} ,..., e'_{i_m} on the hypothesis side, and the word string $\bar{e}_i$ covers the consecutive words e_{i_1} ,..., e_{i_n} on the backbone side. In an alignment unit, the word string on the hypothesis side can be discontinuous. The minimum unit $\bar{a}_i = (\bar{e}'_i, \bar{e}_i)$ must observe the following rules:

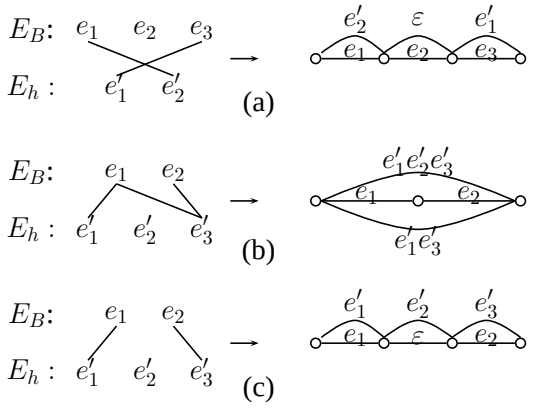

Figure 3: Different cases of $null$ insertion

- $\forall\ e'_{i_k} \in \bar{e}'_i, \quad e_{a'_{i_k}} \in \bar{e}_i$
- $\forall\ e_{i_k} \in \bar{e}_i, \quad e'_{a_{i_k}} = null$ or $e'_{a_{i_k}} \in \bar{e}'_i$
- $\nexists\ \bar{a}_j = (\bar{e}'_j, \bar{e}_j), \quad \bar{e}_j = e_{i_1}, ..., e_{i_k}$ or $\bar{e}_j = e_{i_k}, ..., e_{i_n}, \quad k \in [1, n]$

Where a'_{i_k} denotes the position of the word in the backbone that e'_{i_k} is aligned to, and a_{i_k} denotes the position of the word in the hypothesis that e_{i_k} is aligned to.

An actual $null$ word may be inserted to a proper position if a word, either from the hypothesis or from the backbone, is aligned to $null$. In this way, the minimum alignment set is extended to an alignment unit set, which includes not only minimum alignment units but also alignment units which are generated by adding $null$ words to minimum alignment units. In general, the following three conditions should be taken into consideration:

- A backbone word is aligned to $null$. A $null$ word is inserted to the hypothesis as shown in Figure 3 (a).
- A hypothesis word is aligned to $null$ and it is between the span of a minimum alignment unit. A new alignment unit is generated by inserting the hypothesis word aligned to null to the minimum alignment unit. The new hypothesis string must remain the original word order of the hypothesis. It is illustrated in Figure 3 (b).
- A hypothesis word is aligned to $null$ and it is not between the hypothesis span of any minimum alignment unit. In this case, a $null$ word

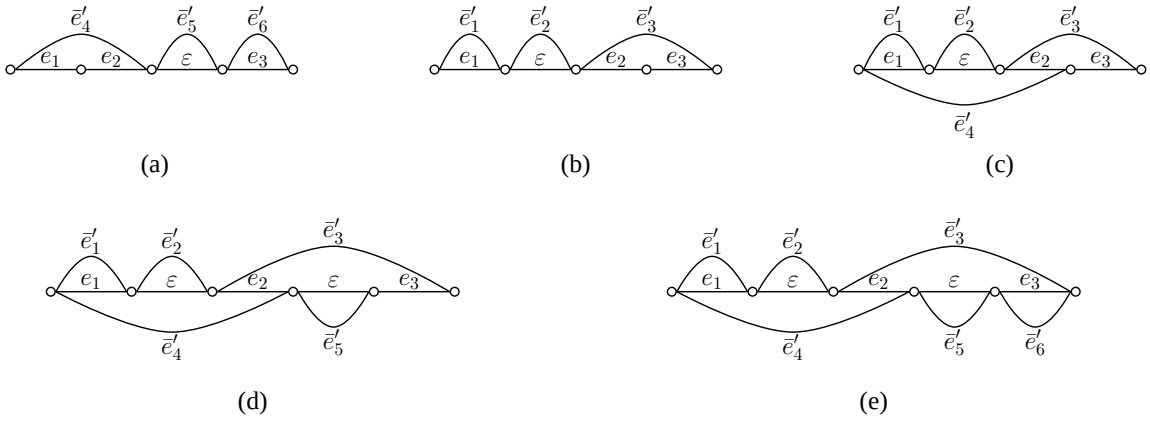

Figure 4: A toy instance of lattice construction

are inserted to the backbone. This is shown in Figure 3 (c).

4.2 Lattice Construction Algorithm

The lattice is constructed by adding the normalized alignment pairs incrementally. One backbone arc in a lattice can only span one backbone word. In contrast, all hypothesis words in an alignment unit must be packed into one hypothesis arc. First the lattice is initialized with a normalized alignment pair. Then given all other alignment pairs one by one, the lattice is modified dynamically by adding the hypothesis words of an alignment pair in a left-to-right fashion.

A toy instance is given in Figure 4 to illustrate the procedure of lattice construction. Assume the current inputs are: an alignment pair as in Figure 4 (a), and a lattice as in Figure 4 (b). The backbone words of the alignment pair are compared to the backbone words of the lattice one by one. The procedure is as follows:

- e_1 is compared with e_1. Since they are the same, the hypothesis arc $\bar{e}'_4$, which comes from the same node with e_1 in the alignment pair, is compared with the hypothesis arc $\bar{e}'_1$, which comes from the same node with e_1 in the lattice. The two hypothesis arcs are not the same, so $\bar{e}'_4$ is added to the lattice as shown in Figure 4(c). Both go to the next backbone words.

- e_2 is compared with ε. The lattice remains the same. The lattice goes to the next backbone word e_2.

- e_2 is compared with e_2. There is no hypothesis arc coming from the same node with the bone arc e_2 in the alignment pair, so the lattice remains the same. Both go to the next backbone words.

- ε is compared with e_3. A $null$ backbone arc is inserted into the lattice between e_2 and e_3. The hypothesis arc $\bar{e}'_5$ is inserted to the lattice, too. The modified lattice is shown in Figure 4(d). The alignment pair goes to the next backbone word e_3.

- e_3 is compared with e_3. For they are the same and there is no hypothesis arc $\bar{e}'_6$ in the lattice, $\bar{e}'_6$ is inserted to the lattice as in Figure 4(e).

- Both arrive at the end and it is the turn of the next alignment pair.

When comparing a backbone word of the given alignment pair with a backbone word of the lattice, the following three cases should be handled:

- The current backbone word of the given alignment pair is a $null$ word while the current backbone word of the lattice is not. A $null$ backbone word is inserted to the lattice.

- The current backbone word of the lattice is a $null$ word while the current word of the given alignment pair is not. The current $null$ backbone word of the lattice is skipped with nothing to do. The next backbone word of the lattice is compared with the current backbone word of the given alignment pair.

Algorithm 1 Lattice construction algorithm.

1: **Input**: alignment pairs $\{p_n\}_{n=1}^{N}$
2: $L \leftarrow p_1$
3: $Unique(L)$
4: **for** $n \leftarrow 2$ .. N **do**
5: $pnode = p_n \cdot first$
6: $lnode = L \cdot first$
7: **while** $pnode \cdot barcnext \neq NULL$ **do**
8: **if** $lnode \cdot barcnext = NULL$ or $pnode \cdot bword = null$ and $lnode \cdot bword \neq null$ **then**
9: INSERTBARC($lnode$, $null$)
10: $pnode = pnode \cdot barcnext$
11: **else**
12: **if** $pnode \cdot bword \neq null$ and $lnode \cdot bword = null$ **then**
13: $lnode = lnode \cdot barcnext$
14: **else**
15: **for** each $harc$ of $pnode$ **do**
16: **if** NotExist($lnode, pnode \cdot harc$) **then**
17: INSERTHARC($lnode$, $pnode \cdot harc$)
18: $pnode = pnode \cdot barcnext$
19: $lnode = lnode \cdot barcnext$
20: **Output:** lattice L

- The current backbone words of the given alignment pair and the lattice are the same. Let $\{harc_l\}$ denotes the set of hypothesis arcs, which come from the same node with the current backbone arc in the lattice, and $harc_h$ denotes one of the corresponding hypothesis arcs in the given alignment pair. In the $\{harc_l\}$, if there is no arc which is the same with the $harc_h$, a hypothesis arc projecting to $harc_h$ is added to the lattice.

The algorithm of constructing a lattice is illustrated in Algorithm 1. The backbone words of the alignment pair and the lattice are processed one by one in a left-to-right manner. Line 2 initializes the lattice with the first alignment pair, and Line 3 removes the hypothesis arc which contains the same words with the backbone arc. $barc$ denotes the backbone arc, storing one backbone word only, and $harc$ denotes the hypothesis arc, storing the hypothesis words. For there may be many alignment units span the same backbone word range, there may be more than one $harc$ coming from one node. Line $8-10$ consider the condition 1 and function *InsertBarc* in Line 9 inserts a $null$ bone arc to the position right before the current node. Line $12-13$ deal with condition 2 and jump to the next backbone word of the lattice. Line $15-19$ handle condition 3 and function *InsertHarc* inserts to the lattice a $harc$ with the same hypothesis words and the same backbone word span with the current hypothesis arc.

5 Decoding

In confusion network decoding, a translation is generated by traveling all the nodes from left to right. So a translation path contains all the nodes. While in lattice decoding, a translation path may skip some nodes as some hypothesis arcs may cross more than one backbone arc.

Similar to the features in Rosti et al. (2007a), the features adopted by lattice-based model are arc posterior probability, language model probability, the number of $null$ arcs, the number of hypothesis arcs possessing more than one non-null word and the number of all non-null words. The features are combined in a log-linear model with the arc posterior probabilities being processed specially as follows:

$$\begin{aligned}\log p(\mathbf{e}/\mathbf{f}) = &\sum_{i=1}^{N_{arc}} \log (\sum_{s=1}^{N_s} \lambda_s p_s(arc)) \\ &+ \zeta L(\mathbf{e}) + \alpha N_{nullarc}(\mathbf{e}) \\ &+ \beta N_{longarc}(\mathbf{e}) + \gamma N_{word}(\mathbf{e})\end{aligned} \tag{9}$$

where $\mathbf{f}$ denotes the source sentence, $\mathbf{e}$ denotes a translation generated by the lattice-based system, N_{arc} is the number of arcs the path of $\mathbf{e}$ covers, N_s is the number of candidate systems and λ_s is the weight of system s. ζ is the language model weight and $L(\mathbf{e})$ is the LM log-probability. $N_{nullarcs}(\mathbf{e})$ is the number of the arcs which only contain a $null$ word, and $N_{longarc}(\mathbf{e})$ is the number of the arcs which store more than one non-null word. The above two numbers are gotten by counting both backbone arcs and hypothesis arcs. α and β are the corresponding weights of the numbers, respectively. $N_{word}(\mathbf{e})$ is the non-null word number and γ is its weight.

Each arc has different confidences concerned with different systems, and the confidence of system s is denoted by $p_s(arc)$. $p_s(arc)$ is increased by

$1/(k+1)$ if the hypothesis ranking k in the system s contains the arc (Rosti et al., 2007a; He et al., 2008).

Cube pruning algorithm with beam search is employed to search for the consensus output (Huang and Chiang, 2005). The nodes in the lattice are searched in a topological order and each node retains a list of N best candidate partial translations.

6 Experiments

The candidate systems participating in the system combination are as listed in Table 1: System A is a BTG-based system using a MaxEnt-based reordering model; System B is a hierarchical phrase-based system; System C is the Moses decoder (Koehn et al., 2007); System D is a syntax-based system. 10-best hypotheses from each candidate system on the dev and test sets were collected as the input of the system combination.

In our experiments, the weights were all tuned on the NIST MT02 Chinese-to-English test set, including 878 sentences, and the test data was the NIST MT05 Chinese-to-English test set, including 1082 sentences, except the experiments in Table 2. A 5-gram language model was used which was trained on the XinHua portion of Gigaword corpus. The results were all reported in case sensitive BLEU score and the weights were tuned in Powell's method to maximum BLEU score. The IHMM-based alignment module was implemented according to He et al. (2008), He (2007) and Vogel et al. (1996). In all experiments, the parameters for IHMM-based alignment module were set to: the smoothing factor for the surface similarity model, $\rho = 3$; the controlling factor for the distortion model, $K = 2$.

6.1 Comparison with Confusion-network-based model

In order to compare the lattice-based system with the confusion-network-based system fairly, we used IHMM-based system combination model on behalf of the confusion-network-based model described in He et al. (2008). In both lattice-based and IHMM-based systems, the bilingual dictionaries were extracted on the FBIS data set which included 289K sentence pairs. The interpolation factor of the similarity model was set to $\alpha = 0.1$.

The results are shown in Table 1. *IHMM* stands for the IHMM-based model and *Lattice* stands for the lattice-based model. On the dev set, the lattice-based system was 3.92 BLEU points higher than the best single system and 0.36 BLEU point higher than the IHMM-based system. On the test set, the lattice-based system got an absolute improvement by 3.73 BLEU points over the best single system and 1.23 BLEU points over the IHMM-based system.

System	MT02 BLEU%	MT05 BLEU%
SystemA	31.93	30.68
SystemB	32.16	32.07
SystemC	32.09	31.64
SystemD	33.37	31.26
IHMM	36.93	34.57
Lattice	37.29	35.80

Table 1: Results on the MT02 and MT05 test sets

The results on another test sets are reported in Table 2. The parameters were tuned on the newswire part of NIST MT06 Chinese-to-English test set, including 616 sentences, and the test set was NIST MT08 Chinese-to-English test set, including 1357 sentences. The BLEU score of the lattice-based system is 0.93 BLEU point higher than the IHMM-based system and 3.0 BLEU points higher than the best single system.

System	MT06 BLEU%	MT08 BLEU%
SystemA	32.51	25.63
SystemB	31.43	26.32
SystemC	31.50	23.43
SystemD	32.41	26.28
IHMM	36.05	28.39
Lattice	36.53	29.32

Table 2: Results on the MT06 and MT08 test sets

We take a real example from the output of the two systems (in Table 3) to show that higher BLEU scores correspond to better alignments and better translations. The translation of System C is selected as the backbone. From Table 3, we can see that because of 1-to-1 mappings, "*Russia*" is aligned to "*Russian*" and "*'s*" to "*null*" in the IHMM-based model, which leads to the error translation "*Russian*

Source:	俄罗斯 国营 石油 公司 正 与 俄罗斯 国营 瓦斯 公司 进行合并
SystemA:	Russia merger of state-owned oil company and the state-run gas company in Russia
SystemB:	Russia 's state-owned oil company is working with Russia 's state-run gas company mergers
SystemC:	Russian state-run oil company is combined with the Russian state-run gas company
SystemD:	Russia 's state-owned oil companies are combined with Russia 's state-run gas company
IHMM:	Russian 's state-owned oil company working with Russia 's state-run gas company
Lattice:	Russia 's state-owned oil company is combined with the Russian state-run gas company

Table 3: A real translation example

's". Instead, "*Russia 's*" is together aligned to "*Russian*" in the lattice-based model. Also due to 1-to-1 mappings, $null$ word aligned to "*is*" is inserted. As a result, "*is*" is missed in the output of IHMM-based model. In contrast, in the lattice-based system, "*is working with*" are aligned to "*is combined with*", forming a phrase pair.

6.2 Effect of Dictionary Scale

The dictionary is important to the semantic similarity model in IHMM-based alignment method. We evaluated the effect of the dictionary scale by using dictionaries extracted on different data sets. The dictionaries were respectively extracted on similar data sets: 30K sentence pairs, 60K sentence pairs, 289K sentence pairs (FBIS corpus) and 2500K sentence pairs. The results are illustrated in Table 4. In order to demonstrate the effect of the dictionary size clearly, the interpolation factor of similarity model was all set to $\alpha = 0.1$.

From Table 4, we can see that when the corpus size rise from 30k to 60k, the improvements were not obvious both on the dev set and on the test set. As the corpus was expanded to 289K, although on the dev set, the result was only 0.2 BLEU point higher, on the test set, it was 0.63 BLEU point higher. As the corpus size was up to 2500K, the BLEU scores both on the dev and test sets declined. The reason is that, on one hand, there are more noise on the 2500K sentence pairs; on the other hand, the 289K sentence pairs cover most of the words appearing on the test set. So we can conclude that in order to get better results, the dictionary scale must be up to some certain scale. If the dictionary is much smaller, the result will be impacted dramatically.

	MT02 BLEU%	MT05 BLEU%
30k	36.94	35.14
60k	37.09	35.17
289k	37.29	35.80
2500k	37.14	35.62

Table 4: Effect of dictionary scale

6.3 Effect of Semantic Alignments

For the IHMM-based alignment method, the translation probability of an English word pair is computed using a linear interpolation of the semantic similarity and the surface similarity. So the two similarity models decide the translation probability together and the proportion is controlled by the interpolation factor. We evaluated the effect of the two similarity models by varying the interpolation factor α.

We used the dictionaries extracted on the FBIS data set. The result is shown in Table 5. We got the best result with $\alpha = 0.1$. When we excluded the semantic similarity model ($\alpha = 0.0$) or excluded the surface similarity model ($\alpha = 1.0$), the performance became worse.

7 Conclusion

The alignment model plays an important role in system combination. Because of the expression limitation of confusion networks, only 1-to-1 mappings are employed in the confusion-network-based model. This paper proposes a lattice-based system combination model. As a general form of confusion networks, lattices can express n-to-n mappings. So a lattice-based model processes phrase pairs while

	MT02 BLEU%	MT05 BLEU%
$\alpha = 1.0$	36.41	34.92
$\alpha = 0.7$	37.21	35.65
$\alpha = 0.5$	36.43	35.02
$\alpha = 0.4$	37.14	35.55
$\alpha = 0.3$	36.75	35.66
$\alpha = 0.2$	36.81	35.55
$\alpha = 0.1$	37.29	35.80
$\alpha = 0.0$	36.45	35.14

Table 5: Effect of semantic alignments

a confusion-network-based model processes words only. As a result, phrase pairs must be extracted before constructing a lattice.

On NIST MT05 test set, the lattice-based system gave better results with an absolute improvement of 1.23 BLEU points over the confusion-network-based system (He et al., 2008) and 3.73 BLEU points over the best single system. On NIST MT08 test set, the lattice-based system outperformed the confusion-network-based system by 0.93 BLEU point and outperformed the best single system by 3.0 BLEU points.

Abstract

We present a scalable joint language model designed to utilize fine-grain syntactic tags. We discuss challenges such a design faces and describe our solutions that scale well to large tagsets and corpora. We advocate the use of relatively simple tags that do not require deep linguistic knowledge of the language but provide more structural information than POS tags and can be derived from automatically generated parse trees – a combination of properties that allows easy adoption of this model for new languages. We propose two fine-grain tagsets and evaluate our model using these tags, as well as POS tags and SuperARV tags in a speech recognition task and discuss future directions.

1 Introduction

In a number of language processing tasks, particularly automatic speech recognition (ASR) and machine translation (MT), there is the problem of selecting the best sequence of words from multiple hypotheses. This problem stems from the *noisy channel* approach to these applications. The noisy channel model states that the observed data, e.g., the acoustic signal, is the result of some input translated by some unknown stochastic process. Then the problem of finding the best sequence of words given the acoustic input, not approachable directly, is transformed into two separate models:

$$\underset{w_1^n}{argmax}\ p(w_1^n|A) = \underset{w_1^n}{argmax}\ p(A|w_1^n) \cdot p(w_1^n) \quad (1)$$

where A is the acoustic signal and w_1^n is a sequence of n words. $p(A|w_1^n)$ is called an acoustic model and $p(w_1^n)$ is the language model[1].

Typically, these applications use language models that compute the probability of a sequence in a generative way:

$$p(w_1^n) = \prod_{i=1}^{n} p(w_i|w_1^{i-1})$$

Approximation is required to keep the parameter space tractable. Most commonly the context is reduced to just a few immediately preceding words. This type of model is called an *ngram* model:

$$p(w_i|w_1^{i-1}) \approx p(w_i|w_{i-n+1}^{i-1})$$

Even with limited context, the parameter space can be quite sparse and requires sophisticated techniques for reliable probability estimation (Chen and Goodman, 1996). While the ngram models perform fairly well, they are only capable of capturing very shallow knowledge of the language.

There is extensive literature on a variety of methods that have been used to imbue models with syntactic and semantic information in different ways. These methods can be broadly categorized into two types:

- The first method uses surface words within its context, sometimes organizing them into deterministic classes. Models of this type include: (Brown et al., 1992; Zitouni, 2007), which use semantic word clustering, and (Bahl et al., 1990), which uses variable-length context.
- The other method adds stochastic variables to express the ambiguous nature of surface words[2]. To obtain the probability of the next

[1]Real applications use $argmax_{w_1^n}\ p(A|w_1^n) \cdot p(w_1^n)^\alpha \cdot n^\beta$ instead of Eq. 1, where α and β are set to optimize a heldout set.

[2]These variables have to be predicted by the model.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1114–1123,
Singapore, 6-7 August 2009.

word we need to sum over all assignments of the stochastic variables, as in Eq. 2.

$$p(w_i|w_1^{i-1}) = \sum_{t_1 \ldots t_i} p(w_i t_i|w_1^{i-1} t_1^{i-1}) \quad (2)$$
$$= \frac{\sum_{t_1 \ldots t_i} p(w_i t_i|w_1^{i-1} t_1^{i-1}) p(w_1^{i-1} t_1^{i-1})}{\sum_{t_1 \ldots t_{i-1}} p(w_1^{i-1} t_1^{i-1})}$$

Models of this type, which we call *joint* models since they essentially predict joint events of words and some random variable(s), include (Chelba and Jelinek, 2000) which used POS tags in combination with "parser instructions" for constructing a full parse tree in a left-to-right manner; (Wang et al., 2003) used SuperARVs (complex tuples of dependency information) without resolving the dependencies, thus called *almost parsing*; (Niesler and Woodland, 1996; Heeman, 1999) utilize part of speech (POS) tags. Note that some models reduce the context by making the following approximation:

$$p(w_i t_i|w_1^{i-1} t_1^{i-1}) \approx p(w_i|t_i) \cdot p(t_i|t_1^{i-1}) \quad (3)$$

thus, transforming the problem into a standard HMM application. However, these models perform poorly and have only been able to improve over the ngram model when interpolated with it (Niesler and Woodland, 1996).

Although joint models have the potential to better express variability in word usage through the introduction of additional latent variables, they do not necessarily perform better because the increased dimensionality of the context substantially increases the already complex problem of parameter estimation. The complexity of the space also makes computation of the probability a challenge because of space and time constraints. This makes the choice of the random variables a matter of utmost importance.

The model presented in this paper has some elements borrowed from prior work, notably (Heeman, 1999; Xu and Jelinek, 2004), while others are novel.

1.1 Paper Outline

The message we aim to deliver in this paper can be summarized in two theses:

- *Use fine-grain syntactic tags in a joint LM.* We propose a joint language model that can be used with a variety of tagsets. In Section 2, we describe those that we used in our experiments. Rather than tailoring our model to these tagsets, we aim for flexibility and propose an information theoretic framework for quick evaluation for tagsets, thus simplifying the creation of new tagsets. We show that our model with fine-grain tagsets outperform the coarser POS model, as well as the ngram baseline, in Section 5.

- *Address the challenges* that arise in a joint language model with fine-grain tags. While the idea of using joint language modeling is not novel (Chelba and Jelinek, 2000; Heeman, 1999), nor is the idea of using fine-grain tags (Bangalore, 1996; Wang et al., 2003), none of prior papers focus on the issues that arise from the combination of joint language modeling with fine-grain tags, both in terms of reliable parameter estimation and scalability in the face of the increased computational complexity. We dedicate Sections 3 and 4 to this problem.

In Section 6, we summarize conclusions and lay out directions for future work.

2 Structural Information

As we have mentioned, the selection of the random variable in Eq. 2 is extremely important for the performance of the model. On one hand, we would like for this variable to provide maximum information. On the other hand, as the number of parameters grow, we must address reliable parameter estimation in the face of sparsity, as well as increased computational complexity. In the following section we will compare the use of SuperARVs, POS tags, and other structural tags derived from parse trees.

2.1 POS Tags

Part-of-speech tags can be easily obtained for unannotated data using off-the-shelf POS taggers or PCFG parsers. However, the amount of information these tags typically provide is very limited,

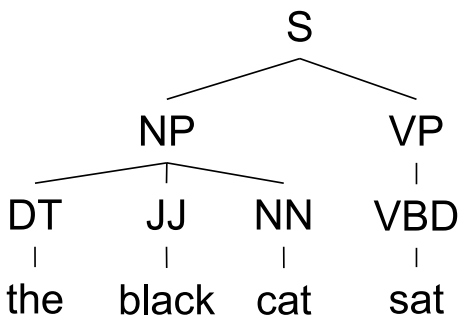

Figure 1: A parse tree example

e.g., while it is helpful to know whether *fly* is a verb or a noun, knowing that *you* is a personal pronoun does not carry the information whether it is a subject or an object (given the Penn Tree Bank tagset), which would certainly help to predict the following word.

2.2 SuperARV

The SuperARV essentially organizes information concerning one consistent set of dependency links for a word that can be directly derived from its syntactic parse. SuperARVs encode lexical information as well as syntactic and semantic constraints in a uniform representation that is much more fine-grained than POS. It is a four-tuple $(C; F; R+; D)$, where C is the lexical category of the word, F is a vector of lexical features for the word, $R+$ is a set of governor and need labels that indicate the function of the word in the sentence and the types of words it needs, and D represents the relative position of the word and its dependents. We refer the reader to the literature for further details on SuperARVs (Wang and Harper, 2002; Wang et al., 2003).

SuperARVs can be produced from parse trees by applying deterministic rules. In this work we use SuperARVs as individual tags and do not cluster them based of their structure. While SuperARVs are very attractive for language modeling, developing such a rich set of annotations for a new language would require a large amount of human effort.

We propose two other types of tags which have not been applied to this task, although similar information has been used in parsing.

2.3 Modifee Tag

This tag is a combination of the word's POS tag and the POS tag of its governor role. We designed it to resemble dependency parse structure. For example, the sentence in Figure 1 would be tagged: *the/DT-NN black/JJ-NN cat/NN-VBD sat/VBD-root*. Henceforth, we will refer to this kind of tag as *head*.

2.4 Parent Constituent

This tag is a combination of the word's POS tag with its immediate parent in the parse tree, along with the POS tag's relative position among its siblings. We refer to this type of tags as *parent*. The example in Figure 1 will be tagged: *the/DT-NP-start black/JJ-NP-mid cat/NN-NP-end sat/VB-VP-single*. This tagset is designed to represent constituency information.

Note that the *head* and *parent* tagsets are more language-independent (all they require is a treebank) than the SuperARVs which, not only utilized the treebank, but were explicitly designed by a linguist for English only.

2.5 Information Theoretic Comparison of Tags

As we have mentioned in Section 1, the choice of the tagset is very important to the performance of the model. There are two conflicting intuitions for tags: on one hand they should be specific enough to be helpful in the language model's task; on the other hand, they should be easy for the LM to predict.

Of course, in order to argue which tags are more suitable, we need some quantifiable metrics. We propose an information theoretic approach:

- To quantify how hard it is to predict a tag, we compute the conditional entropy:

$$\begin{aligned} H_p(t_i|w_i) &= H_p(t_i w_i) - H_p(w_i) \\ &= \sum_{w_i t_i} p(t_i w_i) \log p(t_i|w_i) \end{aligned}$$

- To measure how helpful a tagset is in the LM task, we compute the reduction of the conditional cross entropy:

$$\begin{aligned} & H_{\tilde{p},q}(w_i|w_{i-1}t_{i-1}) - H_{\tilde{p},q}(w_i|w_{i-1}) = \\ & \quad - \sum_{w_{i-1}^i t_{i-1}} \tilde{p}(w_{i-1}^i t_{i-1}) \log q(w_i|w_{i-1}t_{i-1}) \\ & \quad + \sum_{w_{i-1}^i} \tilde{p}(w_{i-1}^i) \log q(w_i|w_{i-1}) \\ = & \quad - \sum_{w_{i-1}^i t_{i-1}} \tilde{p}(w_{i-1}^i t_{i-1}) \log \frac{q(w_i|w_{i-1}t_{i-1})}{q(w_i|w_{i-1})} \end{aligned}$$

Note that in this case we use conditional *cross* entropy because conditional entropy has the tendency to overfit the data as we select more and more fine-grain tags. Indeed, $H_p(w_i|w_{i-1}t_{i-1})$ can be reduced to zero if the tags are specific enough, which would never happen in reality. This is not a problem for the former metric because the context there, w_i, is fixed. For this metric, we use a smoothed distribution $\tilde{p}$ computed on the training set[3] and the test distribution q.

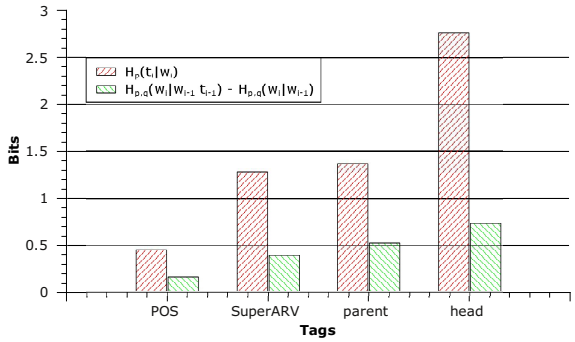

Figure 2: Changes in entropy for different tagsets

The results of these measurements are presented in Figure 2. POS tags, albeit easy to predict, provide very little additional information about the following word, and therefore we would not expect them to perform very well. The *parent* tagset seems to perform somewhat better than SuperARVs – it provides 0.13 bits more information while being only 0.09 bits harder to predict based on the word. The *head* tagset is interesting: it provides 0.2 bits more information about the following word (which would correspond to 15% perplexity reduction if we had perfect tags), but on the other hand the model is less likely to predict these tags accurately.

This approach is only a crude estimate (it uses only unigram and bigram context) but it is very useful for designing tagsets, e.g., for a new language, because it allows us to assess relative performance of tagsets without having to train a full model.

[3]We used *one-count* smoothing (Chen and Goodman, 1996).

3 Language Model Structure

The size and sparsity of the parameter space of the joint model necessitate the use of dimensionality reduction measures in order to make the model computationally tractable and to allow for accurate estimation of the model's parameters. We also want the model to be able to easily accommodate additional sources of information such as morphological features, prosody, etc. In the rest of this section, we discuss avenues we have taken to address these problems.

3.1 Decision Tree Clustering

Binary decision tree clustering has been shown to be effective for reducing the parameter space in language modeling (Bahl et al., 1990; Heeman, 1999) and other language processing applications, e.g., (Magerman, 1994). Like any clustering algorithm, it can be represented by a function H that maps the space of histories to a set of equivalence classes.

$$p(w_i t_i | w_{i-n+1}^{i-1} t_{i-n+1}^{i-1}) \approx p(w_i t_i | H(w_{i-n+1}^{i-1} t_{i-n+1}^{i-1})) \quad (4)$$

While the tree construction algorithm is fairly standard – to recursively select binary questions about the history optimizing some function – there are important decisions to make in terms of which questions to ask and which function to optimize. In the remainder of this section, we discuss the decisions we made regarding these issues.

3.2 Factors

The Factored Language Model (FLM) (Bilmes and Kirchhoff, 2003) offers a convenient view of the input data: it represents every word in a sentence as a tuple of factors. This allows us to extend the language model with additional parameters. In an FLM, however, all factors have to be deterministically computed in a joint model; whereas, we need to distinguish between the factors that are given or computed and the factors that the model must predict stochastically. We call these types of factors *overt* and *hidden*, respectively. Examples of overt factors include surface words, morphological features such as suffixes, case information when available, etc., and the hidden factors are POS, SuperARVs, or other tags.

Henceforth, we will use *word* to represent the set of overt factors and *tag* to represent the set of hidden factors.

3.3 Hidden Factors Tree

Similarly to (Heeman, 1999), we construct a binary tree where each tag is a leaf; we will refer to this tree as the *Hidden Factors Tree* (HFT). We use Minimum Discriminative Information (MDI) algorithm (Zitouni, 2007) to build the tree. The HFT represents a hierarchical clustering of the tag space. One of the reasons for doing this is to allow questions about subsets of tags rather than individual tags alone[4].

Unlike (Heeman, 1999), where the tree of tags was only used to create questions, this representation of the tag space is, in addition, a key feature of our decoding optimizations, which we discuss in Section 4.

3.4 Questions

The context space is partitioned by means of binary *questions*. We use different types of questions for hidden and overt factors.

- Questions about surface words are constructed using the Exchange algorithm (Martin et al., 1998). This algorithm takes the set of words that appear at a certain position in the training data associated with the current node in the history tree and divides the set into two complementary subsets greedily optimizing some target function (we use the average entropy of the marginalized word distribution, the same as for question selection). Note that since the algorithm only operates on the words that appear in the training data, we need to do something more to account for the unseen words. Thus, to represent this type of question, we create the history tree structure depicted in Fig. 4.

  For other overt factors with smaller vocabularies, such as suffixes, we use equality questions.

- As we mentioned in Section 3.3, we use the Hidden Factors Tree to create questions about hidden factors. Note that every node in a binary tree can be represented by a binary path from the root with all nodes under an inner node sharing the same prefix. Thus, a question about whether a tag belongs to a subset of tags dominated by a node can be expressed as whether the tag's path matches the binary prefix.

[4]Trying all possible subsets of tags is not feasible since there are $2^{|T|}$ of them. The tree allows us to reduce the number to $O(T)$ of the most meaningful (as per the clustering algorithm) subsets.

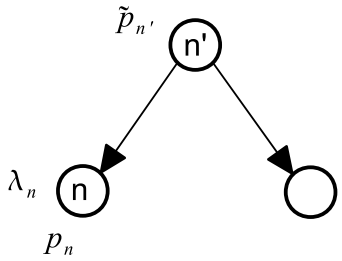

Figure 3: Recursive smoothing: $\tilde{p_n} = \lambda_n p_n + (1 - \lambda_n)\tilde{p_{n'}}$

3.5 Optimization Criterion and Stopping Rule

To select questions we use the average entropy of the marginalized word distribution. We found that this criterion significantly outperforms the entropy of the distribution of joint events. This is probably due to the increased sparsity of the joint distribution and the fact that our ultimate metrics, i.e., WER and word perplexity, involve only words.

3.6 Distribution Representation

In a cluster H_x, we factor the joint distribution as follows:

$$p(w_i t_i | H_x) = p(w_i | H_x) \cdot p(t_i | w_i, H_x)$$

where $p(t_i|w_i, H_x)$ is represented in the form of an HFT, in which each leaf has the probability of a tag and each internal node contains the sum of the probabilities of the tags it dominates. This representation is designed to assist the decoding process described in Section 4.

3.7 Smoothing

In order to estimate probability distributions at the leaves of the history tree, we use the following recursive formula:

$$\tilde{p}_n(w_i t_i) = \lambda_n p_n(w_i t_i) + (1 - \lambda_n)\tilde{p}_{n'}(w_i t_i) \quad (5)$$

where n' is the n-th node's parent, $p_n(w_i t_i)$ is the distribution at node n (see Figure 3). The

root of the tree is interpolated with the distribution $p_{unif}(w_i t_i) = \frac{1}{|V|} p_{ML}(t_i|w_i)$[5]. To estimate interpolation parameters λ_n, we use the EM algorithm described in (Magerman, 1994); however, rather than setting aside a separate development set of optimizing λ_n, we use 4-fold cross validation and take the geometric mean of the resulting coefficients[6]. We chose this approach because a small development set often does not overlap with the training set for low-count nodes, leading the EM algorithm to set $\lambda_n = 0$ for those nodes.

Let us consider one leaf of the history tree in isolation. Its context can be represented by the path to the root, i.e., the sequence of questions and answers $q_1, \ldots q_{(n')'} q_{n'}$ (with q_1 being the answer to the topmost question):

$$\tilde{p}_n(w_i t_i) = \tilde{p}(w_i t_i | q_1 \ldots q_{(n')'} q_{n'})$$

Represented this way, Eq. 5 is a variant of Jelinek-Mercer smoothing:

$$\begin{aligned}\tilde{p}(w_i t_i | q_1 \ldots q_{n'}) \;\; = \;\; & \lambda_n p(w_i t_i | q_1 \ldots q_{n'}) \; + \\ & (1 - \lambda_n) \tilde{p}(w_i t_i | q_1 \ldots q_{(n')'})\end{aligned}$$

For backoff nodes (see Fig. 4), we use a lower order model[7] interpolated with the distribution at the backoff node's grandparent (see node A in Fig. 4):

$$\begin{aligned}&\tilde{p}_B(w_i t_i | w_{i-n+1}^{i-1} t_{i-n+1}^{i-1}) = \\ &\quad \alpha_A \tilde{p}_{bo}(w_i t_i | w_{i-n+2}^{i-1} t_{i-n+2}^{i-1}) \; + \; (1 - \alpha_A) \tilde{p}_A(w_i t_i)\end{aligned}$$

How to compute α_A is an open question. For this study, we use a simple heuristic based on observation that the further node A is from the root the more reliable the distribution $\tilde{p}_A(w_i t_i)$ is, and hence α_A is lower. The formula we use is as follows:

$$\alpha_A = \frac{1}{\sqrt{1 + distanceToRoot(A)}}$$

[5]We use this distribution rather than uniform joint distribution $\frac{1}{|V||T|}$ because we do not want to allow word-tag pairs that have never been observed. The idea is similar to (Thede and Harper, 1999).

[6]To avoid a large number of zeros due to the product, we set a minimum for λ to be 10^{-7}.

[7]The lower order model is constructed by the same algorithm, although with smaller context. Note that the lower order model can back off on words or tags, or both. In this paper we backoff both on words and tags, i.e., $p(w_i t_i | w_{i-2}^{i-1} t_{i-2}^{i-1})$ backs off to $p(w_i t_i | w_{i-1} t_{i-1})$, which in turn backs off to the unigram $p(w_i t_i)$.

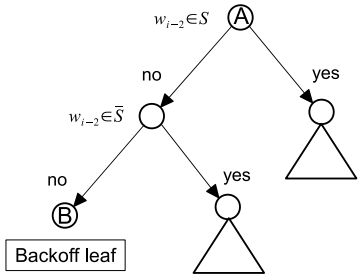

Figure 4: A fragment of the decision tree with a backoff node. $S \cup \bar{S}$ is the set of words observed in the training data at the node A. To account for unseen words, we add the backoff node B.

4 Decoding

As in HMM decoding, in order to compute probabilities for i-th step, we need to sum over $|T|^{n-1}$ possible combinations of tags in the history, where T is the set of tags and n is the order of the model. With $|T|$ predictions for the i-th step, we have $O(|T|^n)$ computational complexity per word. Straightforward computation of these probabilities is problematic even for a trigram model with POS tags, i.e., $n = 3, |T| \approx 40$. A standard approach to limit computational requirements is to use beam search where only $\mathcal{N}$ most likely paths are retained. However, with fine-grain tags where $|T| \approx 1,500$, a tractable beam size would only cover a small fraction of the whole space, leading to search errors such as pruning good paths.

Note that we have a history clustering function (Eq. 4) represented by the decision tree, and we should be able to exploit this clustering to eliminate unnecessary computations involving equivalent histories. Note that words in the history are known exactly, thus we can create a projection of the clustering function H in Eq. 4 to the plane $w_{i-n+1}^{i-1} = const$, i.e., where words in the context are fixed to be whatever is observed in the history:

$$H(w_{i-n+1}^{i-1} t_{i-n+1}^{i-1}) \;\Rightarrow\; \hat{H}_{w_{i-n+1}^{i-1} = const}(t_{i-n+1}^{i-1}) \tag{6}$$

The number of distinct clusters in the projection $\hat{H}$ depends on the decision tree configuration and can vary greatly for different words w_{i-n+1}^{i-1} in the history, but generally it is relatively small:

$$|\hat{H}_{w_{i-n+1}^{i-1} = const}(t_{i-n+1}^{i-1})| \;\ll\; |T^{n-1}| \tag{7}$$

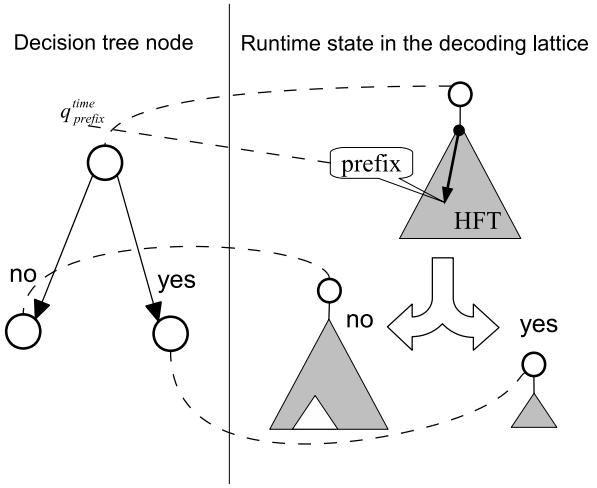

Figure 5: Questions about hidden factors split states (see Figure 6) in the decoding lattice represented by HFTs.

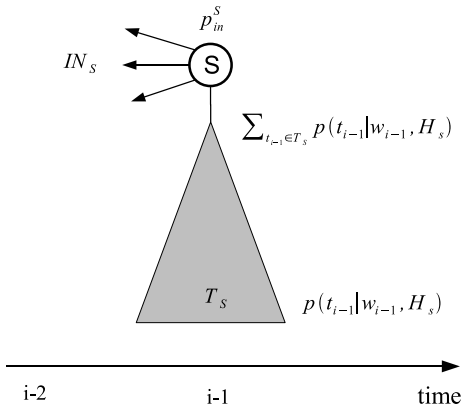

Figure 6: A state S in the decoding lattice. p_{in}^{S} is the probability of reaching the state S through the set of links IN_S. The probabilities of generating the tags $p(t_{i-1}|w_{i-1}, H_s), (t_{i-1} \in T_S)$ are represented in the form of the HFT.

thus, the number of probabilities that we need to compute is $|\hat{H}_{w_{i-n+1}^{i-1}=const}| \cdot |T|$.

Our decoding algorithm works similarly to HMM decoding with the exception that the set of hidden states is not predetermined. Let us illustrate how it works in the case of a bigram model. Recall that the set of tags T is represented as a binary tree (HFT) and the only type of questions about tags is about matching a binary prefix in the HFT. Such a question dissects the HFT into two parts as depicted in Figure 5. The cost of this operation is $O(\log |T|)$.

We represent states in the decoding lattice as shown in the Figure 6, where p_{in}^{S} is the probability of reaching the state S:

$$p_{in}^{S} = \sum_{S' \in IN_S} \left[p_{in}^{S'}\, p(w_{i-2}|H_{S'}) \sum_{t \in T_{S'}} p(t|w_{i-2}H_{S'}) \right]$$

where IN_S is the set of incoming links to the state S from the previous time index, and $T_{S'}$ is the set of tags generated from the state S' represented as a fragment of the HFT. Note, that since we maintain the property that the probability assigned to an inner node of the HFT is the sum of probabilities of the tags it dominates, the sum $\sum_{t \in T_{S'}} p(t|w_{i-2}H_{S'})$ is located at the root of $T_{S'}$, and therefore this is an $O(1)$ operation.

Now given the state S at time $i-1$, in order to generate tag predictions for i-th word, we apply questions from the history clustering tree, starting from the top. Questions about overt factors always follow either a *true* or *false* branch, implicitly computing the projection in Eq. 6. Questions about hidden factors, can split the state S into two states S_{true} and S_{false}, each retaining a part of T_S as shown in the Figure 5.

The process continues until each fragment of each state at the time $i-1$ reaches the bottom of the history tree, at which point new states for time i are generated from the clusters associated with leaves. The states at $i-1$ that generate the cluster $H_{\tilde{S}}$ become the incoming links to the state $\tilde{S}$.

Higher order models work similarly, except that at each time we consider a state S at time $i-1$ along with one of its incoming links (to some depth according to the size of the context).

5 Experimental Setup

To evaluate the impact of fine-grain tags on language modeling, we trained our model with five settings: In the first model, questions were restricted to be about overt factors only, thus making it a tree-based word model. In the second model, we used POS tags. To evaluate the effect of fine-grain tags, we train two models: *head* and *parent* described in Section 2.3 and Section 2.4 respectively. Since our joint model can be used with any kind of tags, we also trained it with SuperARV tags (Wang et al., 2003). The SuperARVs were created from the same parse trees that were used to produce POS and fine-grain tags. All our models, including SuperARV, use trigram context. We include standard trigram, four-gram, and five-

gram models for reference. The ngram models were trained using SRILM toolkit with interpolated modified Kneser-Ney smoothing.

We evaluate our model with an nbest rescoring task using 100-best lists from the DARPA WSJ'93 and WSJ'92 20k open vocabulary data sets. The details on the acoustic model used to produce the nbest lists can be found in (Wang and Harper, 2002). Since the data sets are small, we combined the 93et and 93dt sets for evaluation and used 92et for the optimization[8]. We transformed the nbest lists to match PTB tokenization, namely separating possessives from nouns, *n't* from auxiliary verbs in contractions, as well as contractions from personal pronouns.

All language models were trained on the NYT 1994-1995 section of the English Gigaword corpus (approximately 70M words). Since the New York Times covers a wider range of topics than the Wall Street Journal, we eliminated the most irrelevant stories based on their trigram coverage by sections 00-22 of WSJ. We also eliminated sentences over 120 words, because the parser's performance drops significantly on long sentences. After parsing the corpus, we deleted sentences that were assigned a very low probability by the parser. Overall we removed only a few percent of the data; however, we believe that such a rigorous approach to data cleaning is important for building discriminating models.

Parse trees were produced by an extended version of the Berkeley parser (Huang and Harper, 2009). We trained the parser on a combination of the BN and WSJ treebanks, preprocessed to make them more consistent with each other. We also modified the trees for the speech recognition task by replacing numbers and abbreviations with their verbalized forms. We pre-processed the NYT corpus in the same way, and parsed it. After that, we removed punctuation and downcased words. For the ngram model, we used text processed in the same way.

In *head* and *parent* models, tag vocabularies contain approximately 1,500 tags each, while the SuperARV model has approximately 1,400 distinct SuperARVs, most of which represent verbs (1,200).

In these experiments we did not use overt factors other than the surface word because they split <unk>, effectively changing the vocabulary thus making perplexity incomparable to models without these factors, without improving WER noticeably. However, we do plan to use more overt factors in Machine Translation experiments where a language model faces a wider range of OOV phenomena, such as abbreviations, foreign words, numbers, dates, time, etc.

Models	WER
trigram (baseline)	17.5
four-gram	17.7
five-gram	17.8
Word Tree	17.3
POS Tags	17.0
Head Tags	16.8
Parent Tags	**16.7**
SuperARV	16.9

Table 1: WER results, optimized on 92et set, evaluated on combined 93et and 93dt set. The Oracle WER is 9.5%.

Table 1 summarizes performance of the LMs on the rescoring task. The *parent* tags model outperforms the trigram baseline model by 0.8% WER. Note that four- and five-gram models fail to outperform the trigram baseline. We believe this is due to the sparsity as well as relatively short sentences in the test set (16 words on average).

Interestingly, whereas the improvement of the POS model over the baseline is not statistically significant ($p < 0.10$)[9], the fine-grain models outperform the baseline much more reliably: $p < 0.03$ (SuperARV) and $p < 0.007$ (*parent*).

We present perplexity evaluations in Table 2. The perplexity was computed on Section 23 of WSJ PTB, preprocessed as the rest of the data we used. The *head* model has the lowest perplexity outperforming the baseline by 9%. Note, it even outperforms the five-gram model, although by a small 2% margin.

Although the improvements by the fine-grain tagsets over POS are not significant (due to the small size of the test set), the reductions in perplexity suggest that the improvements are not random.

[8]We optimized the LM weight and computed WER with scripts in the SRILM and NIST SCTK toolkits.

[9]For statistical significance, we used SCTK implementation of the *mapsswe* test.

6 Conclusion and Future Work

In this paper, we presented a joint language modeling framework. Unlike any prior work known to us, it was not tailored for any specific tag set, rather it was designed to accommodate any set of tags, especially large sets ($\sim 1,000$), which present challenges one does not encounter with smaller tag sets, such at POS tags. We discussed these challenges and our solutions to them. Some of the solutions proposed are novel, particularly the decoding algorithm.

We also proposed two simple fine-grain tagsets, which, when applied in language modeling, perform comparably to highly sophisticated tag sets (SuperARV). We would like to stress that, while our fine-grain tags did not significantly outperform SuperARVs, the former use much less linguistic knowledge and can be automatically induced for any language with a treebank.

Because a joint language model inherently predicts hidden events (tags), it can also be used to generate the best sequence of those events, i.e., tagging. We evaluated our model in the POS tagging task and observed similar results: the fine-grain models outperform the POS model, while both outperform the state-of-the-art HMM POS taggers. We refer to (Filimonov and Harper, 2009) for details on these experiments.

We plan to investigate how parser accuracy and data selection strategies, e.g., based on parser confidence scores, impact the performance of our model. We also plan on evaluating the model's performance on other genres of speech, as well as in other tasks such as Machine Translation. We are also working on scaling our model further to accommodate amounts of data typical for modern large-scale ngram models. Finally, we plan to apply the technique to other languages with treebanks, such as Chinese and Arabic.

We intend to release the source code of our model within several months of this publication.

Abstract

This paper investigates the effect of direction in phrase-based statistial machine translation decoding. We compare a typical phrase-based machine translation decoder using a left-to-right decoding strategy to a right-to-left decoder. We also investigate the effectiveness of a bidirectional decoding strategy that integrates both mono-directional approaches, with the aim of reducing the effects due to language specificity. Our experimental evaluation was extensive, based on 272 different language pairs, and gave the surprising result that for most of the language pairs, it was better decode from right-to-left than from left-to-right. As expected the relative performance of left-to-right and right-to-left strategies proved to be highly language dependent. The bidirectional approach outperformed the both the left-to-right strategy and the right-to-left strategy, showing consistent improvements that appeared to be unrelated to the specific languages used for translation. Bidirectional decoding gave rise to an improvement in performance over a left-to-right decoding strategy in terms of the BLEU score in 99% of our experiments.

1 Introduction

Human language production by its very nature is an ordered process. That is to say, words are written/uttered in a sequence. The current generation of phrase-based statistical machine translation (SMT) systems also generate their target word sequences according to an order. Since the generation process is symmetrical, there are two possible strategies that could be used to generate the target: from beginning to end; or from end to beginning. Generating the target in the 'wrong' direction (the opposite direction to the way in which humans do) is counter intuitive, and possibly as a result of this, SMT systems typically generate the target word sequence in the same order as human language production. However it is not necessarily the case that this is most effective strategy for all language pairs. In this paper we investigate the effect of direction in phrase-based SMT decoding.

For the purposes of this paper, we will refer to target word sequence generation that follows the same order as human language production as *forward* generation, and generation in the opposite direction to human language production as *reverse* generation. These are often referred "left-to-right" and "right-to-left" respectively in the literature, but we avoid this notation as many languages are naturally written from right-to-left.

In earlier work (Watanabe and Sumita, 2002), it was hypothesized that the optimal direction for decoding was dependent on the characteristics of the target language. Their results show that for Japanese to English translation a reverse decoding strategy was the most effective, whereas for English to Japanese translation, a forward decoding strategy proved superior. In addition they implemented a bidirectional decoder, but their results were mixed. For English to Japanese translation, decoding bidirectionally gives higher performance, but for Japanese to English translation they were unable to improve performance by decoding bidirectionally. Their experiments were performed using a decoder based on IBM Model 4 using the translation techniques developed at IBM (Brown et al., 1993).

This work is closely related to the techniques proposed in (Watanabe and Sumita, 2002), but in our case we decode within the framework of a phrase-based SMT system, rather than the IBM model. Our intention was to explore the effect of direction in decoding within the context of a more

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1124–1132,
Singapore, 6-7 August 2009.

contemporary machine translation paradigm, and to experiment with a broader range of languages. The underlying motivation for our studies however remains the same. Languages have considerably different structure, and certain grammatical constructs tend to occupy particular positions within sentences of the same language, but different positions across languages. These differences may make it easier to tackle the automatic translation of a sentence in a given language from a particular direction. Our approach differs in that the decoding process of a phrased-based decoder is quite different from that used by (Watanabe and Sumita, 2002) since decoding is done using larger units making the re-ordering process much simpler. In (Watanabe and Sumita, 2002) only one language pair is considered, for our experiments we extended this to include translation among 17 different languages including the Japanese and English pair used in (Watanabe and Sumita, 2002). We felt that it was important to consider as many languages as possible in this study, as intuition and evidence from the original study suggests that the effect of direction in decoding is likely to be strongly language dependent.

The next section briefly describes the mechanisms underlying phrase-based decoding. Then we explain the principles behind the forward, reverse and bidirectional decoding strategies used in our experiments. Section 3 presents the experiments we performed. Section 4 gives the results and some analysis. Finally in Section 5, we conclude and offer possible directions for future research.

2 Phrase-based Translation

For our experiments we use the phrase-based machine translation techniques described in (Koehn, 2004) and (Koehn et al., 2007), integrating our models within a log-linear framework (Och and Ney, 2002).

One of the advantages of a log-linear model is that it is possible to integrate a diverse set of features into the model. For the decoders used in the experiments in this paper, we included the following feature functions:

- An n-gram language model over the target word sequence
  - Ensures the target word sequence is a likely sequence of words in the target language
- A phrase translation model
  - Effects the segmentation of the source word sequence, and is also responsible for the transformation of source phrases into target phrases.
- A target word sequence length model
  - Controls the length of the target word sequence. This is usually a constant term added for each word in the translation hypothesis.
- A lexicalized distortion model
  - Influences the reordering of the translated source phrases in the target word sequence using lexical context on the boundaries of the phrases being reordered.

2.1 Decoding

In a phrase-based SMT decoder, the word sequence of the target language is typically generated in order in a forward manner. The words at the start of the translation are generated first, then the subsequent words, in order until the final word of the target word sequence is generated. As the process is phrase-based, the translation is generated in a phrase-by-phrase manner, rather word-by-word. The basic idea is to segment the source word sequence into subsequences (phrases), then translate each phrase individually, and finally compose the target word sequence by reordering the translations of the source phrases. This composition must occur in a particular order, such that target words are generated sequentially from the start (or end in the case of reverse decoding) of the sentence. The reason that the target needs to be generated sequentially is to allow an n-gram language model to be applied to the partial target word sequence at each step of the decoding process.

This process is illustrated in Figure 1. In the decoding for both forward and reverse decoders the source sentence is segmented into 2 phrases: ”where is” and ”the station” (although in this example the segmentation is the same for both decoding strategies, it is not necessarily the case since the search processes are different). In the forward decoding process, first the English phrase “the station” is translated into the Japanese phrase “eki wa”. Initially the target sequence consists

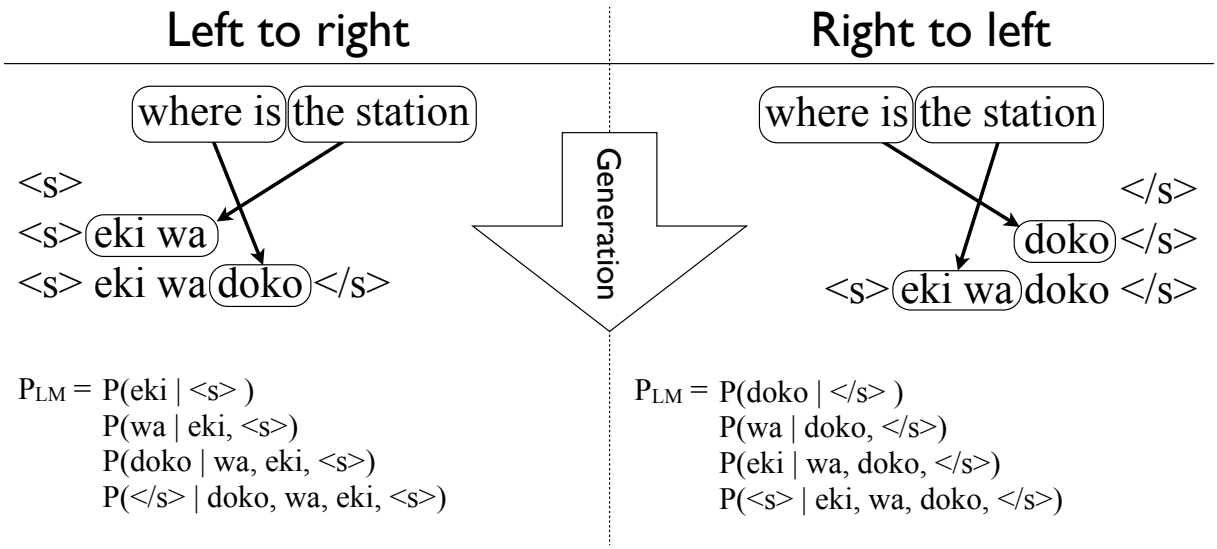

Figure 1: The phrase-based decoding process for an English to Japanese translation, in both forward and reverse directions. The n-gram language model probability calculation for the completed translation hypotheses are also shown on the bottom of the figure. See Section 2.1 for a description of the decoding process.

of only the start of sentence marker "$\langle$s$\rangle$". This marker only serves as context to indicate the start of the sequence for the benefit of the language model. The first target phrase is separated into its component words and each word is added in order to the target word sequence. Each addition causes an application of the language model, hence in Figure 1 the first term of P_{LM} is $P(\text{eki}|\langle\text{s}\rangle)$, the second is $P(\text{wa}|\langle\text{s}\rangle)$ and so on. For reverse decoding, the target sentence is generated starting from the end of sentence marker $\langle/\text{s}\rangle$ with the language model context being to the right of the current word. For the case of bidirectional decoding, the model probability for the hypothesis is a linear interpolation of the scores for both forward and reverse hypotheses.

2.2 Direction in Decoding

Direction in decoding influences both the models used by the decoder and the search process itself. The direction of decoding determines the order in which *target* words are generated, the source phrases being translated in any order, therefore it is likely to be features of the target language rather than those of the the source language that determine the effect that the decoding direction has on decoder performance.

2.2.1 The Language Model

The fundamental difference between the language models of a forward decoder and that of a reverse decoder is the direction in which the model looks for its context. The forward model looks back to the start of the sentence, whereas the reverse model looks forward to the end of the sentence.

2.2.2 The Search

Assuming a full search, a unigram language model and no limitations on reordering, the forward and reverse decoding processes are equivalent. When these constraints are lifted, as is the case in the experiments in this paper, the two search processes diverge and can give rise to hypotheses that are different in character.

The partial hypotheses from early in the search process for forward decoding represent hypotheses for the first few words of the target word sequence, whereas the early partial hypotheses of a reverse decoder hold the last few words. This has two consequences for the search. The first is that (assuming a beam search as used in our experiments), certain candidate word sequences in the early stages of the search might be outside the beam and be pruned. The consequence of this is that sentences that start with (or end with in the case of reverse decoding) the pruned word sequence will not be considered during the remainder of the search. The second is that word se-

quences in the partial hypotheses are used in the context of the models used in the subsequent decoding. Thus, correctly decoding the start (or end for reverse decoding) of the sentence will benefit the subsequent decoding process.

3 Experiments

3.1 Experimental Data

The experiments were conducted on all possible pairings among 17 languages. A key to the acronyms used for languages together with information about their respective characteristics is given in Table 1.

We used all of the first ATR Basic Travel Expression Corpus (BTEC1) (Kikui et al., 2003) for these experiments. This corpus contains the kind of expressions that one might expect to find in a phrase-book for travelers. The corpus is similar in character to the IWSLT06 Evaluation Campaign on Spoken Language Translation (Paul, 2006) J-E open track. The sentences are relatively short (see Table 1) with a simple structure and a fairly narrow range of vocabulary due to the limited domain.

The experiments were conducted on data that contained no case information, and also no punctuation (this was an arbitrary decision that we believe had no impact on the results).

We used a 1000 sentence development corpus for all experiments, and the corpus used for evaluation consisted of 5000 sentences with a single reference for each sentence.

3.2 Training

Each instance of the decoder is a standard phrase-based machine translation decoder that operates according to the same principles as the publicly available PHARAOH (Koehn, 2004) and MOSES (Koehn et al., 2007) SMT decoders. In these experiments 5-gram language models built with Witten-Bell smoothing were used along with a lexicalized distortion model. The system was trained in a standard manner, using a minimum error-rate training (MERT) procedure (Och, 2003) with respect to the BLEU score (Papineni et al., 2001) on held-out development data to optimize the log-linear model weights. For simplicity, the MERT procedure was performed on independently on the forward and reverse decoders for the bidirectional system, rather them attempting to tune the parameters for the full system.

3.3 Translation Engines

3.3.1 Forward

The forward decoding translation systems used in these experiments represent the baseline of our experiments. They consist of phrase-based, multi-stack, beam search decoders commonly used in the field.

3.3.2 Reverse

The reverse decoding translation systems used in these experiments were exactly the same as the forward decoding systems. The difference being the that word sequences in the training, development, and source side of the test corpora were reversed prior to training the systems. The final output of the reverse decoders was reordered in a post processing step before evaluation.

3.3.3 Bidirectional

The decoder used for the bidirectional decoding experiments was modified in order to be able to decode both forward and reverse in separate instances of the decoder. Models for decoding in forward and reverse directions are loaded, and two decoding instances created. Scores for hypotheses that share the same target word sequence from the two decoders were combined at the end of the decoding process linearly using equal interpolation weights. Hypotheses that were generated by only one of the component decoders were not pruned. The scores from these hypotheses only had a contribution from the decoder that was able to generate them, the contribution from the other decoder being zero.

3.4 Decoding Constraints

The experiments reported in this paper were conducted with loose constraints on the decoding as overconstraining the decoding process could lead to differences between unidirectional and bidirectional strategies. More specificially, the decoding was done with a beam width of 100, no beam thresholding and no constraints on the reordering process. Figure 2 shows the effect of varying the beam width (stack size) in the search for forward decoder of the English to Japanese translation experiment. At the beam width of 100 used in our experiments, the gains from doubling the beam with are small (0.07 BLEU percentage points).

It is also important to note that a future cost identical to that used in the MOSES decoder

(Koehn et al., 2007) was also included in the scores for partial hypothesis during the decoding.

3.5 Computational Overhead

In the current implementation, bidirectional decoding takes twice as long as a mono-directional system. However, in a multi-threaded environment, each instance of the decoder is able to run on its own thread in parallel, and so this slowdown can be mitigated in some circumstances. Future generations of the bidirectional decoder will more tightly couple the two decoders, and we believe this will lead to faster and more effective search.

3.6 Evaluation

The results presented in this paper are given in terms of the BLEU score (Papineni et al., 2001). This metric measures the geometric mean of n-gram precision of n-grams drawn from the output translation and a set of reference translations for that translation.

There are large number of proposed methods for carrying out machine translation evaluation. Methods differ in their focus of characteristics of the translation (for example fluency or adequacy), and moreover anomolous results can occur if a single metric is relied on. Therefore, we also carried out evaluations using the NIST (Doddington, 2002), METEOR (Banerjee and Lavie, 2005), WER (Hunt, 1989), PER (Tillmann et al., 1997) and TER (Snover et al., 2005) machine translation evaluation techniques.

4 Results

The results of the experiments in terms of the BLEU score are given in Tables **??**, 5, 3 and 3. These results show the performance of the reverse and bidirectional decoding strategies relative to the usual forward decoding strategy. The cells in the tables that represent experiments in which

Table 2: Baseline BLEU scores for all systems. The figures represent the scores in BLEU percentage points of the baseline left-to-right decoding systems. Source languages are indicated by the column headers, the row headers denoting the target languages.

the forward strategy outperformed the contrasting strategy are shaded in gray. The numbers in the cells represent the difference in BLEU percentage points for the systems being compared in that cell.

It is clear from Table 3 that for most of the language pairs (67% of them for BLEU, and a similar percentage for all the other metrics except METEOR), better evaluation scores were achieved by using a reverse decoding strategy than a forward strategy. This is a surprising result because language is produced naturally in a forward manner (by definition), and therefore one might expect this to also be the optimal direction for word sequence generation in decoding.

4.1 Word Order Typography

Following (Watanabe and Sumita, 2002), to explain the effects we observe in our results we look to the word order typography of the target language (Comrie and Vogel, 2000). The word order of a language is defined in terms of the order in which you would expect to encounter the finite verb (V) and its arguments, subject (S) and object (O). In most languages S precedes O and V. Whether or not O precedes or follows V defines the two most prevalent word order types SOV and SVO (Comrie and Vogel, 2000).

Two of the target languages in this study (Japanese and Korean) have the SOV word type, the remainder having the SVO word order type. In Table 3 looking at the rows for *ja* and *ko* we can see that for both of these languages reverse decoding outperformed forward decoding in only 4 out of 12 experiments. Furthermore these two languages were the two languages that benefited the most (in terms of the number of experimental cases) from forward decoding. The two languages also agree on the best decoding direction for 12 of the 16 language pairs. This apparent correlation may reflect similarities between the two languages (word order type, or other common features of the languages).

Given this evidence, it seems plausible that word order does account in part for the differences in performance when decoding in differing directions, but this can only be part of the explanation since there are 4 source languages for which reverse decoding yielded higher performance.

It should be noted that our results differ from those of (Watanabe and Sumita, 2002) for English to Japanese translation, who observed gains when decoding in the reverse direction for this language pair. It is hard to compare our results directly with theirs however, due to the differences in the decoders used in the experiments (ours being phrase-based, and theirs based on the IBM ap-

Table 3: Gains in BLEU score from reverse decoding over a forward decoding strategy The numbers in the cells are the differences in BLEU percentage points between the systems. Shaded cells indicate the cases where forward decoding give a higher score. Source languages are indicated by the column headers, the row headers denoting the target languages.

Metric	Bi>For	Bi>Rev	Rev>For
BLEU	98.90	84.93	67.65
NIST	98.53	78.31	75.00
METEOR	99.63	95.96	50.74
WER	99.26	92.85	66.18
PER	98.53	84.97	70.59
TER	99.63	91.18	68.75

Table 4: Summary of the results using several automatic metrics for evaluation. Numbers in the table correspond to the percentage of experiments in which the condition at the head of the column was true (for example figure in the first row and first column means that for 98.9 percent of the language pairs the BLEU score for the bidirectional decoder was better than that of the forward decoder)

proach (Brown et al., 1993)).

The results were the similar in character when other MT evaluation methods were used. These results are summarized in Table 3.

4.2 Bidirectional Decoding

Table 5 shows the performance of the bidirectional decoder relative to a forward decoder. As can be seen from the table, in 269 out of the 272 experiments the bidirectional decoder outperformed the unidirectional decoder. The gains ranged from a maximum of 1.81 BLEU (translating from Thai to Arabic) points, to a minimum of -0.04 BLEU points (translating from Indonesian to Japanese) with the average gain over all experiments being 0.56 BLEU points. It is clear from our experiments that there is much to be gained from decoding bidirectionally. Our results were almost unanimously positive, and in all three negative cases the drop in performance was small.

5 Conclusion

In this paper we have investigated the effects on phrase-based machine translation performance of three different decoding strategies: forward, reverse and bidirectional. The experiments were conducted on a large set of source and target languages consisting of 272 experiments representing all possible pairings from a set of 17 languages. These languages were very diverse in character and included a broad selection of European and Asian languages. The experimental results revealed that for SVO word order languages it is usually better to decode in a reverse manner, and in contrast, for SOV word order languages it is usu-

ally better to decode in a forward direction. Our main contribution has been to show that a bidirectional decoding strategy is superior to both monodirectional decoding strategies. It might be argued that the gains arise simply from system combination. However, our systems are combined in a simple linear fashion, and gains will only arise when the second system contributes novel and useful information to into the combination. Furthermore, our systems are trained on two copies of the same data, no additional data is required. The gains from decoding bidirectionally were obtained very consistently, with only loose constraints on the decoding. This can be seen clearly in Table 5 where the results are almost unanimously positive. Moreover, these gains appear to be independent of the linguistic characteristics of the source and target languages.

In the future we would like to explore the possibilities created by more tightly coupling the forward and reverse components of the bidirectional decoder. Scores from partial hypotheses of both processes could be combined and used at each step of the decoding, making the search more informed. Furthermore, forward partial hypotheses and reverse hypotheses would 'meet' during decoding (when one decoding direction has covered words in the source that the other has yet to cover), and provide paths for each other to a final state in the search.

Abstract

We describe a process for automatically detecting decision-making sub-dialogues in multi-party, human-human meetings in real-time. Our basic approach to decision detection involves distinguishing between different utterance types based on the roles that they play in the formulation of a decision. In this paper, we describe how this approach can be implemented in real-time, and show that the resulting system's performance compares well with other detectors, including an off-line version.

1 Introduction

In collaborative and organized work environments, people share information and make decisions through multi-party conversations, commonly referred to as meetings. The demand for automatic methods that process, understand and summarize information contained in audio and video recordings of meetings is growing rapidly, as evidenced by on-going projects which are focused on this goal, (Waibel et al., 2003; Janin et al., 2004). Our research is part of a general effort to develop a system that can automatically extract and summarize information such as conversational topics, action items, and decisions.

This paper concerns the development of a real-time decision detector — a system which can detect and summarize decisions as they are made during a meeting. Such a system could provide a summary of all of the decisions which have been made up until the current point in the meeting, and this is something which we expect will help users to enjoy more productive meetings. Certainly, good decision-making relies on access to relevant information, and decisions made earlier in a meeting often have a bearing on the current topic of discussion, and so form part of this relevant information. However, in a long and winding meeting, participants might not have these earlier decisions at the forefront of their minds, and so an accurate and succinct reminder, as provided by a real-time decision detector, could potentially be very useful. A record of earlier decisions could also help users to identify outstanding issues for discussion, and to therefore make better use of the remainder of the meeting.

Our approach to decision detection uses an annotation scheme which distinguishes between different types of utterance based on the roles which they play in the decision-making process. Such a scheme facilitates the detection of decision discussions (Fernández et al., 2008), and by indicating which utterances contain particular types of information, it also aids their summarization. To automatically detect decision discussions, we use what we refer to as *hierarchical classification*. Here, independent binary *sub-classifiers* detect the different decision dialogue acts, and then based on the sub-classifier hypotheses, a *super-classifier* determines which dialogue regions are decision discussions. In this paper then, we address the challenges for applying this approach in real-time, and produce a system which is able to detect decisions soon after they are made, (for example within a minute). We conduct tests and compare this system's performance with other detectors, including an off-line equivalent.

The remainder of the paper proceeds as follows. Section 2 describes related work, and Section 3 describes our annotation scheme for decision discussions, and our experimental data. Next, Section 4 explains the hierarchical classification approach in more detail, and Section 5 considers how it can be applied in real-time. Section 6 describes the experiments in which we test the real-time detector, and finally, Section 7 presents conclusions and ideas for future work.

Singapore, 6-7 August 2009.

2 Related Work

Decisions are one of the most important meeting outputs. User studies (Lisowska et al., 2004; Banerjee et al., 2005) have confirmed that meeting participants consider this to be the case, and Whittaker et al. (2006) found that the development of an automatic decision detection component is critical to the re-use of meeting archives. As a result, with the new availability of substantial meeting corpora such as the ISL (Burger et al., 2002), ICSI (Janin et al., 2004) and AMI (McCowan et al., 2005) Meeting Corpora, recent years have seen an increasing amount of research on decision-making dialogue.

This recent research has tackled issues such as the automatic detection of agreement and disagreement (Hillard et al., 2003; Galley et al., 2004), and of the level of involvement of conversational participants (Wrede and Shriberg, 2003; Gatica-Perez et al., 2005). In addition, Verbree et al. (2006) created an argumentation scheme intended to support automatic production of argument structure diagrams from decision-oriented meeting transcripts. Only very recent research has specifically investigated the automatic detection of decisions, namely (Hsueh and Moore, 2007) and (Fernández et al., 2008).

Hsueh and Moore (2007) used the AMI Meeting Corpus, and attempted to automatically identify dialogue acts (DAs) in meeting transcripts which are "decision-related". Within any meeting, the authors decided which DAs were decision-related based on two different kinds of manually created summary: the first was an extractive summary of the whole meeting, and the second, an abstractive summary of the decisions which were made. Those DAs in the extractive summary which support any of the decisions in the abstractive summary were manually tagged as decision-related. Hsueh and Moore (2007) then trained a Maximum Entropy classifier to recognize this single DA class, using a variety of lexical, prosodic, dialogue act and conversational topic features. They achieved an F-score of 0.35, which gives an indication of the difficulty of this task.

Unlike Hsueh and Moore (2007), Fernández et al. (2008) made an attempt at modelling the structure of decision-making dialogue. They designed an annotation scheme that takes account of the different roles which different utterances play in the decision-making process — for example, their scheme distinguishes between decision DAs (DDAs) which initiate a discussion by raising a topic/issue, those which propose a resolution, and those which express agreement for a proposed resolution and cause it to be accepted as a decision. The authors applied the annotation scheme to a portion of the AMI corpus, and then took what they refer to as a *hierarchical classification* approach in order to automatically identify decision discussions and their component DAs. Here, one binary *Support Vector Machine (SVM)* per DDA class hypothesized occurrences of that DDA class, and then based on the hypotheses of these so-called *sub-classifiers*, a *super-classifier*, (a further SVM), determined which regions of dialogue represented decision discussions. This approach produced better results than the kind of "flat classification" approach pursued by Hsueh and Moore (2007) where a single classifier looks for examples of a single decision-related DA class. Using manual transcripts, and a variety of lexical, utterance, speaker, DA and prosodic features for the sub-classifiers, the super-classifier's F1-score was 0.58 according to a lenient match metric. Note that (Purver et al., 2007) had previously pursued the same basic approach as Fernández et al. (2008) in order to detect action items.

While both Hsueh and Moore (2007), and Fernández et al. (2008) attempted off-line decision detection, in this paper, we attempt real-time decision detection. We take the same basic approach as Fernández et al. (2008), and make changes to its implementation so that it can work effectively in real-time.

3 Data

The AMI corpus (McCowan et al., 2005), is a freely available corpus of multi-party meetings containing both audio and video recordings, as well as a wide range of annotated information including dialogue acts and topic segmentation. Conversations are all in English, but participants can include non-native English speakers. All of the meetings in our sub-corpus last around 30 minutes, and are scenario-driven, wherein four participants play different roles in a company's design team: *project manager*, *marketing expert*, *interface designer* and *industrial designer*. The discussions concern how to design a remote control.

We used the off-line version of the Decipher speech recognition engine (Stolcke et al., 2008) in

order to obtain off-line ASR transcripts for these 17 meetings, and the real-time version, to obtain real-time ASR transcripts. Decipher generates the transcripts by first producing Word Confusion Networks (WCNs) and then extracting their best paths. The real-time recognizer generates "live" transcripts with 5 to 15 seconds of latency for immediate display. In processing completed meetings, the off-line system makes seven recognition passes, including acoustic adaptation and language model rescoring, in about 4.2 times real-time (on a 4-score 2.6 GHz Opteron server). In general usage with multi-party dialogue, the word error rate (WER) for the off-line version of Decipher is approximately 23%, and for the real-time version, approximately 35%[1]. Stolcke et al. (2008) report a WER of 26.9% for the off-line version on AMI meetings.

The real-time ASR transcripts for the 17 meetings contain a total of 8440 utterances/dialogue acts, (around 496 per meeting), and the off-line ASR transcripts, 7495 utterances/dialogue acts, (around 441 per meeting).

3.1 Modelling Decision Discussions

We use the same annotation scheme as (Fernández et al., 2008) in order to model decision-making dialogue. As stated in Section 2, this scheme distinguishes between a small number of dialogue act types based on the role which they perform in the formulation of a decision. Recall that using this scheme in conjunction with *hierarchical classification* produced better decision detection than a "flat classification" approach with a single "decision-related" DA class. Since it indicates which utterances contain particular types of information, such a scheme also aids the summarization of decision discussions.

The annotation scheme (see Table 1 for a summary) is based on the observation that a decision discussion contains the following main structural components: (a) a topic or issue requiring resolution is raised, (b) one or more possible resolutions are considered, (c) a particular resolution is agreed upon, that is, it becomes the decision. Hence the scheme distinguishes between three corresponding decision dialogue act (DDA) classes: *Issue* (*I*), *Resolution* (*R*), and *Agreement* (*A*). Class *R* is further subdivided into *Resolution Proposal* (*RP*) and *Resolution Restatement* (*RR*). Note that an utterance can be assigned to more than one of these DDA classes, and that within a decision discussion, more than one utterance may correspond to a particular DDA class.

Here we use the sample decision discussion below in 1 in order to provide examples of the different DDA types. *I* utterances introduce the topic of the decision discussion, examples being *"Are we going to have a backup?"* and *"But would a backup really be necessary?"* On the other hand, *R* utterances specify the resolution which is ultimately adopted as the decision. *RP* utterances propose this resolution (e.g. *"I think maybe we could just go for the kinetic energy..."*), while *RR* utterances close the discussion by confirming/summarizing the decision (e.g. *"Okay, fully kinetic energy"*). Finally, *A* utterances agree with the proposed resolution, so causing it to be adopted as the decision, (e.g. *"Yeah"*, *"Good"* and *"Okay"*.

(1) A: Are we going to have a backup?
Or we do just–
B: But would a backup really be necessary?
A: I think maybe we could just go for the kinetic energy and be bold and innovative.
C: Yeah.
B: I think– yeah.
A: It could even be one of our selling points.
C: Yeah –*laugh*–.
D: Environmentally conscious or something.
A: Yeah.
B: Okay, fully kinetic energy.
D: Good.[2]

3.2 Experimental data for real-time decision detection

Originally, two individuals used the annotation scheme described above in order to annotate the manual transcripts of 9 and 10 meetings respectively. The annotators overlapped on two meetings, and their *kappa* inter-annotator agreement ranged from 0.63 to 0.73 for the four DDA classes. The highest agreement was obtained for class *RP*, and the lowest for class *A*. Although these kappa values are not extremely high, if we used a single, less homogeneous "decision-related" DA class like Hsueh and Moore (2007), then its kappa score

[1] This information was obtained through personal communication.

[2] This example was extracted from the AMI dialogue ES2015c and has been modified slightly for presentation purposes.

key	DDA class	description
I	*issue*	utterances introducing the issue or topic under discussion
R	*resolution*	utterances containing the resolution adopted as the decision
RP	*– proposal*	– utterances where the decision is originally proposed
RR	*– restatement*	– utterances where the decision is confirmed or restated
A	*agreement*	utterances explicitly signalling agreement with the decision

Table 1: Set of decision dialogue act (DDA) classes

would probably be significantly lower. The decision discussion annotations used by Hsueh and Moore (2007) are part of the AMI corpus, and are for the manual transcriptions. The reader can find a comparison between these annotations and our own manual transcript annotations in (Fernández et al., 2008).

After obtaining the new off-line and real-time ASR transcripts, we transferred the DDA annotations from the manual transcripts. In both sets of ASR transcripts, each meeting contains on average around 26 DAs tagged with one or more of the DDA sub-classes in Table 1. DDAs are thus very sparse, corresponding to only 5.3% of utterances in the real-time transcripts, and 6.0% in the off-line. In the real-time transcripts, *Issue* utterances make up less than 1.2% of the total number of utterances in a meeting, while *Resolution* utterances are around 1.6%: 1.2% are *RP* and less than 0.4% are *RR* on average. Almost half of DDA utterances (slightly over 2.6% of all utterances on average) are tagged as belonging to class *Agreement*. In the off-line transcripts, the percentages are fairly similar: 1.6% of utterances are *Issue* DDAs, 2.0% are *RP*, 0.5% are *RR*, and 2.4% are *A*.

We now move on to describe the *hierarchical classification* approach which we use to try to automatically detect decision sub-dialogues and their component DDAs.

4 Hierarchical Classification

Hierarchical classification is designed to exploit the fact that within decision discussions, our DDAs can be expected to co-occur in particular types of patterns. It involves two different types of classifier:

1. **Sub-classifier:** One independent binary *sub-classifier* per DDA class classifies each utterance.

2. **Super-classifier:** A sliding window shifts through the meeting one utterance at a time, and following each shift, a binary *super-classifier* determines whether the region of dialogue within the window is part of a decision discussion.

In our decision detectors, the sub-classifiers run in parallel in order to reduce processing time. For each utterance, the sub-classifiers use features which are derived from the properties of that utterance in context. On the other hand, the super-classifier's features are the hypothesized class labels and confidence scores for the utterances within the window. In various experiments, we have found that a suitable size for the window, is the average length of a decision discussion in our data in utterances. The super-classifier also "corrects" the sub-classifiers. This means that if a DA is classified as positive by a sub-classifier, but does not fall within a region classified as part of a decision discussion by the super-classifier, then the sub-classifier's hypothesis is changed to negative.

We now move on to consider how this basic approach to decision detection can be implemented in a real-time system.

5 Design considerations for our real-time system

A real-time decision detector should detect decisions as soon after they are made as possible. It is for this reason that we have set our real-time detector to automatically run at frequent and regular intervals during a meeting. An alternative would be to give the user (a meeting participant) responsibility for instructing the detector when to run. However, a user may sometimes leave substantial gaps between giving run commands. When this happens, the detector will have to process a large number of utterances in a single run, and so the user may wait some time before being presented with any results. In addition, giving the user responsibility for instructing the detector when to

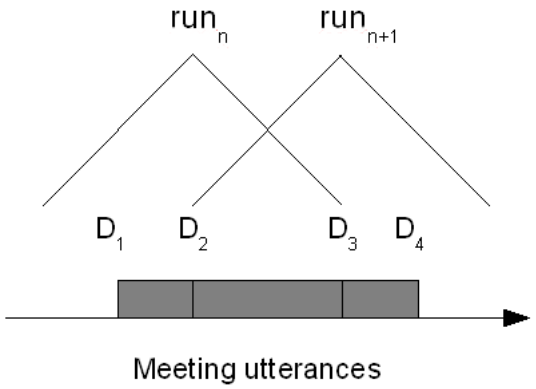

Figure 1: Decision discussion regions hypothesized by consecutive runs overlap (D_1 to D_3 and D_2 to D_4) and so are merged.

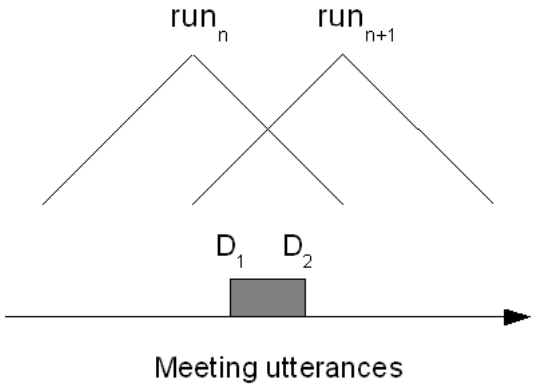

Figure 2: Consecutive runs hypothesize the same decision discussion region D_1 to D_2, and so one of the duplicates is discarded.

run means burdening the user with an extra task to perform during the meeting, and this goes against the general philosophy behind the system's development. The system is intended to be as unobtrusive as possible during the meeting, and to relieve users of tasks which distract their attention away from the current discussion (e.g. note-taking), not to create new tasks, however small.

Obviously, on the first occasion that the detector runs during a meeting, it can only process "new" (previously unprocessed) utterances, but on subsequent runs, it has the option to reprocess some number of "old" utterances (utterances which it has already processed in a previous run). Certainly, the detector should reprocess some of the most recent old utterances because it is possible that a decision discussion straddles these utterances and new utterances. However, the number of old utterances that are reprocessed should be limited. If the meeting has lasted a while already, then the processing of a large portion of the earlier old utterances is likely to be redundant — it will simply produce the same results for these utterances as the previous run.

The fact that the real-time detector processes recent old utterances means that consecutive runs can produce hypotheses for decision discussion regions which overlap, or which are duplicates. Figure 1 gives an example of the former. We deal with overlapping hypotheses by merging them into one, so forming a larger single decision discussion region. Figure 2 gives an example of duplicate hypotheses. Here, on run n, the detector hypothesizes decision discussion D_1 to D_2, and then on run $n+1$, since the bounds of this original hypothesis are now wholly contained within the region of old reprocessed utterances, the detector hypothesizes a duplicate. We deal with such cases by discarding the duplicate.

6 Experiments

We conducted various experiments related to real-time decision detection, our goal being to produce a system which:

- relative to alternative versions, detects decision discussions accurately,
- generates results for any portion of dialogue very soon after that portion of dialogue has ended.

The current version of our real-time detector is set to process the same number of old and new utterances on each run. Here, we refer to this value as i, and hence on each run the system processes a total of $2i$ utterances (i old and i new). Another of the system's characteristics is that runs take place every i utterances, meaning that as we decrease i, the system provides new results more frequently and is hence "more real-time". One of the things we investigate here then, is what to set i to in order to best satisfy the two design goals given above. Having found this value, we compare the hierarchical real-time detector's performance with alternative detectors, these being:

- an off-line detector applied to off-line ASR transcripts,
- a flat real-time detector,
- an off-line detector applied to the real-time ASR transcripts.

Lexical	unigrams after text normalization
Utterance	length in words, duration in word rate
Speaker	speaker ID & AMI speaker role
Context	features as above for utterances u +/- 1...u +/- 5

Table 2: Features for decision DA detection

Note that the off-line detectors use hierarchical classification, and that the flat real-time detector uses a single binary classifier which treats all DDAs as members of a single merged DDA class.

6.1 Classifiers and features

All classifiers (sub and super-classifiers) in all detectors are linear-kernel *Support Vector Machines (SVMs)*, produced using *SVMlight* (Joachims, 1999). For the sub-classifiers, we are obviously restricted to using features which can be computed in a very short period of time, and in the experiments here, we use *lexical*, *utterance* and *speaker* features. These are summarized in Table 2. An utterance's lexical features are the words in its transcription, its utterance features are its duration, number of words, and word rate (number of words divided by duration), and its speaker features are the speaker's role (see Section 3) and ID. We also use lexical features for the previous and where available, next utterances: the *I*, *RP* and *RR* sub-classifiers use the lexical features for the previous/next utterance and the *A* sub-classifier, those from the previous/next 5 utterances. These settings produced the best results in preliminary experiments. We do not use DA features because we lack an automatic DA tagger, nor do we use prosodic features because (Fernández et al., 2008) was unable to derive any value from them with SVMs.

6.2 Evaluation

We evaluate each of our decision detectors in 17-fold cross validations, where in each fold, the detector trains on 16 meetings and then tests on the remaining one. Evaluation can be made at three levels:

1. The sub-classifiers' detection of each of the DDA classes.

2. The sub-classifiers' detection of each of the DDA classes after correction by the super-classifier.

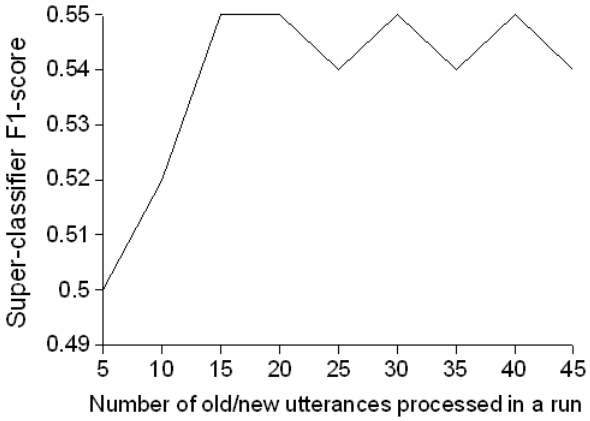

Figure 3: The relationship between the number of old/new utterances processed in a single run, and the super-classifier's F1-score. Here the sub-classifiers use only lexical features.

3. The super-classifier's detection of decision discussion regions.

For 1 and 2, we use the same lenient-match metric as (Fernández et al., 2008; Hsueh and Moore, 2007), which allows a margin of 20 seconds preceding and following a hypothesized DDA. Note that here we only give credit for hypotheses based on a 1-1 mapping with the gold-standard labels. For 3, we follow (Fernández et al., 2008; Purver et al., 2007) and use a windowed metric that divides the dialogue into 30-second windows and evaluates on a per window basis.

6.3 Results and analysis

Here, Section 6.3.1 will present results for different values of i, the number of old/new utterances processed in a single run. Section 6.3.2 then compares the performance of the real-time and off-line systems, (and also real-time systems which use hierarchical *vs.* flat classification), and Section 6.3.3 presents some feature analysis.

6.3.1 Varying the number of old/new utterances processed in a run

Figure 3 shows the relationship between i, the setting for the number of old/new utterances processed in a single run, and the super-classifier's F1-score. Here, the sub-classifiers are using only lexical features. We can see from the graph that as i increases to 15, the super-classifier's F1-score also increases, but thereafter, it plateaus. Hence 15 is apparently the value which best satisfies the two design goals given at the start of Section 6. It should also be noted that 15 is the mean length of a decision discussion in our data, and so per-

	sub-classifiers				super

Table 4: Results for the hierarchical off-line decision detector on off-line ASR transcripts, using lexical, utterance and speaker features.

haps this is a transferable finding. The mean duration of a run when $i = 15$ is approximately 4 seconds, while the mean duration of 15 utterances in our data-set is approximately 60 seconds, meaning that for the average case, the detector returns the results for the current run, long before it is due to make the next. Significant lee-way is perhaps necessary here, because the final version of the real-time detector will include a summarization component which extracts key phrases from *Issue/Resolution* utterances, and its processing can last some time, even for a single decision.

We should say then, that the system is not strictly real-time because in general, it detects decisions soon after they are made (for example within a minute), rather than immediately after. In the future we intend to modify the system so that it can run more frequently than once every i utterances. However it is important that runs do not occur too frequently — for example, if $i = 15$ and the system runs after every utterance, then the extra processing will cause it to gradually fall further and further behind the meeting.

6.3.2 Real-time *vs.* off-line results

Table 3 shows the results achieved by a hierarchical real-time decision detector whose run settings are as described above, and whose sub-classifiers[3] use lexical, utterance and speaker features. These results compare well with those of an equivalent off-line detector, which are shown in Table 4. The F1-scores for the real-time and off-line decision super-classifiers are $.54$ and $.55$ respectively, and the difference is not statistically significant. This may indicate that the hierarchical classification approach is fairly robust to increasing ASR Word Error Rates (WERs). Combining the output from each of the independent sub-classifiers might compensate somewhat for any decreases in their individual accuracy, as there was here for the *I* and *RP* sub-classifiers.

[3] In Tables 3 to 6, sub-classifier results are post-correction (see Section 6.2).

	sub-classifiers				super
	I	RP	RR	A	classifier
Re	.50	.51	.09	.63	.83
Pr	.11	.11	.03	.14	.41

	sub-classifiers				super
	I	RP	RR	A	classifier
Re	.67	.74	.84	.66	.85
Pr	.07	.08	.03	.14	.41
F1	.13	.15	.05	.24	.55

Table 6: Results for the hierarchical real-time decision detector, using lexical features only.

The hierarchical real-time detector's F1-score is also 10 points higher than a flat classifier ($.54$ *vs.* $.44$). Hence, while Fernández et al. (2008) demonstrated that the hierarchical classification approach could improve off-line decision detection, we have demonstrated here that it can also improve real-time decision detection.

Table 5 shows the results when an off-line detector is applied to real-time ASR transcripts. Here, the super-classifier obtains an F1-score of $.55$, one point higher than the real-time detector, but again, the difference is not statistically significant.

6.3.3 Feature analysis

We also investigated the contribution of the utterance and speaker features. Table 6 shows the results for the hierarchical real-time decision detector when its sub-classifiers use only lexical features. The sub-classifier F1-scores are all slightly lower than when utterance and speaker features are used (see Table 3), and the super-classifier

score is only 1 point different. None of these differences are statistically significant.

Since lexical features are important, we used *information gain* in order to investigate which words are predictive of each DDA type. Due to differences in the transcripts, the predictive words for the off-line and real-time systems are not the same, but we can find commonalities, and these commonalities make sense given the DDA definitions. Firstly in *Resolution* and particularly *Issue* DAs, some of the most predictive words could be used to define discussion topics, and so we might expect to find them in the meeting agenda. Examples are "energy", and "color". Predictive words for *Resolutions* also include semantically-related words which are key in defining the decision ("kinetic","green"). Additional predictive words for *RPs* are the personal pronouns "I" and "we", and the verbs, "think" and "like", and for *RRs*, words which we would associate with summing up ("consensus", "definitely", and "okay"). Unsurprisingly, for *Agreements*, "yeah" and "okay" both score very highly.

7 Conclusion

(Fernández et al., 2008) described an approach to decision detection in multi-party meetings and demonstrated how it could work relatively well in an off-line system. The approach has two defining characteristics. The first is its use of an annotation scheme which distinguishes between different utterance types based on the roles which they play in the decision-making process. The second is its use of hierarchical classification, whereby binary *sub-classifiers* detect instances of each of the decision DAs (DDAs), and then based on the sub-classifier hypotheses, a *super-classifier* determines which regions of dialogue are decision discussions.

In this paper then, we have taken the same basic approach to decision detection as Fernández et al. (2008), but changed the way in which it is implemented so that it can work effectively in real-time. Our implementation changes include running the detector at regular and frequent intervals during the meeting, and reprocessing recent utterances in case a decision discussion straddles these and brand new utterances. The fact that the detector reprocesses utterances means that on consecutive runs, overlapping and duplicate hypothesized decision discussions are possible. We have therefore added facilities to merge overlapping hypotheses and to remove duplicates.

In general, the resulting system is able to detect decisions soon after they are made (for example within a minute), rather than immediately after. It has performed well in testing, achieving an F1-score of .54, which is only one point lower than an equivalent off-line system, and in any case, the difference was not statistically significant. A flat real-time detector achieved .44.

In future work, we plan to extend the decision discussion annotation scheme and try to extract supporting arguments for decisions. We will also experiment with using sequential models in order to try to exploit any sequential ordering patterns in the occurrence of the DDAs.

On the Role of Lexical Features in Sequence Labeling

Abstract

We use the technique of SVM anchoring to demonstrate that lexical features extracted from a training corpus are not necessary to obtain state of the art results on tasks such as Named Entity Recognition and Chunking. While standard models require as many as 100K distinct features, we derive models with as little as 1K features that perform as well or better on different domains. These robust reduced models indicate that the way rare lexical features contribute to classification in NLP is not fully understood. Contrastive error analysis (with and without lexical features) indicates that lexical features do contribute to resolving some semantic and complex syntactic ambiguities – but we find this contribution does not generalize outside the training corpus. As a general strategy, we believe lexical features should not be directly derived from a training corpus but instead, carefully inferred and selected from other sources.

1 Introduction

Common NLP tasks, such as Named Entity Recognition and Chunking, involve the identification of spans of words belonging to the same phrase. These tasks are traditionally reduced to a tagging task, in which each word is to be classified as either **B**eginning a span, **I**nside a span, or **O**utside of a span. The decision is based on the word to be classified and its neighbors. Features supporting the classification usually include the word forms themselves and properties derived from the word forms, such as prefixes, suffixes, capitalization information, and parts-of-speech. While early approaches to the NP-chunking task (Cardie and Pierce, 1998) relied on part-of-speech information alone, it is widely accepted that lexical information (word forms) is crucial for building accurate systems for these tasks. Indeed, all the better-performing systems in the CoNLL shared tasks competitions for Chunking (Sang and Buchholz, 2000) and Named Entity Recognition (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) make extensive use of such lexical information.

Is this belief justified? In this paper, we show that the influence of lexical features on such sequence labeling tasks is more complex than is generally assumed. We find that exact word forms aren't necessary for accurate classification. This observation is important because relying on the exact word forms that appear in a training corpus leads to over-fitting, as well as to larger models.

In this work, we focus on learning with Support Vector Machines (SVMs) (Vapnik, 1995). SVM classifiers can handle very large feature spaces, and produce state-of-the-art results for NLP applications (see *e.g.* (Kudo and Matsumoto, 2000; Nivre et al., 2006)). Alas, when trained on pruned feature sets, in which rare lexical items are removed, SVM models suffer a loss in classification accuracy. It would seem that rare lexical items are indeed crucial for SVM classification performance. However, in Goldberg and Elhadad (2007), we suggested that the SVM learner is using the rare lexical features for singling out hard cases rather than for learning meaningful generalizations. We provide further evidence to support this claim in this paper.

*Supported by the Lynn and William Frankel Center for Computer Sciences, Ben Gurion University

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1142–1151,
Singapore, 6-7 August 2009.

We show that by using a variant of SVM – *Anchored SVM Learning* (Goldberg and Elhadad, 2007) with a polynomial kernel, one can learn accurate models for English NP-chunking (Marcus and Ramshaw, 1995), base-phrase chunking (CoNLL 2000), and Dutch Named Entity Recognition (CoNLL 2002), on a heavily pruned feature space. Our models make use of only a fraction of the lexical features available in the training set (less than 1%), and yet provide highly-competitive accuracies.

For the Chunking and NP-Chunking tasks, the most heavily pruned experiments, in which we consider only features appearing at least 100 times in the training corpus, do show a small but significant drop in accuracy on the testing corpus compared to the non-pruned models exposed to all available features in the training data. We provide detailed error analysis of a development set in Section 6, revealing the causes for these differences. We suggest one additional binary feature in order to account for some of the performance gap. Moreover, we show that the differences in accuracy vanish when the lexicalized and unlexicalized models are tested on text from slightly different sources than the training corpus (Section 7).

This goes to show that with an appropriate learning method, orthographic and structural (in the form of POS tag sequences) information is sufficient for achieving state-of-the-art performance on these kind of sequence labeling tasks. This does not mean semantic information is not needed for these tasks. It does mean that current models capture only a tiny amount of such semantic information through rare lexical features, and in a manner that does not generalize well.

We believe this data motivates a different strategy to incorporate lexical features into classification models: instead of collecting the raw lexical forms appearing in a training corpus, we should attempt to actively construct a feature space including lexical features derived from external sources. The feature representation of (Collobert and Weston, 2008) could be a step in that direction. We also believe that hard cases for sequence labeling (POS ambiguity, coordination, long syntactic constructs) could be directly approached with specialized classifiers.

1.1 Related Work

This work complements a similar line of results from the parsing literature. While it was initially believed that lexicalization of PCFG parsers (Collins, 1997; Charniak, 2000) is crucial for obtaining good parsing results, Gildea (2001) demonstrated that the lexicalized Model-1 parser of Collins (1997) does not benefit from bilexical information when tested on a new text domain, and only marginally benefits from such information when tested on the same text domain as the training corpora. This was followed by (Bikel, 2004) who showed that bilexical-information is used in only 1.49% of the decisions in Collins' Model-2 parser, and that removing this information results in "an exceedingly small drop in performance". However, uni-lexical information was still considered crucial. Klein and Manning (2003) bridged the gap between lexicalized and unlexicalized parsing performance, providing a competitive unlexicalized parsing model, relying on lexical information for only a few closed-class lexical items. This was recently followed by (Matsuzaki et al., 2005; Petrov et al., 2006) who introduce state-of-the-art nearly unlexicalized PCFG parsers.

Similarly for discriminative dependency parsing, state-of-the-art parsers (McDonald, 2006; Nivre et al., 2006) are highly lexicalized. However, the model analysis in (McDonald, 2006) reveals that bilexical features hardly contribute to the performance of a discriminative MST-based dependency parser, while Kawahara and Uchimoto (2007) demonstrate that minimally-lexicalized shift-reduce based dependency parsers can produce near state-of-the-art accuracy.

In this work, we address the same question of determining the impact of lexical features on a different family of tasks: sequence labeling, as illustrated by named entity recognition and chunking. As discussed above, all state-of-the-art published methods rely on lexical features for such tasks (Zhang et al., 2001; Sha and Pereira, 2003; Finkel et al., 2005; Ratinov and Roth, 2009). Sequence labeling includes both a structural aspect (bracketing the chunks) and a tagging aspect (classifying the chunks). While we expect the structural aspect can benefit from techniques similar to those used in the parsing literature, it is unclear whether the tagging component could perform well without detailed lexical information. We demonstrate in this work that, indeed, lexical features are not necessary to obtain competitive performance. Our approach consists in performing a detailed analysis

of the role played by rare lexical features in SVM models. We distinguish the information brought to the model by such features from the role they play in a specific learning method.

2 Learning with Less Features

We adopt the common feature representation in which each data-point is represented as a sparse D dimensional binary-valued vector f. Each of the D possible features f_i is an indicator function. The indicator functions look at properties of the current or neighbouring words. An example of such function f_i is `1 iff the previous word-form is DOG, 0 otherwise`. The lexical (word-form) features result in extremely high-dimensional (yet very sparse) feature vectors – each word-form in the vocabulary of the training set correspond to (at-least) one indicator function.

Due to the Zipfian distribution of language data, many of the lexical features are very rare, and appear only a couple times in the training set. Ideally, we would like our classifiers to learn only from robust features: consider only features that appear at least k times in the training data (rare-feature pruning). These features are more likely to appear in unseen test data, and thus such features can support more robust generalization.

However, we find empirically that performing such feature pruning *prior* to learning SVM models hurts the performance of the learned models. Our intuition is that this sensitivity to rare lexical features is not explained by the richness of information such rare features bring to the model. Instead, we believe that rare lexical features help the classifier because they make the data *artificially* more separable. To demonstrate this claim, we experiment with anchored SVM, which introduces artificial mechanical anchors into the model to achieve separability, and make rare lexical features unnecessary.

3 Learning Method

SVM are discriminative, max-margin, linear classifiers (Vapnik, 1995), which can be kernelized. For the formulation of SVMs in the context of NLP applications, see (Kudo and Matsumoto, 2001). SVMs with a polynomial kernel of degree 2 were shown to provide state-of-the-art performance in many NLP application, see for example (Kudo and Matsumoto, 2000; Nivre et al., 2006; Isozaki and Kazawa, 2002; Goldberg et al., 2006).

SVMs cope with inseparable data by introducing a *soft-margin* – allowing some of the training instances to be classified incorrectly subject to a penalty, controlled by a parameter C.

Anchored SVM As we show in Section 5, the soft-margin heuristic performs sub-optimally for NLP tasks when the data is inseparable. We use instead the *Anchored Learning* heuristic, introduced in (Goldberg and Elhadad, 2007). The idea behind anchored learning is that some training instances are inherently ambiguous. This ambiguity stems from ambiguity in language structure, which cannot be resolved with a given feature representation. When a data-point cannot be classified, it might be due to missing information, which is not available in the data representation. Instead of allowing ambiguous items to be misclassified during training, we make the training data artificially separable. This is achieved by adding a unique feature to each training example (an *anchor*). These anchor features cause each data-point to be slightly more similar to itself than to any other data point. At test time, we remove anchor features.
In terms of kernel-based learning, anchored learning can be achieved by redefining the dot product between two vectors to take into account the identity of the vectors: $x_i \cdot_{anc} x_j = x_i \cdot x_j + \delta_{ij}$.

The classifier learned over the anchored data takes into account the fine interactions between the various inseparable data points. In our experiments, SVM models over anchored data have many more support vectors than soft-margin SVM models. However, the anchored models generalize much better when less features are available.

Relation to L2 SVM The classic soft-margin SVM formulation uses L1-penalty for misclassified instances. Specifically, the objective of the learner is to minimize $\frac{1}{2}||w||^2 + C\sum_i \xi_i$ subject to some margin constraints, where w is a weight vector to be learned and ξ_i is the misclassification error for instance i. This is equivalent to maximizing the dual problem:
$\sum_{i=1}^{M} \alpha_i - \frac{1}{2}\sum_{i,j} \alpha_i \alpha_j y_i y_j K(x_i, x_j)$

Another variant is L2-penalty SVM (Koshiba and Abe, 2003), in which there is a quadratic penalty for misclassified instances.
Here, the learning objective is to minimize: $\frac{1}{2}||w||^2 + \frac{1}{2}C\sum_i \xi_i^2$ or alternatively maximize the dual: $\sum_i \alpha_i - \frac{1}{2}\sum_{i,j} \alpha_i \alpha_j y_i y_j (K(x_i, x_j) + \frac{\delta_{ij}}{C})$.

Interestingly, for the linear kernel, SVM-

anchoring reduces to L2-SVM with C=1. However, for the case of non-linear kernels, anchored and L2-SVM produce different results, as the anchoring is applied prior to the kernel expansion. Specifically for the case of the second-degree polynomial kernel, L2-SVM aims to maximize:

$\sum_i \alpha_i - \frac{1}{2}\sum_{i,j}\alpha_i\alpha_j y_i y_j((x_i \cdot x_j + 1)^2 + \frac{\delta_{ij}}{C})$,

while the anchored-SVM variant would maximizes: $\sum_i \alpha_i - \frac{1}{2}\sum_{i,j}\alpha_i\alpha_j y_i y_j(x_i \cdot x_j + \delta_{ij} + 1)^2$.

In our experiments, as discussed in Section 5.4, we find that anchored-SVM and soft-margin SVM with tuned C value both reach good results when we reduce the amount of lexical features. Anchored-SVM, however, does not require fine-tuning of the error-parameter C since it insures separability. As a result, we learn anchored-SVM models quickly (few hours) as opposed to several days per model for C-tuned soft-margin SVM. Anchored-SVMs also provide an easy explanation of the role of features in terms of separability. Therefore, we use anchored-SVMs in our experiments as the learning method, but we expect that other learning methods are capable of learning with the same reduced feature sets.

4 Experiment Setup

How important are the rare lexical features for learning accurate NLP models? To investigate this question, we experiment with 3 different NLP sequence-labeling tasks. For each task, we train a sequence of polynomial kernel (d=2) SVM classifiers, using both soft-margin (C=1) and anchored SVM. Each classifier is trained on a pruned feature set, in which only features appearing at least k times in the training data are kept. We vary the pruning parameter k. Pruning is performed over all the features in the model, but lexical features are most affected by it.

For all the models, we use the B-I-O representation, and perform multiclass classification using pairwise-voting. For our features, we consider properties of tokens in a 5-token window centered around the token to be classified, as well as the two previous classifier predictions. Results are reported as F-measure over labeled identified spans.

Polynomial vs. Linear models The polynomial kernel of degree 2 allows us to efficiently and implicitly include in our models all feature pairs. Syntactic structure information as captured by pairs of POS-tags and Word-POS pairs is certainly important for such syntactic tasks as Chunking and NER, as demonstrated by the many systems described in (Sang and Buchholz, 2000; Tjong Kim Sang, 2002). By using the polynomial kernel, we can easily make use of this information without intensive feature-tuning for the most successful feature pairs.

L1-SVM, L2-SVM and the choice of the C parameter Throughout our experiments, we use the "standard" variant of SVM, L1-penalty soft margin SVM, as implemented by the TinySVM[1] software package, with the default C value of 1. This setting is shown to produce good results for sequence labeling tasks in previous work (Kudo and Matsumoto, 2000), and is what most end-users of SVM classifiers are likely to use. As we show in Sect.5.4, fine-tuning the C parameter reaches better accuracy than L1-SVM with C=1. However, as this fine-tuning is computationally expensive, we first report the comparison L1-SVM/C=1 vs. anchored-SVM, which consistently reached the best results, and was the quickest to train.

Feature Pruning vs. Feature Selection Our aim in this set of experiments is not to find the optimal set of lexical features, but rather to demonstrate that most lexical items are not needed for accurate classification in sequence labeling tasks. To this end, we perform very crude frequency based feature pruning. We believe better motivated feature selection technique taking into account linguistic (*e.g. prune only open-class words*) or statistic information could result in slightly more accurate models with even fewer lexical items.

5 Experiments and Results

5.1 Named Entity Recognition (NER)

We use the Dutch data set from the CoNLL 2002 shared task (Tjong Kim Sang, 2002). The aim is to identify named entities (persons, locations, organizations and miscellaneous) in text. The task has two stages: identification of the entities, and classification of the identified entities into their corresponding types. We focus here on the identification task.

Features: We use the following properties for each of the relevant tokens: word-form, POS, ORT, prefix1, prefix2, prefix3, suffix1, suffix2, suffix3. The ORT feature can take one of the following values: {number, contains-digit, contains-hyphen, capitalized, all-capitalized, URL, punctuation, regular}.

[1] http://chasen.org/~taku/software/TinySVM/

PRUNING	#FEATURES	SOFT-MARGIN	ANCHORED
0	186,421	90.92	90.78
100	5,804	90.73	90.75
1000	1,207	88.56	90.10
1500	821	85.92	89.29

Table 1: Named Entity Identification results (F-score) on dev set, with various pruning thresholds.

Results are presented in Table 1. Without feature pruning, we achieve an F-score of 90.9. This dataset proved to be quite resilient to feature pruning. Pruning features appearing less than 100 times results in just a slight decrease in F-score. Extremely aggressive pruning, keeping only features appearing more than 1,000 or 1,500 times in the training data, results in a big drop in F-score for the soft-margin SVM (from about 91 to 86). Much less so for the Anchored-SVM. Using Anchored SVM we achieve an F-score of 90.1 after pruning with $k = 1,000$. This model has 1207 active features, and 27 unique active lexical forms.

5.2 NP Chunking

The goal of this task (Marcus and Ramshaw, 1995) is the identification of non-recursive NPs. We use the data from the CoNLL 2000 shared task: NP chunks are extracted from Sections 15-18 (train) and 20 (test) of the Penn WSJ corpus. POS tagged are automatically assigned by the Brill Tagger.

Features: We consider the POS and word-form of each token.

PRUNING	#FEATURES	SOFT-MARGIN	ANCHORED
0	92,805	94.12	94.08
1	46,527	93.78	94.09
2	32,583	93.58	94.00
5	18,092	93.42	94.01
10	10,812	93.00	93.98
20	5,952	92.48	93.92
50	2,436	92.33	93.96
100	1,168	91.94	93.83

Table 2: NP-Chunking results (F-score), with various pruning thresholds.

Results are presented in Table 2. Without feature pruning ($k = 0$), the soft-margin SVM performs slightly better than the Anchored-SVM. Either of the results are state-of-the-art for this task. However, even modest pruning ($k = 2$) hurts the soft-margin model significantly. Not so for the anchored-SVM. Even with relatively aggressive pruning ($k = 100$), the anchored model still achieves an impressive F-score of 93.83. Remarkably, in that last model, there are only 1,168 active features, and only 209 unique active lexical forms.

5.3 Chunking

The goal of the Chunking task (Sang and Buchholz, 2000) is the identification of an assortment of linguistic base-phrases. We use the data from the CoNLL 2000 shared task.

Features: We perform two experiments. In the first experiment, we consider the POS and word-form of each token. In this setting, feature pruning resulted in a bigger loss in performance than in the two previous tasks. Preliminary error analysis revealed that many errors are due to tagger errors, especially of the present participle forms. This led us to the second experiment, in which we added as features the 2- and 3- letter suffixes for the word to be classified (but not for the surrounding words).

Results are presented in Tables 3 and 4. In the first experiment (POS + Word), the non-pruned soft-margin model is the same system as the top-performing system in the original shared task, and yields state-of-the-art results. Unlike the NP-chunking case, here feature pruning has a relatively large impact on the results even for the anchored models. However, the anchored models are still far more robust than the soft-margin ones. With $k = 100$ pruning, the soft-margin model suffers a drop of 2.5 F points, while the anchored model suffers a drop of only 0.84 F points. Even after this drop, the anchored $k = 100$ model still performs above the top-third system in the CoNLL 2000 shared task. This anchored $k = 100$ model has 1,180 active features, and only 209 unique active lexical features.

The second experiment (POS + word-form + suffixes for main word) adds crude morphological information to the learner, helping it to avoid common tagger mistakes. This additional information is helpful: pruning with $k = 100$ leads to an accurate anchored model (93.12 F) with only 209 unique lexical items. Note that with the addition of the suffix features, the pruned model $k = 20$ beats the purely lexical model (no suffix features) with no pruning (93.51 vs. 93.44) with 10 times less features. When we combine suffixes and all lexical forms, we still see a slight advantage to the lexical model (93.73 vs. 93.12 with pruning at $k = 100$).

Even less lexicalization How robust are the suffixes? We performed a third experiment, in which

PRUNING	#FEATURES	SOFT-MARGIN	ANCHORED
0	92,837	93.44	93.40
1	46,557	93.20	93.32
2	32,614	93.10	93.31
5	18,126	92.89	93.29
10	10,834	92.73	93.23
20	5,975	92.18	93.16
50	2,463	91.80	92.89
100	1,180	90.94	92.56

Table 3: Chunking results (F), with various pruning thresholds. Experiment 1. Features: POS, Word.

PRUNING	#FEATURES	SOFT-MARGIN	ANCHORED
0	104,304	93.73	93.69
1	72,228	93.56	93.68
2	57,578	93.50	93.64
5	37,210	93.35	93.62
10	23,968	93.26	93.56
20	14,060	92.84	93.51
50	6,326	92.28	93.37
100	3,340	91.83	93.12

Table 4: Chunking results (F), with various pruning thresholds. Experiment 2. Features: POS, Word, {Suff2, Suff3} of main Word.

we replaced any explicit word-forms by 2- and 3-letter suffixes. This gives us the complete word form of many function words, and a reasonable amount of morphological marking. Results are presented in Table 5. Surprisingly, this information proves to be quite robust. Without feature pruning, both the anchored and soft-margin model achieve near state-of-the-art performance of 93.25F. Pruning with $k = 100$ hurts the result of the soft-margin model, but the anchored model remains robust with an F-score of 93.18. This last model has 2,563 active features. With further pruning ($k = 250$), the result of the anchored model drops to 92.87F (still 3rd place in the CoNLL shared task), with only 1,508 active features in the model.

5.4 Fine-tuned soft-margin SVMs

For the sake of completeness, and to serve as a better comparison to the soft-margin SVM, we report results of some experiments with both L1 and L2 SVMs, with tuned C values. NP-chunking performance with tuned C values and various pruning thresholds is presented in Table 6.

For these results, the C parameter was tuned on a development set using Brent's 1-dimension minimization method (Brent, 1973). While taking about 40 hours of computation to fit, the final results catch up with those of the anchored-SVM but still remain slightly lower. This further highlights our main point: accurate models can be achieved also with mostly unlexicalized models, and the lexical features do not contribute substantial semantic information, but rather affect the separability of the data. This is nicely demonstrated by SVM-anchoring, in which lexical information is practically replaced by artificial semantically void indexes, but similar performance can also be achieved by fine-tuning other learning parameters.

PRUNING	#FEATURES	SOFT-MARGIN	ANCHORED
0	19,910	93.25	93.23

6 Error Analysis

Our experiments so far indicate that very aggressive feature pruning hurts performance slightly (by about 0.5F point). The feature-pruned models are still accurate, indicating that lexical features contribute little to the classification accuracy. We now investigate the differences between the lexicalized and pruned models, in order to characterize the kind of information that is available to the lexicalized models but missing from the pruned ones. In the next section, we also verify that pruned-models are more stable than the fully lexicalized ones when tested over different text genres and domains.

We focus our analysis on the chunking task, which is a superset of the NP-chunking task. We compare the fully lexicalized soft-margin SVM model with the POS+suffix2+suffix3 anchored-SVM model with $k = 100$ pruning. We analyze the models' respective performance on section 05 of the WSJ corpus. This dataset is different than the official test set. It is, however, part of the same annotated corpus as both the training and test sets. On this dataset, the fully lexicalized SVM model

achieves an F-score of 93.24, vs. 92.59 for the suffix-based pruned anchored-SVM model. (The pruned anchored-SVM model ($k = 100$) from experiment 2, achieve a slightly higher F-score of 92.84)

We investigate only those chunks which are identified correctly by one model but not by the other. Overall, there are 440 chunks (363 unique) which are identified correctly only by the lexicalized model, and 258 chunks (232 unique) only by the pruned model.

Where the pruned model is always wrong

Some errors are unique to the pruned model.

Over 45 of the cases that are identified correctly only in the lexicalized model (more than 10%) are due to the words "including" (18 cases) and "If" (9 cases), as well as other -ing forms such as "following", "according", "rising" and "suspecting."

The word "including" appears 80 times in the training data, always tagged as VBG and functioning as a PP chunk, which is an odd chunk for VBGs. The lexicalized model easily picked up on this behaviour, while the pruned model couldn't. Similarly, the word "following/VBG" appears 32 times, 20 of which as PP, and the word "according/VBG" 53 times, all of them as PP. The pruned model could not distinguish those from the rest of the VBGs and tagged them as VPs. What seems to happen in these cases, is that certain verbal forms participate in idiomatic constructions and behave syntactically as prepositions. The POS tagger does not pick this ambiguity in function and contributes only the most likely tag for the words (VBG). Lexical models learn that certain VBGs are "becoming" prepositions in the observed dataset. These words do not appear as specific features in the pruned models, and hence these usage shifts are often misclassified. Interestingly, the pruned model did learn that verbal forms can sometimes be PPs: it made use of that information by mis-identifying 11 verbal VBGs and 6 verbal VBNs as PPs.

The word "If/IN", unlike most prepositions, it always starts an SBAR rather than a PP chunk in the corpus. The pruned model learned this behaviour correctly for the lower-cased "if/IN", but missed the upper-cased version appearing in 79 sentence initial locations in the corpus.

These cases are caused by a mismatch between the POS tag and the syntactic function observed in the chunked dataset.

Additional cases include the adverbs (Already, Nearby, Soon, Maybe, Perhaps, once, Then): they are sometimes not chunked as ADVP but are left outside of any chunk. Some one-word ADJP chunks being chunked as NPs (short, general, sure, worse, ...) (6 cases) and some are chunked as ADVPs (hard, British-born, ...) (4 cases).

There are 10 cases where the pruned model splits an NP into ADVP and NP, such as: [later] [this week], [roughly][18 more U.S. stores]. In addition, the pruned model failed to learn the construction "typical of", resulting in 2 NP chunks such as: [The more intuitive approach typical].

Some mistakes of the pruned model seem like mistakes/pecularities of the annotated corpus, which the lexicalized model found a way to work around. Consider the following gold-standard cases from the annotated corpus:

- [VP seems] [ADVP rarely] [VP to cut]
- [ADVP just] [PP after]
- [VP is] [NP anything] [O but] [VP fixing]
- [ADJP as high] [PP as] [NP 8.3 %]
- [ADJP less] [PP than] [ADJP rosy]
- [NP 40 %] [PP to] [NP 45 %]

Which were each identified as a single chunk by the pruned model. It can be argued these are mistakes in the tagged dataset.

Where the lexical model is sometimes better

Both models fail on conjunctions, but the lexicalized model do slightly better. Conjunction error types come in two main varieties, either chunking [x][and][y] instead of [x and y] (pruned: 21 cases, lex: 14 cases) or chunking [x and y] instead of [x][and][y] (pruned: 26 cases, lex: 24 cases).

Joining VP and NP into an NP, due to a verb/adj ambiguity. For example chunking [NP fired six executives] instead of [VP fired] [NP six executives], or [NP keeping viewers] instead of [VP keeping] [NP viewers]. 12 such cases are resolved correctly only by the lexicalized model, and 5 only by the pruned one.

SBAR/PP confusion for words such as: "as","after","with","since" (both ways). 13 cases for the pruned model, 6 for lexicalized one.

Where both model are similar

Merging back-to-back NPs: Both models tend to erroneously join back-to-back NPs to a single NP, *e.g.* : [NP Westinghouse this year], or [NP themselves fashion enterprises]. No model is better than the other on these cases, each model failed

on 16 cases the other model succeeded on.

Joining NP and VP into an NP due to Verb/Noun ambiguity and tagger mistakes:

- [NP the weekend] [VP making] → [NP the weekend making]
- [NP the competition] [VP can] → [NP the competition can]

(lexicalized: 6 errors, pruned: 8 errors)

And splitting some NPs to VP+NP due to the same reasons:

- [VP operating] [NP profit]
- [VP improved] [NP average yield]

(lexicalized: 5 errors, pruned: 7 errors)

The word "that" is confused between SBAR and NP (5 mistakes for each model)

Erroneously splitting range NPs, *e.g.* :

- [about $115][to][$125] (2 cases for each model).

Where the pruned model is better

There are some cases where the pruned models is doing better than the lexicalized one:

VP wrongly split into VP and ADJP:

- [remains] [banned]

4 mistakes for lexicalized, 1 for pruned

VP wrongly split into VP and VP:

- [were scheduled] [to meet]
- [used] [to complain]

3 mistakes for lexicalized, 1 for pruned

VP wrongly split into ADVP and VP:

- [largly][reflecting]
- [selectively][leaking]

6 mistakes for lexicalized, 1 for pruned

PP and SBAR confusion:

- of, with, As, after

9 mistakes for lex, 5 for pruned

VP chunked as NP due to tagger mistake:

- [NP ruling], [NP drives], [NP cuts]

6 mistakes for lex, 2 for pruned

"that" tagged as NP instead of SBAR:

2 mistakes for lex, 0 for pruned

To conclude

Both the pruned and the fully lexicalized models have problems dealing with non-local phenomena such as coordination and relative clauses, as well as verb/adjective ambiguities and VBG/Noun ambiguities. They also perform poorly on embeded syntactic constructions (such as an NP containing an ADJP), and on identification of back-to-back NPs, which often requires semantic knowledge.

Both models suffer from tagging mistakes of the underlying tagger and systematic ambiguity between the morphological tag assigned by the tagger and the syntactic tag in which the word operates (e.g., "including" used as a preposition).

The main advantage of the fully lexcialized model is in dealing with:

- Some coordinated constructions.
- Some cases of verb/adjective ambiguities.
- Specific function words not seen much in training.
- Idiomatic usages of some VBG/VBN forms functioning as prepositions.

The first two items are semantic in nature, and hint that lexical features do capture some semantic information. While this might be true on the specific corpus, we believe that such corpus-derived semantic knowledge is very restricted, is not generalizable, and will not transfer well to other corpora, even on the same genre. We provide evidence for this claim in Section 7.

The last two items are syntactic. We address them by introducing a slightly modified feature model.

6.1 Another chunking Experiment

Based on the observations from the error analysis, we performed another pruned-chunking experiment, with the following features:

- Word and POS for a -2,+2 window around the current token, and 2-and-3-letter suffixes of the token to be classified (same as Experiment 2 in Section 5.2 above).
- Features of words appearing as a preposition (IN) anywhere in the training set are not pruned (this result in a model with 310 unique lexical items after $k = 100$ pruning).
- *An additional binary feature* indicating for each token whether it can function as a PP. The list of possible-PP forms is generated by considering all tokens seen inside a PP in the training corpus. It can be easily extended if additional lexicographic resources are available, without retraining the model.

This last proposed feature incorporates important lexical knowledge without relying on features for specific lexical forms, and is more generalizable. The accuracy of this new model on the development and test set with various pruning thresholds is presented in Table 7.

The addition of the CanBePrep feature improves the fully-lexicalized model accuracy on the development set (93.24 to 93.68), and does not affect fully lexicalized result on the test set (93.71

CORPUS	SOURCE	CONTENT	#TOKENS

Test Set			
0	92,989	93.68	–
100	4,066	–	93.26

Table 7: Chunking results (F), with various pruning thresholds. Experiment 4. Features: POS, Word , Suff2, Suff3 for main word, CanBePrep .

vs. 93.73). The pruned model performance improves in both cases, more so on the development set (93.12 to 93.22 on the test set, 92.84 to 93.26 on the development set). The new model helps bridging the gap between the fully lexicalized and the pruned model, yet we still observe a lead of 0.4F for the fully lexicalized model. We now turn to explore how meaningful this difference is in real-world situation in which one does not operate on the Penn-WSJ corpus.

7 Corpus Variation and Model Performance

When tested on the exact same resource as the models are trained on, the fully lexicalized model still has a slight edge over the pruned ones. How well does this lexical knowledge transfer to different text genres? We compare the models' performance on text from various genres, ranging from very similar to the training material (recent articles from the WSJ Business section) to a well-edited but different domain text ("Featured-content" wikipedia pages) to a non-edited noisy text (live-journal blog posts from the "life" category). As we do not have gold-annotated data for these text genres, we analyze the few differences between the models, manually inspecting the instances on which the models disagree.

Table 8 describes our test corpora for this experiment. We applied the fully-lexicalized and the pruned ($k = 100$) anchored models described in Section 6.1 to these texts, and compared the chunking results. The results are presented in Table 9.

When moving outside of the canonic training

TEXT	#DIFF	PRUNED CORRECT	LEX CORRECT	BOTH WRONG
WSJ	13	**9**	4	0
Jaguar	45	20	20	7
FreeWill	118	**51**	38	29
LJ-Life	15	**8**	6	1

Table 9: Comparison of Models' performance on different text genres

corpus, the fully lexicalized model have no advantage over the heavily pruned one. On the contrary, the pruned models seem to have a small advantage in most cases (though it is hard to tell if the differences are significant). This is true even for texts in the very same domain, genre and editing guidelines as the training corpus was derived from.

8 Discussion

For all the sequence labeling tasks we analyzed, the anchored-SVM proved to be robust to feature pruning. The experiments support the claim that rare lexical features do not provide substantial information to the model, but instead play a role in maintaining separability. When this role is taken over by anchoring, we can obtain the same level of performance with very few robust lexical features. Yet, we cannot conclude that lexical information is not needed. There is a significant difference between the pruned and non-pruned models for the chunking task. We showed that this difference can be bridged to some extent by a binary feature relating to idiomatic word usage, and that the difference vanishes when testing outside of the annotated corpus. The high classification accuracies achieved with the heavily pruned anchored-SVM models sheds new light on the actual role of lexical features, and indicating that there is still a lot to be learned regarding the effective incorporation of lexical and semantic information into our models. It is our view that semantic knowledge should not be expected to be learned by inspection of raw lexical counts from an annotated text corpus, but instead collected from sources external to the annotated corpora – either based on a very large unannotated corpora, or on manually constructed lexical resources.

Simple Coreference Resolution with Rich Syntactic and Semantic Features

Aria Haghighi and Dan Klein
Computer Science Division
UC Berkeley
{aria42, klein}@cs.berkeley.edu

Abstract

Coreference systems are driven by syntactic, semantic, and discourse constraints. We present a simple approach which completely modularizes these three aspects. In contrast to much current work, which focuses on learning and on the discourse component, our system is deterministic and is driven entirely by syntactic and semantic compatibility as learned from a large, unlabeled corpus. Despite its simplicity and discourse naivete, our system substantially outperforms all unsupervised systems and most supervised ones. Primary contributions include (1) the presentation of a simple-to-reproduce, high-performing baseline and (2) the demonstration that most remaining errors can be attributed to syntactic and semantic factors external to the coreference phenomenon (and perhaps best addressed by non-coreference systems).

1 Introduction

The resolution of entity reference is influenced by a variety of constraints. Syntactic constraints like the binding theory, the i-within-i filter, and appositive constructions restrict reference by configuration. Semantic constraints like selectional compatibility (e.g. a *spokesperson* can *announce* things) and subsumption (e.g. *Microsoft* is a *company*) rule out many possible referents. Finally, discourse phenomena such as salience and centering theory are assumed to heavily influence reference preferences. As these varied factors have given rise to a multitude of weak features, recent work has focused on how best to learn to combine them using models over reference structures (Culotta et al., 2007; Denis and Baldridge, 2007; Klenner and Ailloud, 2007).

In this work, we break from the standard view. Instead, we consider a vastly more modular system in which coreference is predicted from a deterministic function of a few rich features. In particular, we assume a three-step process. First, a self-contained syntactic module carefully represents syntactic structures using an augmented parser and extracts syntactic paths from mentions to potential antecedents. Some of these paths can be ruled in or out by deterministic but conservative syntactic constraints. Importantly, the bulk of the work in the syntactic module is in making sure the parses are correctly constructed and used, and this module's most important training data is a treebank. Second, a self-contained semantic module evaluates the semantic compatibility of headwords and individual names. These decisions are made from compatibility lists extracted from unlabeled data sources such as newswire and web data. Finally, of the antecedents which remain after rich syntactic and semantic filtering, reference is chosen to minimize tree distance.

This procedure is trivial where most systems are rich, and so does not need any supervised coreference data. However, it is rich in important ways which we argue are marginalized in recent coreference work. Interestingly, error analysis from our final system shows that its failures are far more often due to syntactic failures (e.g. parsing mistakes) and semantic failures (e.g. missing knowledge) than failure to model discourse phenomena or appropriately weigh conflicting evidence.

One contribution of this paper is the exploration of strong modularity, including the result that our system beats all unsupervised systems and approaches the state of the art in supervised ones. Another contribution is the error analysis result that, even with substantial syntactic and semantic richness, the path to greatest improvement appears to be to further improve the syntactic and semantic modules. Finally, we offer our approach as a very strong, yet easy to implement, baseline. We make no claim that learning to reconcile disparate features in a joint model offers no benefit, only that it must not be pursued to the exclusion of rich, non-reference analysis.

2 Coreference Resolution

In coreference resolution, we are given a document which consists of a set of mentions; each

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1152–1161,
Singapore, 6-7 August 2009.

mention is a phrase in the document (typically an NP) and we are asked to cluster mentions according to the underlying referent entity. There are three basic mention types: proper (*Barack Obama*), nominal (*president*), and pronominal (*he*).[1] For comparison to previous work, we evaluate in the setting where mention boundaries are given at test time; however our system can easily annotate reference on all noun phrase nodes in a parse tree (see Section 3.1.1).

2.1 Data Sets

In this work we use the following data sets:

Development: (see Section 3)

- **ACE2004-ROTH-DEV**: Dev set split of the ACE 2004 training set utilized in Bengston and Roth (2008). The ACE data also annotates pre-nominal mentions which we map onto nominals. 68 documents and 4,536 mentions.

Testing: (see Section 4)

- **ACE2004-CULOTTA-TEST**: Test set split of the ACE 2004 training set utilized in Culotta et al. (2007) and Bengston and Roth (2008). Consists of 107 documents.[2]
- **ACE2004-NWIRE**: ACE 2004 Newswire set to compare against Poon and Domingos (2008). Consists of 128 documents and 11,413 mentions; intersects with the other ACE data sets.
- **MUC-6-TEST**: MUC6 formal evaluation set consisting of 30 documents and 2,068 mentions.

Unlabeled: (see Section 3.2)

- **BLIPP**: 1.8 million sentences of newswire parsed with the Charniak (2000) parser. No labeled coreference data; used for mining semantic information.
- **WIKI**: 25k articles of English Wikipedia abstracts parsed by the Klein and Manning (2003) parser.[3] No labeled coreference data; used for mining semantic information.

[1] Other mention types exist and are annotated (such as pre-nominal), which are treated as nominals in this work.

[2] The evaluation set was not made available to non-participants.

[3] Wikipedia abstracts consist of roughly the first paragraph of the corresponding article

2.2 Evaluation

We will present evaluations on multiple coreference resolution metrics, as no single one is clearly superior:

- Pairwise F1: precision, recall, and F1 over all pairs of mentions in the same entity cluster. Note that this over-penalizes the merger or separation of clusters quadratically in the size of the cluster.
- b^3 (Amit and Baldwin, 1998): For each mention, form the intersection between the predicted cluster and the true cluster for that mention. The precision is the ratio of the intersection and the true cluster sizes and recall the ratio of the intersection to the predicted sizes; F1 is given by the harmonic mean over precision and recall from all mentions.
- MUC (Vilain et al., 1995): For each true cluster, compute the number of predicted clusters which need to be merged to cover the true cluster. Divide this quantity by true cluster size minus one. Recall is given by the same procedure with predicated and true clusters reversed.[4]
- CEAF (Luo, 2005): For a similarity function between predicted and true clusters, CEAF scores the best match between true and predicted clusters using this function. We use the ϕ_3 similarity function from Luo (2005).

3 System Description

In this section we develop our system and report developmental results on ACE2004-ROTH-DEV (see Section 2.1); we report pairwise F1 figures here, but report on many more evaluation metrics in Section 4. At a high level, our system resembles a pairwise coreference model (Soon et al., 1999; Ng and Cardie, 2002; Bengston and Roth, 2008); for each mention m_i, we select either a single-best antecedent amongst the previous mentions $m_1, \ldots, m_{i-1}$, or the NULL mention to indicate the underlying entity has not yet been evoked. Mentions are linearly ordered according to the position of the mention head with ties being broken by the larger node coming first.

[4] The MUC measure is problematic when the system predicts many more clusters than actually exist (Luo, 2005; Finkel and Manning, 2008); also, singleton clusters do not contribute to evaluation.

While much research (Ng and Cardie, 2002; Culotta et al., 2007; Haghighi and Klein, 2007; Poon and Domingos, 2008; Finkel and Manning, 2008) has explored how to reconcile pairwise decisions to form coherent clusters, we simply take the transitive closure of our pairwise decision (as in Ng and Cardie (2002) and Bengston and Roth (2008)) which can and does cause system errors.

In contrast to most recent research, our pairwise decisions are not made with a learned model which outputs a probability or confidence, but instead for each mention m_i, we select an antecedent amongst $m_1, \ldots, m_{i-1}$ or the NULL mention as follows:

- **Syntactic Constraint:** Based on syntactic configurations, either force or disallow coreference between the mention and an antecedent. Propagate this constraint (see Figure 4).
- **Semantic/Syntactic Filter**: Filter the remaining possible antecedents based upon compatibility with the mention (see Figure 2).
- **Selection**: Select the 'closest' mention from the set of remaining possible antecedents (see Figure 1) or the NULL antecedent if empty.

Initially, there is no syntactic constraint (improved in Section 3.1.3), the antecedent compatibility filter allows proper and nominal mentions to corefer only with mentions that have the same head (improved in Section 3.2), and pronouns have no compatibility constraints (improved in Section 3.1.2). Mention heads are determined by parsing the given mention span with the Stanford parser (Klein and Manning, 2003) and using the Collins head rules (Collins, 1999); Poon and Domingos (2008) showed that using syntactic heads strongly outperformed a simple rightmost headword rule. The mention type is determined by the head POS tag: proper if the head tag is NNP or NNPS, pronoun if the head tag is PRP, PRP$, WP, or WP$, and nominal otherwise.

For the selection phase, we order mentions $m_1, \ldots, m_{i-1}$ according to the position of the head word and select the closest mention that remains after constraint and filtering are applied. This choice reflects the intuition of Grosz et al. (1995) that speakers only use pronominal mentions when there are not intervening compatible

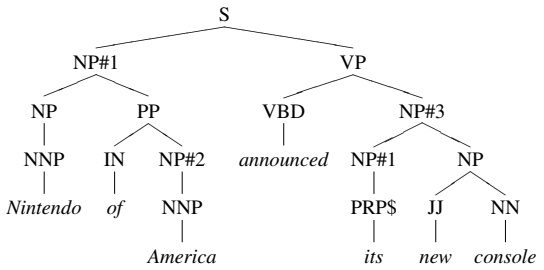

Figure 1: Example sentence where closest tree distance between mentions outperforms raw distance. For clarity, each mention NP is labeled with the underlying entity id.

mentions. This system yields a rather low 48.9 pairwise F1 (see BASE-FLAT in Table 2). There are many, primarily recall, errors made choosing antecedents for all mention types which we will address by adding syntactic and semantic constraints.

3.1 Adding Syntactic Information

In this section, we enrich the syntactic representation and information in our system to improve results.

3.1.1 Syntactic Salience

We first focus on fixing the pronoun antecedent choices. A common error arose from the use of mention head distance as a poor proxy for discourse salience. For instance consider the example in Figure 1, the mention *America* is closest to *its* in flat mention distance, but syntactically *Nintendo of America* holds a more prominent syntactic position relative to the pronoun which, as Hobbs (1977) argues, is key to discourse salience.

Mapping Mentions to Parse Nodes: In order to use the syntactic position of mentions to determine anaphoricity, we must associate each mention in the document with a parse tree node. We parse all document sentences with the Stanford parser, and then for each evaluation mention, we find the largest-span NP which has the previously determined mention head as its head.[5] Often, this results in a different, typically larger, mention span than annotated in the data.

Now that each mention is situated in a parse tree, we utilize the length of the shortest tree path between mentions as our notion of distance. In

[5]If there is no NP headed by a given mention head, we add an NP over just that word.

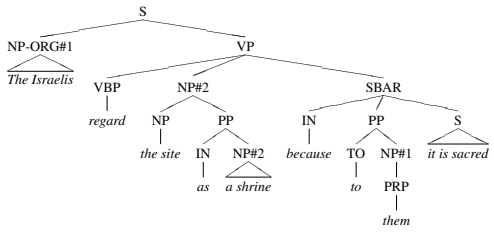

Figure 2: Example of a coreference decision fixed by agreement constraints (see Section 3.1.2). The pronoun *them* is closest to *the site* mention, but has an incompatible number feature with it. The closest (in tree distance, see Section 3.1.1) compatible mention is *The Israelis*, which is correct

particular, this fixes examples such as those in Figure 1 where the true antecedent has many embedded mentions between itself and the pronoun. This change by itself yields 51.7 pairwise F1 (see BASE-TREE in Table 2), which is small overall, but reduces pairwise pronoun antecedent selection error from 51.3% to 42.5%.

3.1.2 Agreement Constraints

We now refine our compatibility filtering to incorporate simple agreement constraints between coreferent mentions. Since we currently allow proper and nominal mentions to corefer only with matching head mentions, agreement is only a concern for pronouns. Traditional linguistic theory stipulates that coreferent mentions must agree in number, person, gender, and entity type (e.g. animacy). Here, we implement person, number and entity type agreement.[6]

A number feature is assigned to each mention deterministically based on the head and its POS tag. For entity type, we use NER labels. Ideally, we would like to have information about the entity type of each referential NP, however this information is not easily obtainable. Instead, we opt to utilize the Stanford NER tagger (Finkel et al., 2005) over the sentences in a document and annotate each NP with the NER label assigned to that mention head. For each mention, when its NP is assigned an NER label we allow it to only be compatible with that NER label.[7] For pronouns, we deterministically assign a set of compatible NER values (e.g. personal pronouns can only be a PERSON, but *its* can be an ORGANIZATION or LOCATION). Since the NER tagger typically does not label non-proper NP heads, we have no NER compatibility information for nominals.

[6]Gender agreement, while important for general coreference resolution, did not contribute to the errors in our largely newswire data sets.

[7]Or allow it to be compatible with all NER labels if the NER tagger doesn't predict a label.

gore	president	florida	state
bush	governor	lebanese	territory
nation	people	arafat	leader
inc.	company	aol	company
nation	country	assad	president

Table 1: Most common recall (missed-link) errors amongst non-pronoun mention heads on our development set. Detecting compatibility requires semantic knowledge which we obtain from a large corpus (see Section 3.2).

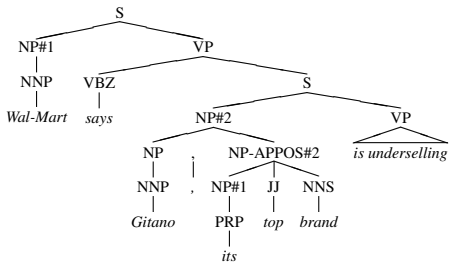

Figure 4: Example of interaction between the appositive and i-within-i constraint. The i-within-i constraint disallows coreference between parent and child NPs unless the child is an appositive. Hashed numbers indicate ground truth but are not in the actual trees.

We incorporate agreement constraints by filtering the set of possible antecedents to those which have compatible number and NER types with the target mention. This yields 53.4 pairwise F1, and reduces pronoun antecedent errors to 42.5% from 34.4%. An example of the type of error fixed by these agreement constraints is given by Figure 2.

3.1.3 Syntactic Configuration Constraints

Our system has so far focused only on improving pronoun anaphora resolution. However, a plurality of the errors made by our system are amongst non-pronominal mentions.[8] We take the approach that in order to align a non-pronominal mention to an antecedent without an identical head, we require evidence that the mentions are compatible.

Judging compatibility of mentions generally requires semantic knowledge, to which we return later. However, some syntactic configurations

[8]There are over twice as many nominal mentions in our development data as pronouns.

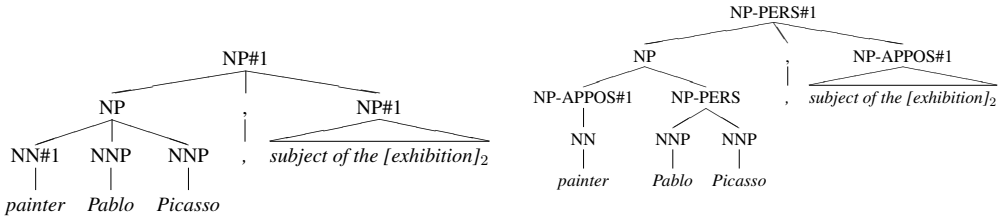

Figure 3: NP structure annotation: In (a) we have the raw parse from the Klein and Manning (2003) parser with the mentions annotated by entity. In (b), we demonstrate the annotation we have added. NER labels are added to all NP according to the NER label given to the head (see Section 3.1.1). Appositive NPs are also annotated. Hashes indicate forced coreferent nodes

guarantee coreference. The one exploited most in coreference work (Soon et al., 1999; Ng and Cardie, 2002; Luo et al., 2004; Culotta et al., 2007; Poon and Domingos, 2008; Bengston and Roth, 2008) is the appositive construction. Here, we represent apposition as a syntactic feature of an NP indicating that it is coreferent with its parent NP (e.g. it is an exception to the i-within-i constraint that parent and child NPs *cannot* be coreferent). We deterministically mark a node as NP-APPOS (see Figure 3) when it is the third child in of a parent NP whose expansion begins with (NP , NP), and there is not a conjunction in the expansion (to avoid marking elements in a list as appositive).

Role Appositives: During development, we discovered many errors which involved a variant of appositives which we call 'role appositives' (see *painter* in Figure 3), where an NP modifying the head NP describes the role of that entity (typically a person entity). There are several challenges to correctly labeling these role NPs as being appositives. First, the NPs produced by Treebank parsers are flat and do not have the required internal structure (see Figure 3(a)). While fully solving this problem is difficult, we can heuristically fix many instances of the problem by placing an NP around maximum length sequences of NNP tags or NN (and JJ) tags within an NP; note that this will fail for many constructions such as *U.S. President Barack Obama*, which is analyzed as a flat sequence of proper nouns. Once this internal NP structure has been added, whether the NP immediately to the left of the head NP is an appositive depends on the entity type. For instance, *Rabbi Ashi* is an apposition but *Iranian army* is not. Again, a full solution would require its own model, here we mark as appositions any NPs immediately to the left of a head child NP where the head child NP is identified as a person by the NER tagger.[9]

We incorporate NP appositive annotation as a constraint during filtering. Any mention which corresponds to an appositive node has its set of possible antecedents limited to its parent. Along with the appositive constraint, we implement the i-within-i constraint that any non-appositive NP cannot be be coreferent with its parent; this constraint is then propagated to any node its parent is forced to agree with. The order in which these constraints are applied is important, as illustrated by the example in Figure 4: First the list of possible antecedents for the appositive NP is constrained to only its parent. Now that all appositives have been constrained, we apply the i-within-i constraint, which prevents *its* from having the NP headed by *brand* in the set of possible antecedents, and by propagation, also removes the NP headed by *Gitano*. This leaves the NP *Wal-Mart* as the closest compatible mention.

Adding these syntactic constraints to our system yields 55.4 F1, a fairly substantial improvement, but many recall errors remain between mentions with differing heads. Resolving such cases will require external semantic information, which we will automatically acquire (see Section 3.2).

Predicate Nominatives: Another syntactic constraint exploited in Poon and Domingos (2008) is the predicate nominative construction, where the object of a copular verb (forms of the verb *be*) is constrained to corefer with its subject (e.g. *Microsoft is a company in Redmond*). While much less frequent than appositive configurations (there are only 17 predicate nominatives in our devel-

[9] Arguably, we could also consider right modifying NPs (e.g., *[Microsoft [Company]$_1$]$_1$*) to be role appositive, but we do not do so here.

Path	Example
	*America Online Inc. (AOL)* *[President and C.E.O] Bill Gates*

Figure 5: Example paths extracted via semantic compatibility mining (see Section 3.2) along with example instantiations. In both examples the left child NP is coreferent with the rightmost NP. Each category in the interior of the tree path is annotated with the head word as well as its subcategorization. The examples given here collapse multiple instances of extracted paths.

opment set), predicate nominatives are another highly reliable coreference pattern which we will leverage in Section 3.2 to mine semantic knowledge. As with appositives, we annotate object predicate-nominative NPs and constrain coreference as before. This yields a minor improvement to 55.5 F1.

3.2 Semantic Knowledge

While appositives and related syntactic constructions can resolve some cases of non-pronominal reference, most cases require semantic knowledge about the various entities as well as the verbs used in conjunction with those entities to disambiguate references (Kehler et al., 2008).

However, given a semantically compatible mention head pair, say *AOL* and *company*, one might expect to observe a reliable appositive or predicative-nominative construction involving these mentions somewhere in a large corpus. In fact, the Wikipedia page for *AOL*[10] has a predicate-nominative construction which supports the compatibility of this head pair: *AOL LLC (formerly America Online) is an American global Internet services and media company operated by Time Warner.*

In order to harvest compatible head pairs, we utilize our BLIPP and WIKI data sets (see Section 2), and for each noun (proper or common) and pronoun, we assign a maximal NP mention node for each nominal head as in Section 3.1.1; we then annotate appositive and predicate-nominative NPs as in Section 3.1.3. For any NP which is annotated as an appositive or predicate-nominative, we extract the head pair of that node and its constrained antecedent.

[10] http://en.wikipedia.org/wiki/AOL

The resulting set of compatible head words, while large, covers a little more than half of the examples given in Table 1. The problem is that these highly-reliable syntactic configurations are too sparse and cannot capture all the entity information present. For instance, the first sentence of Wikipedia abstract for *Al Gore* is:

> *Albert Arnold "Al" Gore, Jr. is an American environmental activist who served as the 45th Vice President of the United States from 1993 to 2001 under President Bill Clinton.*

The required lexical pattern *X who served as Y* is a general appositive-like pattern that almost surely indicates coreference. Rather than opt to manually create a set of these coreference patterns as in Hearst (1992), we instead opt to automatically extract these patterns from large corpora as in Snow et al. (2004) and Phillips and Riloff (2007). We take a simple bootstrapping technique: given a set of mention pairs extracted from appositives and predicate-nominative configurations, we extract counts over tree fragments between nodes which have occurred in this set of head pairs (see Figure 5); the tree fragments are formed by annotating the internal nodes in the tree path with the head word and POS along with the subcategorization. We limit the paths extracted in this way in several ways: paths are only allowed to go between adjacent sentences and have a length of at most 10. We then filter the set of paths to those which occur more than a hundred times and with at least 10 distinct seed head word pairs.

The vast majority of the extracted fragments are variants of traditional appositives and predicate-nominatives with some of the structure of the NPs

specified. However there are some tree fragments which correspond to the novel coreference patterns (see Figure 5) of parenthetical alias as well as conjunctions of roles in NPs.

We apply our extracted tree fragments to our BLIPP and WIKI data sets and extract a set of compatible word pairs which match these fragments; these words pairs will be used to relax the semantic compatibility filter (see the start of the section); mentions are compatible with prior mentions with the same head or with a semantically compatible head word. This yields 58.5 pairwise F1 (see SEM-COMPAT in Table 2) as well as similar improvements across other metrics.

By and large the word pairs extracted in this way are correct (in particular we now have coverage for over two-thirds of the head pair recall errors from Table 1.) There are however word-pairs which introduce errors. In particular city-state constructions (e.g. *Los Angeles, California*) appears to be an appositive and incorrectly allows our system to have *angeles* as an antecedent for *california*. Another common error is that the % symbol is made compatible with a wide variety of common nouns in the financial domain.

4 Experimental Results

We present formal experimental results here (see Table 2). We first evaluate our model on the ACE2004-CULOTTA-TEST dataset used in the state-of-the-art systems from Culotta et al. (2007) and Bengston and Roth (2008). Both of these systems were supervised systems discriminatively trained to maximize b^3 and used features from many different structured resources including WordNet, as well as domain-specific features (Culotta et al., 2007). Our best b^3 result of 79.0 is broadly in the range of these results. We should note that in our work we use neither the gold mention types (we do not model pre-nominals separately) nor do we use the gold NER tags which Bengston and Roth (2008) does. Across metrics, the syntactic constraints and semantic compatibility components contribute most to the overall final result.

On the MUC6-TEST dataset, our system outper-

Table 3: Errors for each type of antecedent decision made by the system. Each row is a mention type and the column the predicted mention type antecedent. The majority of errors are made in the NOMINAL category.

forms both Poon and Domingos (2008) (an unsupervised Markov Logic Network system which uses explicit constraints) and Finkel and Manning (2008) (a supervised system which uses ILP inference to reconcile the predictions of a pairwise classifier) on all comparable measures.[11] Similarly, on the ACE2004-NWIRE dataset, we also outperform the state-of-the-art unsupervised system of Poon and Domingos (2008).

Overall, we conclude that our system outperforms state-of-the-art unsupervised systems[12] and is in the range of the state-of-the art systems of Culotta et al. (2007) and Bengston and Roth (2008).

5 Error Analysis

There are several general trends to the errors made by our system. Table 3 shows the number of pairwise errors made on MUC6-TEST dataset by mention type; note these errors are not equally weighted in the final evaluations because of the transitive closure taken at the end. The most errors are made on nominal mentions with pronouns coming in a distant second. In particular, we most frequently say a nominal is NULL when it has an antecedent; this is typically due to not having the necessary semantic knowledge to link a nominal to a prior expression.

In order to get a more thorough view of the cause of pairwise errors, we examined 20 random errors made in aligning each mention type to an antecedent. We categorized the errors as follows:

- SEM. COMPAT: Missing information about the compatibility of two words e.g. *pay* and *wage*. For pronouns, this is used to mean that we incorrectly aligned a pronoun to a mention with which it is not semantically compatible (e.g. *he* aligned to *board*).
- SYN. COMPAT: Error in assigning linguistic features of nouns for compatibility with pronouns (e.g. disallowing *they* to refer to *team*).
- HEAD: Errors involving the assumption that mentions with the same head are always compatible. Includes modifier and specificity errors such as allowing *Lebanon* and *Southern Lebanon* to corefer. This also includes errors of definiteness in nominals (e.g. *the people in the room* and *Chinese people*). Typically, these errors involve a combination of missing syntactic and semantic information.
- INTERNAL NP: Errors involving lack of internal NP structure to mark role appositives (see Section 3.1.3).
- PRAG. / DISC.: Errors where discourse salience or pragmatics are needed to disambiguate mention antecedents.
- PROCESS ERROR: Errors which involved a tokenization, parse, or NER error.

The result of this error analysis is given in Table 4; note that a single error may be attributed to more than one cause. Despite our efforts in Section 3 to add syntactic and semantic information to our system, the largest source of error is still a combination of missing semantic information or annotated syntactic structure rather than the lack of discourse or salience modeling.

Our error analysis suggests that in order to improve the state-of-the-art in coreference resolution, future research should consider richer syntactic and semantic information than typically used in current systems.

6 Conclusion

Our approach is not intended as an argument against the more complex, discourse-focused approaches that typify recent work. Instead, we note that rich syntactic and semantic processing vastly reduces the need to rely on discourse effects or evidence reconciliation for reference resolution. Indeed, we suspect that further improving the syntactic and semantic modules in our system may produce greater error reductions than any other

[11] Klenner and Ailloud (2007) took essentially the same approach but did so on non-comparable data.

[12] Poon and Domingos (2008) outperformed Haghighi and Klein (2007). Unfortunately, we cannot compare against Ng (2008) since we do not have access to the version of the ACE data used in their evaluation.

Mention Type	SEM. COMPAT	SYN. COMPAT	HEAD	INTENAL NP	PRAG / DISC.	PROCESS ERROR	OTHER	Comment
NOMINAL	7	-	5	6	2	2	1	2 general appos. patterns
PRONOUN	6	3	-	6	3	3	3	2 cataphora
PROPER	6	-	3	4	4	4	1

route forward. Of course, a system which is rich in all axes will find some advantage over any simplified approach.

Nonetheless, our coreference system, despite being relatively simple and having no tunable parameters or complexity beyond the non-reference complexity of its component modules, manages to outperform state-of-the-art unsupervised coreference resolution and be broadly comparable to state-of-the-art supervised systems.

Abstract

In this paper, we provide descriptive and empirical approaches to effectively extracting underlying dependencies among parsing errors. In the descriptive approach, we define some combinations of error patterns and extract them from given errors. In the empirical approach, on the other hand, we re-parse a sentence with a target error corrected and observe errors corrected together. Experiments on an HPSG parser show that each of these approaches can clarify the dependencies among individual errors from each point of view. Moreover, the comparison between the results of the two approaches shows that combining these approaches can achieve a more detailed error analysis.

1 Introduction

For any kind of technology, analyzing causes of errors given by a system is a very helpful process for improving its performance. In recent sophisticated parsing technologies, the process has taken on more and more important roles since critical ideas for parsing performance have already been introduced and the researches are now focusing on exploring the rest of the pieces for making additional improvements.

In most cases for parsers' error analysis, researchers associate output errors with failures in handling certain linguistic phenomena and attempt to avoid them by adding or modifying corresponding settings of their parsers. However, such an analysis cannot been done so smoothly since parsing errors sometimes depend on each other and the underlying dependencies behind superficial phenomena cannot be captured easily.

In this paper, we propose descriptive and empirical approaches to effective extraction of dependencies among parsing errors and engage in a deeper error analysis with them. In our descriptive approach, we define various combinations of error patterns as organized error phenomena on the basis of linguistic knowledge, and then extract such combinations from given errors. In our empirical approach, on the other and, we re-parse a sentence under the condition where a target error is corrected, and errors which are additionally corrected are regarded as dependent errors. By capturing dependencies among parsing errors through systematic approaches, we can effectively collect errors which are related to the same linguistic properties.

In the experiments, we applied both of our approaches to an HPSG parser *Enju* (Miyao and Tsujii, 2005; Ninomiya et al., 2006), and then evaluated the obtained error classes. After examining the individual approaches, we explored the combination of them.

2 Parser and its evaluation

A parser is a system which interprets structures of given sentences from some grammatical or in some cases semantical viewpoints, and interpreted structures are utilized as essential information for various natural language tasks such as information extraction, machine translation, and so on. In most cases, an output structure of a parser is based on a certain grammatical framework such as CFG, CCG (Steedman, 2000), LFG (Kaplan and Bresnan, 1995) or HPSG (Pollard and Sag, 1994). Since such a framework can usually produce more than one probable structure for a sentence, a parser

often utilizes some kind of disambiguation model for choosing the best one.

While various parsers take different manners in capturing linguistic phenomena based on their frameworks, they are at least required to obtain some kinds of relations between the words in sentences. On the basis of the requirements, a parser is usually evaluated on how correctly it gives intended linguistic relations. "Predicate argument relation" is one of the most common evaluation measurements for a parser since it is a very fundamental linguistic behavior and is less dependent on parser systems. This measure divides linguistic structural phenomena in a sentence into minimal predicative events. In one predicate argument relation, a word which represents an event (predicate) takes some words as participants (arguments). Although no fixed formulation exists for the relations, there are to a large extent common conceptions for them based on linguistic knowledge among researchers.

Figure 1 shows an example of predicate argument relations given by *Enju*. In the sentence "*John has come.*", "*has*" is a predicate of type "*aux_arg12*" and takes "*John*" and "*come*" as the first and second arguments. "*come*" is also a predicate of the type "*verb_arg1*" and takes "*John*" as the first and the only argument. In this formalism, each predicate type is represented as a combination of "the grammatical nature of a word" and "the arguments which it takes," which are represented by the descriptions in Table 1. "*aux_arg12*" in Figure 1 indicates that it is an auxiliary word and takes two arguments "ARG1" and "ARG2."

In order to improve the performance of a parser, analyzing parsing errors is very much worth the effort. Since the errors are output according to a given evaluation measurement such as "predicate argument relation," we researchers carefully explore them and infer the linguistic phenomena which cause the erroneous outputs. Figure 2 shows an example of parsing errors for sentence "*I watched the girl on TV.*" Note that the errors are based on predicate argument relations as shown above and that the predicate types are abbreviated in this figure. When we focus on the error output, we can observe that "ARG1" of predicate "*on*" was mistaken by the parser. In this case, "ARG1" represents a modifiee of the preposition, and we then conclude that the ill attachment of a prepositional phrase caused this error. By continuing such error analysis, weak points of the parser are revealed and can be useful clues for further improvements.

However, in most researches on parsing technologies, error analysis has been limited to narrow and shallow explorations since there are various dependencies behind erroneous outputs. In Figure 3, for example, two errors were given: wrong outputs for "ARG1" of "*which*" and "ARG2" of "*read*." Both of these two errors originated from the fact that the relative clause took a wrong antecedent "*the shelf*." In this sentence, the former

Table 2: Patterns defined for descriptive approach

"ARG1" directly corresponds to the antecedent while the latter "ARG2" indirectly referred to the same antecedent as the object of the verb "*read*." The two predicate argument relations thus took the same word as their common arguments, and therefore the two errors co-occurred.

On the other hand, one-way inductive relations also exist among errors. In Figure 4, "ARG1" of "*for*" and "*to*" were mistaken by a parser. We can know that each of the errors was caused by an ill attachment of a prepositional phrase with the same analysis as shown in Figure 2. What is important in this example is the manner in their occurrences. The former error can appear by itself (Analysis 1) while the latter cannot because of the structural conflict with the former error (Analysis 2). The appearance of the latter error thus induces that of the former error. In error analysis, we have to correctly capture such various relations, which leads us to a costly and less rewarding analysis.

In order to make advancements on this problem, we propose two types of approaches to realizing a deeper error analysis on parsing. In the experiments, we examine our approaches for actual errors which are given by the HPSG parser *Enju* (Miyao and Tsujii, 2005; Ninomiya et al., 2006). *Enju* was developed for capturing detailed syntactic or semantic properties and relations for a sentence with an HPSG framework (Pollard and Sag, 1994). In this research, we focus on error analysis based on predicate argument relations, and in the experiments with *Enju*, utilize the relations which are represented in parsed tree structures.

3 Two approaches for error analysis

In this section, we propose two approaches for error analysis which enable us to capture underlying dependencies among parsing errors. Our descriptive approach matches the patterns of error combinations with given parsing errors and collects matched erroneous participants. Our empirical approach, on the other hand, detects co-occurring errors by re-parsing a sentence under a situation where each of the errors is forcibly corrected.

3.1 Descriptive approach

Our descriptive approach for capturing dependencies among parsing errors is to extract certain representative structures of errors and collect the errors which involve them. Parsing errors have a tendency to occur with certain patterns of structures representing linguistic phenomena. We first define such patterns through observations with a part of error outputs, and then match them with the rest.

Table 2 summarizes the patterns for erroneous phenomena which we defined for matching in the experiments. In the table, the patterns for 14 phenomena are given and classified into four types according to their matching manners. Each of the patterns for "Argument selection" examine whether a focused *argument* for a certain *predicate type* is erroneous or not. Figure 5 shows the pattern for "Prepositional attachment," which col-

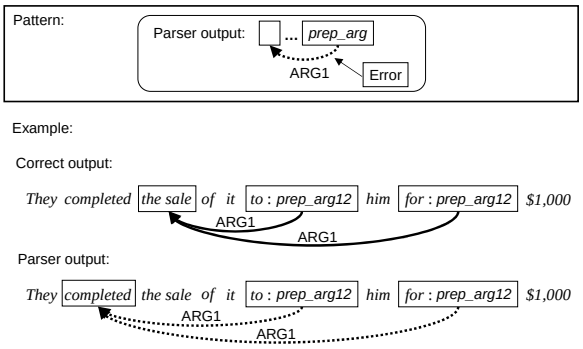

Figure 5: Pattern for "Prepositional attachment"

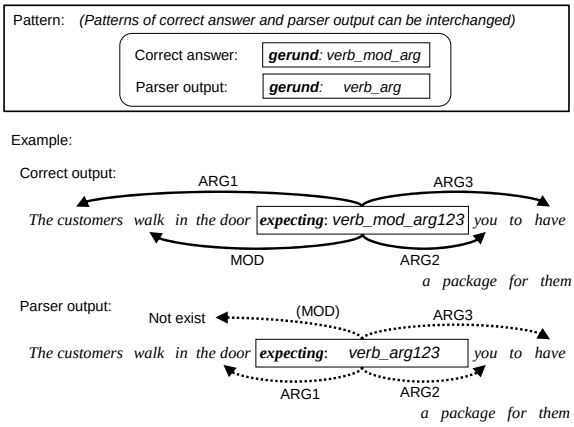

Figure 6: Pattern for "Gerund acts as modifier or not"

lects wrong ARG1 for *predicate type* "*prep_arg*". From the sentence in the figure, we can obtain two errors for "Prepositional attachment" around prepositions "*to*" and "*for*." On the other hand, each "Predicate type selection" pattern collects errors around a word whose *predicate type* is erroneous. Figure 6 shows the pattern for "Gerund acts as modifier or not," which collects errors around gerunds whose *predicate types* are erroneous. From the example sentence in the figure, we can obtain an erroneous predicate type for "*expecting*" and collect errors around it for "Gerund acts as modifier or not."

We can implement more structural errors than simple *argument* or *predicate type* selections. Figures 7 and 8 show the patterns for "To-infinitive for modifier/argument of verb" and "Subject for passive sentence or not" respectively. The pattern for the latter phenomenon collects errors on recognitions of prepositional phrases which behave as subjects for passive expressions. The pattern collects errors not only around prepositions but also around the verbs which take the prepositional phrases as a subject.

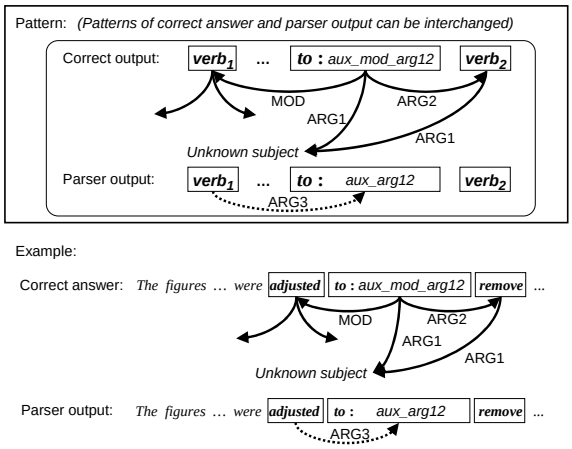

Figure 7: Pattern for "To-infinitive for modifier/argument of verb"

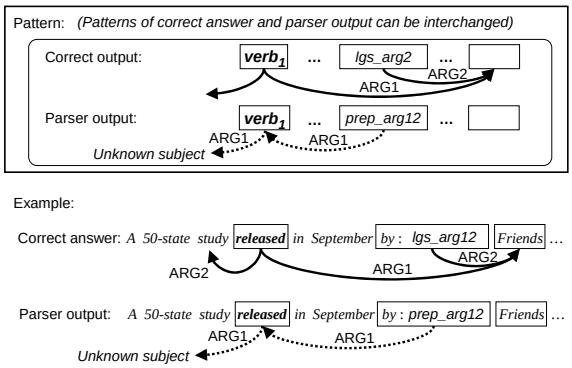

Figure 8: Pattern for "Subject for passive sentence or not"

Since these patterns are based on linguistic knowledge given by a human, the process could provide a relatively precise analysis with a lower cost than a totally manual analysis.

3.2 Empirical approach

Our empirical approach, on the other hand, briefly traces the parsing process which results in each of the target errors. We collect co-occurring errors as strongly relevant ones, and then extract dependencies among the obtained groups. Parsing errors could originate from wrong processing at certain stages in the parsing, and errors with a common origin would by necessity appear together. We reparse a target sentence under the condition where a certain error is forcibly corrected and then collect errors which are corrected together as the "*relative*" ones. An error group where all errors are *relative* to each other can be regarded as a "co-occurring error group." Errors in the same co-

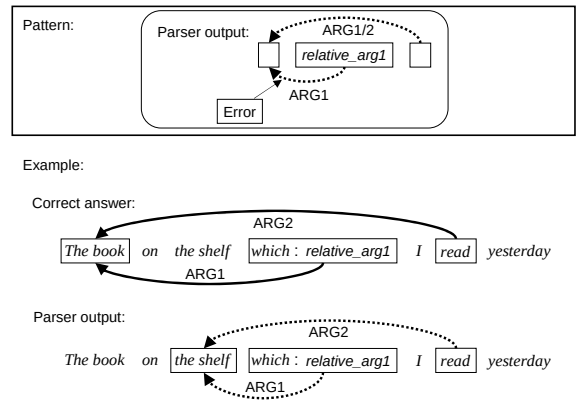

Figure 9: Pattern for "Relative clause attachment"

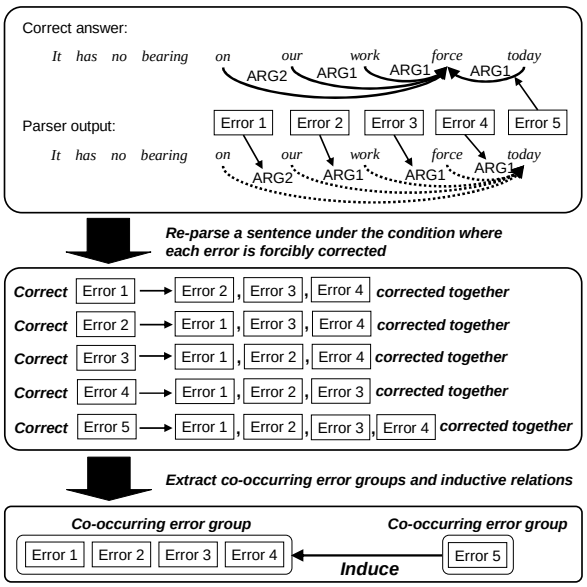

Figure 10: An image of our empirical approach

occurring error group are expected to participate in the same phenomenon. Dependencies among errors are then expected to be summarized with inductions among co-occurring error groups.

Figure 10 shows an image of this approach. In this example, "*today*" should modify noun phrase "*our work force*" while the parser decided that "*today*" was also in the noun phrase. As a result, there are five errors: three wrong outputs for "ARG2" of "*on*" (Error 1) and "ARG1" of "*our*" (Error 2) and "*work*" (Error 3), excess relation "ARG1" of "*force*" (Error 4), and missing relation "ARG1" for "*today*" (Error 5). By correcting each of the errors 1, 2, 3 and 4, all of these errors are corrected together, and therefore classified into the same co-occurring error group. Although error 5 cannot participate in the group, correcting error 5 can correct all of the errors in the group, and therefore an

inductive relation is given from error 5 to the co-occurring error group. We can then finally obtain the inductive relations as shown at the bottom of Figure 10. This approach can trace the actual behavior of the parser precisely, and can therefore capture underlying dependencies which cannot be found only by observing error outputs.

4 Experiments

We applied our approaches to parsing errors given by the HPSG parser *Enju*, which was trained on the Penn Treebank (Marcus et al., 1994) section 2-21. We first examined each approach, and then explored the combination of the approaches.

4.1 Evaluation of descriptive approach

We examined our descriptive approach. We first parsed sentences in the Penn Treebank section 22 with *Enju*, and then observed the errors. Based on the observation, we next described the patterns as shown in Section 3. After that, we parsed section 0 and then applied the patterns to the errors.

Table 3 summarizes the extracted errors. As the table shows, with the 14 error patterns, we successfully matched 1,671 locations in error outputs and covered 2,078 of 4,709 errors, which comprised of more than 40% of the total errors. This was the first step of the application of our approach, and in the future work we would like to

Evaluated sentences (erroneous)	1,811 (1,009)

Table 4: Summary of our empirical approach

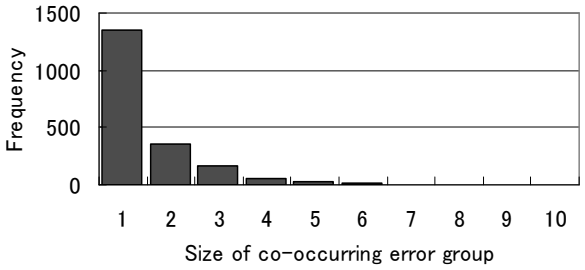

Figure 11: Frequency of each size of co-occurring error group

add more patterns for capturing more phenomena.

When we focused on individual patterns, we could observe that the simple error phenomena such as the attachments were dominant. The first reason for this would be that such phenomena were among minimal linguistic events. This would make the phenomena components of other more complex ones. The second reason for the dominance would be that the patterns for these error phenomena were easy to implement only with argument inconsistencies, and only one or a few patterns could cover every probable error. Among these dominant error types, the number of prepositional attachments was outstanding. The error types which required matching with predicate types were fewer than the attachment errors since the limited patterns on the predicate types would narrow the possible linguistic behavior of the candidate words. When we focus on more structural errors, the table shows that the rates of the participant errors to matched locations were much larger than those for simpler pattern errors. Once our patterns matches, they could collect many errors at the same time.

4.2 Evaluation of empirical approach

Next, we applied our empirical approach in the same settings as in the previous section. We first parsed sentences in section 0 and then applied our approach to the obtained errors. In the experiments, some errors could not be forcibly corrected by our approach. The parser "*cut off*" less probable parse substructures before giving the predicate

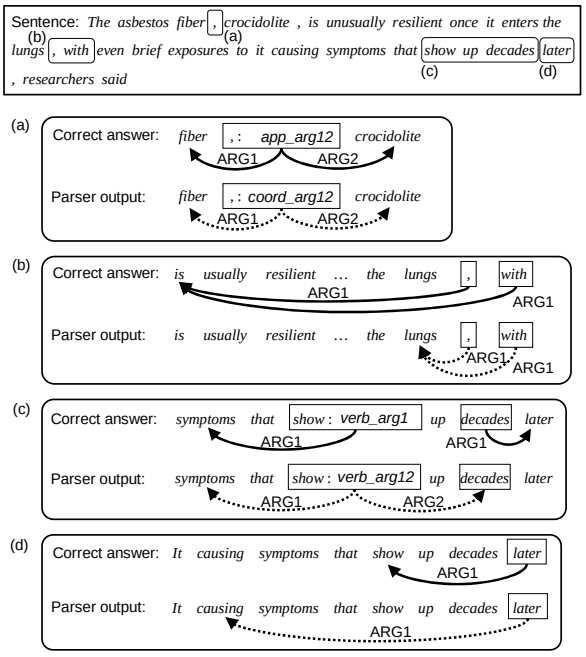

Figure 12: Obtained co-occurring error groups

argument relation for reducing the cost of parsing. In this research, we ignored the errors which were subject to such "cut off" as "*uncorrectable*" ones, and focused only on the remaining "*correctable*" errors. In our future work, we would like to consider the "*uncorrectable*" errors.

Table 4 shows the summary of the analysis with our approach. *Enju* gave 4,709 errors for section 0. Among these errors, the *correctable* errors were 3,085, and from these errors, we successfully obtained 1,978 co-occurring error groups and 501 inductive relations. Figure 11 shows the frequency for each size of co-occurring groups. About a half of the groups contains only single errors, which would indicate that the errors could have only one-way inductive relations with other errors. The rest of this section explores examples of the obtained co-occurring error groups and inductive relations.

Figure 12 shows an example of the extracted co-occurring error groups. For the sentence shown at the top of the figure, *Enju* gave seven errors. By introducing our empirical approach, these errors were definitely classified into four co-occurring error groups (a) to (d), and there were no inductive relations detected among them. Group (a) contains two errors on the comma's local behavior as apposition or coordination. Group (b) contains the errors on the words which gave almost the same attachment behaviors. Group (c) contains the errors on whether the verb "*show*" took "*decades*"

Table 5: Induction relations between errors for each linguistic phenomenon and other errors

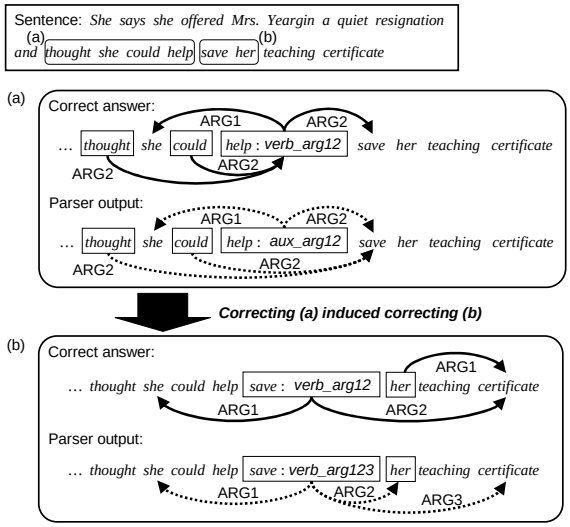

Figure 13: Inductive relation between obtained co-occurring error groups

as its object or not. Group (d) contains an error on the attachment of the adverb "*later*". Regardless of the overlap of the regions in the sentence for (c) and (d), our approach successfully classified the errors into the two independent groups. With our approach, it would be empirically shown that the errors in each group actually co-occurred and the group was independent. This would enable us to concentrate on each of the co-occurring error groups without paying attention to the influences from the errors in other groups.

Figure 13 shows another example of the analysis with our empirical approach. In this case, 8 errors for a sentence were classified into two co-occurring error groups (a) and (b), and our approach showed that correction in group (a) resulted in correcting group (b) together. The errors in group (a) were on whether "*help*" behaved as an auxiliary or pure verbal role. The errors in group (b) were on whether "*save*" took only one object "*her teaching certificate*," or two objects "*her*" and "*teaching certificate*." Between group (a) and (b), no "structural" conflict could be found when correcting only each of the groups. We could then guess that the inductive relation between these two groups was implicitly given by the disambiguation model of the parser. By dividing the errors into minimum units and clarifying the effects of correcting a target error, error analysis with our empirical approach could suggest some policy for parser improvements.

4.3 Combination of two approaches

On the basis of the experiments shown in the previous sections, we would like to explore possibilities for obtaining a more detailed analysis by combining the two approaches.

4.3.1 Interactions between a target linguistic phenomenon and other errors

Our descriptive approach could classify the parsing errors according to the linguistic phenomena they participated in. We then attempt to reveal how such classified errors interacted with other errors from the viewpoints of our empirical approach. In order to enable the analysis by our empirical approach, we focused only on the *correctable* errors.

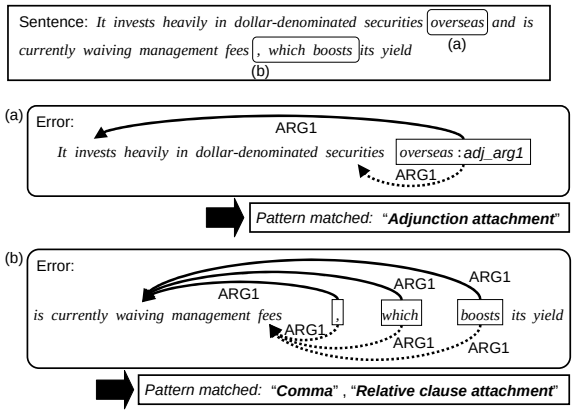

Figure 14: Combination of results given by descriptive and empirical approaches (1)

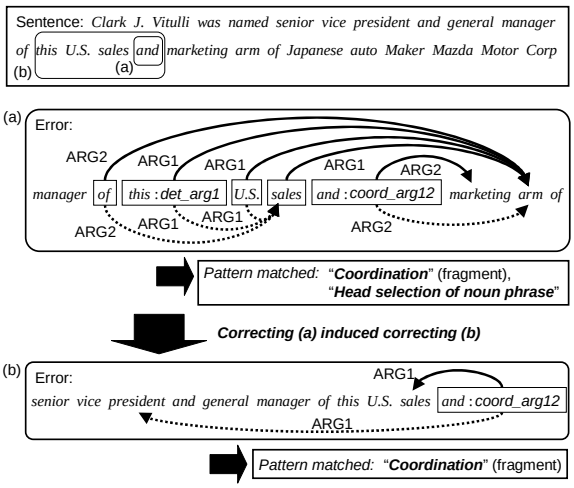

Figure 15: Combination of results given by descriptive and empirical approaches (2)

Table 5 reports the degree to which the classified errors were related to other individual errors. The leftmost numbers show the numbers of *correctable* errors, which were the focused errors in the experiments. The central numbers show the numbers of "*independent*" errors, that is, the errors which could be corrected only by correcting themselves. The rightmost numbers show "*correction effects*," that is, the number of errors which would consequently be corrected if all of the errors for the focused phenomena were forcibly corrected.

"*Independent*" errors are obtained by collecting error phenomena groups which consist of unions of co-occurring error groups and each error in which is not induced by other errors. Figure 14 shows an example of "*independent*" errors. For the sentence at the top of the figure, the parser had four errors on ARG1 of "*overseas*," the comma, "*which*" and "*boosts*." Our empirical approach then classified these errors into two co-occurring error groups (a) and (b), and there was no inductive relation between the groups. Our descriptive approach, on the other hand, matched all of the errors with the patterns for "Adjunction attachment," "Comma" and "Relative clause attachment." Since the error for the "Adjunction attachment" equals to a co-occurring group (a) and is not induced by other errors, the error is "*independent*."

Table 5 shows that, for "Prepositional attachment", "Adjunction attachments," "# of arguments for preposition" and "Adjunction/adjunctive noun," more than half of the errors for the focused phenomena are "*independent*." Containing many "*independent*" errors would mean that the parser should handle these phenomena further more intensively as an independent event.

The "*correction effect*" for a focused linguistic phenomenon can be obtained by counting errors in the union of the *correctable* error set for the phenomenon and the error sets which were induced by the individual errors in the set. We would show an example of *correction effect* in Figure 15. In the figure, the parser had six errors for the sentence at the top: three false outputs for ARG1 of "*and*," "*this*" and "*U.S.*," two false outputs for ARG2 of "*of*" and "*and*," and missing output for ARG1 of "*sales*." Our empirical approach classified these errors into two co-occurring error groups (a) and (b), and extracted an inductive relation from (a) to (b). Our descriptive approach, on the other hand, matched two errors on "*and*" with pattern "Coordination" and one error on "*this*" with "Head selection for noun phrase." When we focus on the error for "Head selection of noun phrase" in co-occurring group (a), the correction of the error induced the rest of the errors in (a), and further induced the error in (b) according to the inductive relation from (a) to (b). Therefore, a "*correction effect*" for the error results in six errors.

Table 5 shows that, for "Conjunction attachment," "Head selection for noun phrase" and "Coordination," each "*correction effect*" results in more than twice the forcibly corrected errors. Improving the parser so that it can resolve such *high-correction-effect* erroneous phenomena may additionally improve the parsing performances to a great extent. On the other hand, "Head selection for noun phrase" contains no "*independent*" error, and therefore could not be handled independently of other erroneous phenomena at all. Consider-

ing the effects from outer events might make the treatment of "Head selection for noun phrase" a more complicated process than other phenomena, regardless of its high "*correction effect*."

Table 5 would thus suggest which phenomenon we should resolve preferentially from the three points of view: the number of errors, the number of "*independent*" errors and its "*correction effect*." Considering these points, "Prepositional attachment" seems most preferable for handling first.

4.3.2 Possibilities for further analysis

Since the errors for the phenomenon were systematically collected with our descriptive approach, we can work on further focused error analyses which would answer such questions as "Which preposition causes most errors in attachments?", "Which pair of a correct answer and an erroneous output for predicate argument relations can occur most frequently?", and so on. Our descriptive approach would enable us to thoroughly obtain such analyses with more closely-defined patterns. In addition, our empirical approach would clarify the influences of the obtained error properties on the parser's behaviors. The results of the focused analyses might reasonably lead us to the features that can be captured as parameters for model training, or policies for re-ranking the parse candidates.

The combination of our approaches would give us interesting clues for planning effective strategies for improving the parser. Our challenges for combining the two approaches are now in the preliminary stage and there would be many possibilities for further detailed analysis.

5 Related work

Although there have been many researches which analyzed errors on their own systems in the part of the experiments, there have been few researches which focused mainly on error analysis itself.

In the field of parsing, McDonald and Nivre (2007) compared parsing errors between graph-based and transition-based parsers. They observed the accuracy transitions from various points of view, and the obtained statistical data suggested that error propagation seemed to occur in the graph structures of parsing outputs. Our research proceeded for one step in this point, and attempted to reveal the way of the propagations. In examining the combination of the two types of parsing, McDonald and Nivre (2007) utilized similar approaches to our empirical analysis. They allowed a parser to give only structures given by the parsers. They implemented the ideas for evaluating the parser's potentials whereas we implemented the ideas for observing error propagations.

Dredze et al. (2007) showed the possibility that many parsing errors in the domain adaptation tasks came from inconsistencies between annotation manners of training resources. Such findings would further suggest that, comparing given errors without considering the inconsistencies could lead to the misunderstanding of what occurs in domain transitions. The summarized error dependencies given by our approaches would be useful clues for extracting such domain-dependent error phenomena.

Giménez and Màrquez (2008) proposed an automatic error analysis approach in machine translation (MT) technologies. They were developing a metric set which could capture features in MT outputs at different linguistic levels with different levels of granularity. As we considered the parsing systems, they explored the way to resolve costly and non-rewarding error analysis in the MT field. One of their objectives was to enable researchers to easily access detailed linguistic reports on their systems and to concentrate only on analyses for the system improvements. From this point of view, our research might provide an introduction into such rewarding analysis in parsing.

6 Conclusions

We proposed empirical and descriptive approaches to extracting dependencies among parsing errors. In the experiments, with each of our approaches, we successfully obtained relevant errors. Moreover, the possibility was shown that the combination of our approaches would give a more detailed error analysis which would bring us useful clues for parser improvements.

In our future work, we will improve the performance of our approaches by adding more patterns for the descriptive approach and by handling *uncorrectable* errors for the empirical approach. With the obtained robust information, we will explore rewarding ways for parser improvements.

Abstract

Textual entailment recognition plays a fundamental role in tasks that require in-depth natural language understanding. In order to use entailment recognition technologies for real-world applications, a large-scale entailment knowledge base is indispensable. This paper proposes a conditional probability based directional similarity measure to acquire verb entailment pairs on a large scale. We targeted 52,562 verb types that were derived from 10^8 Japanese Web documents, without regard for whether they were used in daily life or only in specific fields. In an evaluation of the top 20,000 verb entailment pairs acquired by previous methods and ours, we found that our similarity measure outperformed the previous ones. Our method also worked well for the top 100,000 results.

1 Introduction

We all know that if you snored, you must have been sleeping, that if you are divorced, you must have been married, and that if you won a lawsuit, you must have sued somebody. These relationships between events where one is the logical consequence of the other are called entailment. Such knowledge plays a fundamental role in tasks that require in-depth natural language understanding, e.g., answering questions and using natural language interfaces.

This paper proposes a novel method for verb entailment acquisition. Using a Japanese Web corpus (Kawahara and Kurohashi, 2006a) derived from 10^8 Japanese Web documents, we automatically acquired such verb pairs as *snore* → *sleep* and *divorce* → *marry*, where entailment holds between the verbs in the pair.[1] Our definition of "entailment" is the same as that in WordNet3.0; v_1 entails v_2 if v_1 cannot be done unless v_2 is, or has been, done.[2]

Our method follows the distributional similarity hypothesis, i.e., words that occur in the same context tend to have similar meanings. Just as in the methods of Lin and Pantel (2001) and Szpektor and Dagan (2008), we regard the arguments of verbs as the context in the hypothesis. However, unlike the previous methods, ours is based on conditional probability and is augmented with a simple trick that improves the accuracy of verb entailment acquisition. In an evaluation of the top 20,000 verb entailment pairs acquired by the previous methods and ours, we found that our similarity measure outperformed the previous ones. Our method also worked well for the top 100,000 results,

Since the scope of Natural Language Processing (NLP) has advanced from a formal writing style to a colloquial style and from restricted to open domains, it is necessary for the language resources for NLP, including verb entailment knowledge bases, to cover a broad range of expressions, regardless of whether they are used in daily life or only in specific fields that are highly technical. As we will discuss later, our method can acquire, with reasonable accuracy, verb entailment pairs that deal not only with common and familiar verbs but also with technical and unfamiliar ones like *podcast* → *download* and *jibe* → *sail*.

Note that previous researches on entailment acquisition focused on templates with variables or word-lattices (Lin and Pantel, 2001; Szpektor and Dagan, 2008; Barzilay and Lee, 2003; Shinyama

[1] Verb entailment pairs are described as $v_1 \rightarrow v_2$ (v_1 is the entailing verb and v_2 is the entailed one) henceforth.

[2] WordNet3.0 provides entailment relationships between synsets like *divorce, split up* → *marry, get married, wed, conjoin, hook up with, get hitched with, espouse*.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1172–1181,
Singapore, 6-7 August 2009.

et al., 2002). Certainly these templates or word lattices are more useful in such NLP applications as Q&A than simple entailment relations between verbs. However, our contention is that entailment certainly holds for some verb pairs (like *snore* → *sleep*) by themselves, and that such pairs constitute the core of a future entailment rule database. Although we focused on verb entailment, our method can also acquire template-level entailment pairs with a reasonable accuracy.

The rest of this paper is organized as follows. In §2, related works are described. §3 presents our proposed method. After this, an evaluation of our method and the existing methods is presented in Section 4. Finally, we conclude the paper in §5.

2 Related Work

Previous studies on entailment, inference rules, and paraphrase acquisition are roughly classified into those that require comparable corpora (Shinyama et al., 2002; Barzilay and Lee, 2003; Ibrahim et al., 2003) and those that do not (Lin and Pantel, 2001; Weeds and Weir, 2003; Geffet and Dagan, 2005; Pekar, 2006; Bhagat et al., 2007; Szpektor and Dagan, 2008).

Shinyama et al. (2002) regarded newspaper articles that describe the same event as a pool of paraphrases, and acquired them by exploiting named entity recognition. They assumed that named entities are preserved across paraphrases, and that text fragments in the articles that share several comparable named entities should be paraphrases. Barzilay and Lee (2003) also used newspaper articles on the same event as comparable corpora to acquire paraphrases. They induced paraphrasing patterns by sentence clustering. Ibrahim et al. (2003) relied on multiple English translations of foreign novels and sentence alignment to acquire paraphrases. We decided not to take this approach since using comparable corpora limits the scale of the acquired paraphrases or entailment knowledge bases. Although obtaining comparable corpora has been simplified by the recent explosion of the Web, the availability of plain texts is incomparably better.

Entailment acquisition methods that do not require comparable corpora are mostly based on the distributional similarity hypothesis and use plain texts with a syntactic parser. Basically, they parse texts to obtain pairs of predicate phrases and their arguments, which are regarded as features of the predicates with appropriately assigned weights. Lin and Pantel (2001) proposed a paraphrase acquisition method (non-directional similarity measure) called DIRT which acquires pairs of binary-templates (predicate phrases with two argument slots) that are paraphrases of each other. DIRT employs the following similarity measure proposed by Lin (1998):

$$Lin(l,r) = \frac{\sum_{f \in F_l \cap F_r} [w_l(f) + w_r(f)]}{\sum_{f \in F_l} w_l(f) + \sum_{f \in F_r} w_r(f)}$$

where l and r are the corresponding slots of two binary templates, F_s is s's feature vector (argument nouns), and $w_s(f)$ is the weight of $f \in F_s$ (PMI between s and f). The intuition behind this is that the more nouns two templates share, the more semantically similar they are. Since we acquire verb entailment pairs based on unary templates (Szpektor and Dagan, 2008) we used the Lin formula to acquire unary templates directly rather than using the DIRT formula, which is the arithmetic-geometric mean of Lin's similarities for two slots in a binary template.

Bhagat et al. (2007) developed an algorithm called LEDIR for learning the directionality of non-directional inference rules like those produced by DIRT. LEDIR implements a Directionality Hypothesis: when two binary semantic relations tend to occur in similar contexts and the first one occurs in significantly more contexts than the second, then the second most likely implies the first and not vice versa.

Weeds and Weir (2003) proposed a general framework for distributional similarity that mainly consists of the notions of what they call Precision (defined below) and Recall:

$$Precision(l,r) = \frac{\sum_{f \in F_l \cap F_r} w_l(f)}{\sum_{f \in F_l} w_l(f)}$$

where l and r are the targets of a similarity measurement, F_s is s's feature vector, and $w_s(f)$ is the weight of $f \in F_s$. The best performing weight is PMI. Precision is a directional similarity measure that examines the coverage of l's features by those of r's, with more coverage indicating more similarity.

Szpektor and Dagan (2008) proposed a directional similarity measure called BInc (Balanced-Inclusion) that consists of Lin and Precision, as

$$BInc(l,r) = \sqrt{Lin(l,r) \times Precision(l,r)}$$

where l and r are the target templates. For weighting features, they used PMI. Szpektor and Dagan (2008) also proposed a unary template, which is defined as a template consisting of one argument slot and one predicate phrase. For example, *X take a nap* → *X sleep* is an entailment pair consisting of two unary templates. Note that the slot *X* must be shared between templates. Though most of the previous entailment acquisition studies focused on binary templates, unary templates have an obvious advantage over binary ones; they can handle intransitive predicate phrases and those that have omitted arguments. The Japanese language, which we deal with here, often omits arguments, and thus the advantage of unary templates is obvious.

As shown in §4, our method outperforms Lin, Precision, and BInc in accuracy.

Szpector et al. (2004) addressed broad coverage entailment acquisition. But their method requires an existing lexicon to start, while ours does not.

Apart from the dichotomy of the comparable corpora and the distributional similarity approaches, Torisawa (2006) exploited the structure of Japanese coordinated sentences to acquire verb entailment pairs. Pekar (2006) used the local structure of coherent text by identifying related clauses within a local discourse. Zanzotto et al. (2006) exploited agentive nouns. For example, they acquired *win* → *play* from "*the player wins*."

Geffet and Dagan (2005) proposed the Distributional Inclusion Hypotheses, which claimed that if a word *v* entails another word *w*, then all the characteristic features of *v* are expected to appear with *w*, and vice versa. They applied this to noun entailment pair acquisition, rather than verb pairs.

3 Proposed Method

This section presents our method of verb entailment acquisition. First, the basics of Japanese are described. Then, we present the directional similarity measure that we developed in §3.2. §3.3 describes the structure and acquisition of the web-based data from which entailment pairs are derived. Finally, we show how we acquire verb entailment pairs using our proposed similarity measure and the web-based data in §3.4.

3.1 Basics of Japanese

Japanese explicitly marks arguments including the subject and object by postpositions, and is a head-final language. Thus, a verb phrase consisting of an object *hon* (book) and a verb *yomu* (read), for example, is expressed as *hon-wo yomu* (book-ACC read) "read a book" with the accusative postposition *wo* marking the object.[3] Accordingly, we refer to a unary template as $\langle p, v \rangle$ hereafter, with p and v referring to the *p*ostposition and a *v*erb. Also, we abbreviate a template-level entailment $\langle p_l, v_l \rangle \rightarrow \langle p_r, v_r \rangle$ as $l \rightarrow r$ for simplicity. We define a unary template as a template consisting of one argument slot and one predicate, following Szpektor and Dagan (2008).

3.2 Directional Similarity Measure based on Conditional Probability

The directional similarity measure that we developed and called $Score$ is defined as follows:

$$Score(l, r) = Score_{base}(l, r) \times Score_{trick}(l, r)$$

where l and r are unary templates, and $Score$ indicates the probability of $l \rightarrow r$. $Score_{base}$, which is the base of $Score$, is defined as follows:

$$Score_{base}(l, r) = \sum_{f \in F_l \cap F_r} P(r|f)P(f|l)$$

where F_s is s's feature vector (nouns including compounds). The intention behind the definition of $Score_{base}$ is to *emulate* the conditional probability $P(v_r|v_l)$[4] in a distributional similarity style function. Note that $P(v_r|v_l)$ should be 1 when entailment $v_l \rightarrow v_r$ holds (i.e., v_r is observed whenever v_l is observed) and we have reliable probability values. Then, if we can directly estimate $P(v_r|v_l)$, it is reasonable to assume $v_l \rightarrow v_r$ if $P(v_r|v_l)$ is large enough. However, we cannot estimate $P(v_r|v_l)$ directly since it is unlikely that we will observe the verbs v_r and v_l at the same time. (People do not usually repeat v_r and v_l in the same document to avoid redundancy.) Thus, instead of a direct estimation, we *substitute* $Score_{base}(l, r)$ as defined above. In other words, we assume $P(v_r|v_l) \approx P(r|l) \approx \Sigma_{f \in F_l \cap F_r} P(f|l)P(r|f)$.

Actually, $Score_{base}$ originally had another motivation, inspired by Torisawa (2005), for which no postposition but the instrumental postposition *de* was relevant. In this discussion, all of the nouns (fs) that are marked by the instrumental postposition are seen as "tools," and $P(f|l)$ is interpreted

[3] ACC represents an accusative postposition in Japanese. Likewise, NOM, DAT, INS, and TOP are the symbols for the nominative, dative, instrumental, and topic postpositions.

[4] Remember that v_l and v_r are the verbs of unary templates l and r.

as a measure of how typically the tool f is used to perform the action denoted by (the v_l of) l; if $P(f|l)$ is large enough, f is a typical tool used in l. On the other hand, $P(r|f)$ indicates the probability of (the v_r of) r being the purpose for using the tool f. See (1) for an example.

(1) *konro-de* *chouri-suru*
cooking.stove-INS cook
'cook (something) using a cooking stove.'

The purpose of using a *cooking stove* is to *cook*. Torisawa (2005) has pointed out that when r expresses the purpose of using a tool f, $P(r|f)$ tends to be large. This predicts that $P(r|$*cooking stove*$)$ is large, where r is $\langle de, cook \rangle$.

According to this observation, if f is a single purpose tool and $P(f|l)$, the probability of f being the tool by which l is performed, and $P(r|f)$, the probability of r being the purpose of using the tool f, are large enough, then the typical performance of the action v_l should contain some actions that can be described by v_r, i.e., the purpose of using f. Moreover, if all the typical tools (fs) used in v_l are also used for v_r, most performances of the action v_l should contain a part described by the action v_r. In summary, this means that when $\Sigma_{f \in F_l \cap F_r} P(r|f)P(f|l)$, $Score_{base}$, has a large value, we can expect $v_l \rightarrow v_r$.

For example, let v_l be *deep-fry* and v_r be *cook*. Note that $v_l \rightarrow v_r$ holds for this example. There are many tools that are used for deep-frying, such as *cooking stove*, *pot*, or *pan*. This means that $P($*cooking stove*$|l)$, $P($*pot*$|l)$, or $P($*pan*$|l)$ are large. On the other hand, the purpose of using all of these tools is *cooking*, based on common sense. Thus, probabilities such as $P(r|$*cooking stove*$)$ and $P(r|$*pan*$)$ should have large values. Accordingly, $\Sigma_{f \in F_l \cap F_r} P(f|l)P(r|f)$, $Score_{base}$, should be relatively large for *deep-fry* $\rightarrow$ *cook*,

Actually, we defined $Score_{base}$ based on the above assumption However, through a series of preliminary experiments, we found that the same score could be applied without losing the precision to the other postpositions. Thus, we generalized the framework so that it could deal with most postpositions, namely *ga* (NOM), *wo* (ACC), *ni* (DAT), *de* (INS), and *wa* (TOP). Note that this is a variation of the distributional inclusion hypothesis (Geffet and Dagan, 2005), but that we do not use mutual information as in previous works, based on the hypothesis discussed above. Actually, as shown in §4, our conditional probability based method outperformed the mutual information based metrics in our experiments.

On the other hand, $Score_{trick}$ implements another assumption that if only one feature contributes to $Score_{base}$ and the contribution of the other nouns is negligible, if any, the similarity is unreliable. Accordingly, for $Score_{trick}$, we uniformly ignore the contribution of the most dominant feature from the similarity measurement.

$$Score_{trick}(l, r) = Score_{base}(l, r) - \max_{f \in F_l \cap F_r} P(r|f)P(f|l)$$

As shown in §4, this trick actually improved the entailment acquisition accuracy.

We used maximum likelihood estimation to obtain $P(r|f)$ and $P(f|l)$ in the above discussion.

Bannard and Callison-Burch (2005) and Fujita and Sato (2008) also proposed directional similarity measures based on conditional probability, which are very similar to $Score_{base}$, although either their method's prerequisites or the targets of the similarity measurements were different from ours. The method of Bannard and Callison-Burch (2005) requires bilingual parallel corpora, and uses the translations of expressions as its feature. Fujita and Sato (2008) dealt with productive predicate phrases, while our target is non-productive lexical units, i.e., verbs. Thus, this is the first attempt to apply a conditional probability based similarity measure to verb entailment acquisition. In addition, the trick implemented in $Score_{trick}$ is novel.

3.3 Preparing Template-Feature Tuples

Our method starts from a dataset called template-feature tuples, which was derived from the Web in the following way: **1)** Parse the Japanese Web corpus (Kawahara and Kurohashi, 2006a) derived from 10^8 Japanese Web documents with Japanese dependency parser KNP (Kawahara and Kurohashi, 2006b). **2)** Extract triples $\langle n, p, v \rangle$ consisting of nouns (n), postpositions (p), and verbs (v), where an n marked by a p depends on a v from the parsed Web text. **3)** From the triple database, construct template-feature tuples $\langle n, \langle p, v \rangle \rangle$ by regarding $\langle p, v \rangle$ as a unary template and n as one of its features. **4)** Convert the verbs into their canonical forms as defined by KNP. **5)** Filter out tuples that fall into one of the following categories: 5-1) $Freq(\langle p, v \rangle) < 20$. 5-2) Its verb is passivized,

causativized, or negated. 5-3) Its verb is semantically vague like *be*, *do*, or *become*. 5-4) Its postposition is something other than *ga* (NOM), *wo* (ACC), *ni* (DAT), *de* (INS), or *wa* (TOP).

The resulting unary template-feature tuples included 127,808 kinds of templates that consisted of 52,562 verb types and five kinds of postpositions. The verbs included compound words like *bosi-kansen-suru* (mother.to.child-infection-do) "infect from mothers to infants."

3.4 Acquiring Entailment Pairs

We acquired verb entailment pairs using the following procedure: **i)** From the template-feature tuples mentioned in §3.3, acquire unary template pairs that exhibit an entailment relation between them using the directional similarity measure in §3.2. **ii)** Convert the acquired unary templates $\langle p, v \rangle$ into naked verbs v by stripping the postpositions p. **iii)** Remove the duplicated verb pairs resulting from stripping ps. To be precise, when we removed the duplicated pairs, we left the highest ranked one. **iv)** Retrieve N-best verb pairs as the final output from the result of iii). That is, we first acquired unary template pairs and then transformed them into verb pairs.

Although this paper focuses on verb entailment acquisition, we also evaluated the accuracy of template-level entailment acquisition, in order to show that our similarity measure works well, not only for verb entailment acquisition, but also for template entailment acquisition (See §4.4). we created two kinds of unary templates: the "Scoring Slots" template and the "Nom(inative) Slots" template. The first is simply the result of the procedure **i)**; all of the templates have slots that are used for similarity scoring. The second one was obtained in the following way: **1)** Only templates whose p is not a nominative are sampled from the result of the procedure **i)**. **2)** Their ps are all changed to a nominative. Templates of the second kind are used to show that the corresponding slots between templates (nominative, in this case) that are not used for similarity scoring can be incorporated to resulting template-level entailment pairs if the scoring function really captures the semantic similarity between templates.

Note that, for unary template entailment pairs like (2) to be well-formed, the two unary slots (*X-wo*) between templates must share the same noun as the index i indicates. This is relevant in §4.4.

(2) *X_i-wo musaborikuu* → *X_i-wo taberu*
X_i-ACC gobble X_i-ACC eat

4 Evaluation

We compare the accuracy of our method with that of the alternative methods in §4.1. §4.2 shows the effectiveness of the trick. We examine the entailment acquisition accuracy for frequent verbs in §4.3, and evaluate the performance of our method when applied to template-level entailment acquisition in §4.4. Finally, by showing the accuracy for verb pairs obtained from the top 100,000 results, we claim that our method provides a good starting point from which a large-scale verb entailment resource can be constructed in §4.5.

For the evaluation, three human annotators (not the authors) checked whether each acquired entailment pair was correct. The average of the three Kappa values for each annotator pair was 0.579 for verb entailment pairs and 0.568 for template entailment pairs, both of which indicate the middling stability of this evaluation annotation.

4.1 Experiment 1: Verb Pairs

We applied $Score$, BInc, Lin, and Precision to the template-feature tuples (§3.3), obtained template entailment pairs, and finally obtained verb entailment pairs by removing the postpositions from the templates as described in §3. As a baseline, we created pairs from randomly chosen verbs.

Since we targeted all of the verbs that appeared on the Web (under the condition of $Freq(\langle p, v \rangle) \geq 20$), the annotators were confronted with technical terms and slang that they did not know. In such cases, they consulted dictionaries (either printed or machine readable ones) and the Web. If they still could not find the meaning of a verb, they labeled the pair containing the unknown verb as incorrect.

We used the accuracy $= \frac{\text{\# of correct pairs}}{\text{\# of acquired pairs}}$ as an evaluation measure. We regarded a pair as correct if it was judged correct by one (Accuracy-1), two (Accuracy-2), or three (Accuracy-3) annotators.

We evaluated 200 entailment pairs sampled from the top 20,000 for each method (# of acquired pairs $= 200$). For fairness, the evaluation samples for each method were shuffled and placed in one file from which the annotators worked. In this way, they were unable to know which entailment pair came from which method.

Note that the verb entailment pairs produced by Lin do not provide the directionality of entailment. Thus, the annotators decided the directionality of these entailment pairs as follows: **i)** Copy 200 original samples and reverse the order of v_1 and v_2. **ii)** Shuffle the 400 Lin samples (the original and reversed samples) with the other ones. **iii)** Evaluate all of the shuffled pairs. Each Lin pair was regarded as correct if either direction was judged correct. In other words, we evaluated the upper bound performance of the LEDIR algorithm.

Table 1 shows the accuracy of the acquired verb entailment pairs for each method. Figure 1

Method	Acc-1	Acc-2	Acc-3
$Score$	**0.770**	**0.660**	**0.460**
BInc	0.450	0.255	0.125
Precision	0.725	0.545	0.385
Lin	0.590	0.370	0.160
Random	0.050	0.010	0.005

Table 1: Accuracy of verb entailment pairs.

shows the accuracy figures for the N-best entailment pairs for each method, with N being 1,000, 2,000, ..., or 20,000. We observed the following points from the results. First, $Score$ outperformed all the other methods. Second, $Score$ and Precision, which are directional similarity measures, worked well, while Lin, which is a symmetric one, performed poorly even though the directionality of its output was determined manually.

Looking at the evaluated samples, $Score$ successfully acquired pairs in which the entailed verbs generalized entailing verbs that were technical terms. (3) shows examples of $Score$'s outputs.

(3) a. *RSS-haisin-suru* → *todokeru*
RSS-feed-do deliver
"feed the RSS data"

'crack a (security) system'
→ *koutiku-hosyu-suru*
building-maintenance-do
"build and maintain a system"

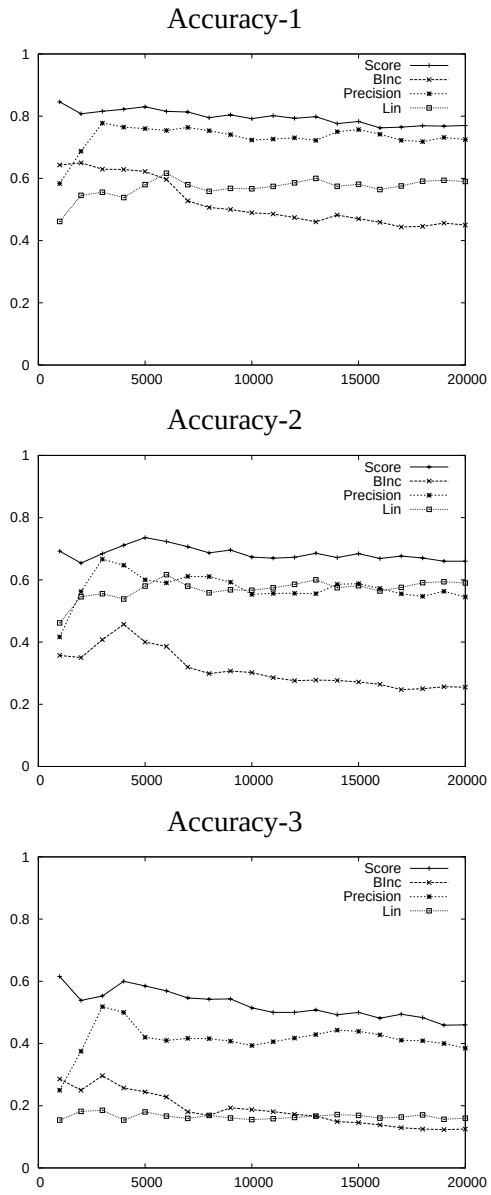

Figure 1: Accuracy of verb entailment pairs.

(5) *suisou-siiku-suru*
tank-raising-do
"raise (fish) in a tank"
→ *siken-houryuu-suru*
test-discharge-do
"stock (with fish) experimentally"

These terms are related in some sense, but they are not entailment pairs.

4.2 Experiment 2: Effectiveness of the Trick

Next, we investigated the effectiveness of the trick described in §3. We evaluated $Score$, $Score_{trick}$, and $Score_{base}$. Table 2 shows the accuracy figures for each method. Figure 2 shows the accuracy figures for the N-best outputs for each method. The

Method	Acc-1	Acc-2	Acc-3
$Score$	**0.770**	**0.660**	**0.460**
$Score_{trick}$	0.725	0.610	0.395
$Score_{base}$	0.590	0.465	0.315

Table 2: Effectiveness of the trick.

results illustrate that introducing the trick significantly improved the performance of $Score_{base}$, and so did multiplying $Score_{trick}$ and $Score_{base}$, which is our proposal $Score$.

(6) shows an example of $Score_{base}$'s errors.

(6) *gazou-sakusei-suru* → *henkou-suru*
image-making-do change-do
"make an image" "change"

This pair has only two shared nouns ($f \in F_l \cap F_r$), and more than 99.99% of the pair's similarity reflects only one of the two. Clearly, the trick would have prevented the pair from being highly ranked.

4.3 Experiment 3: Pairs of Frequent Verbs

We found that the errors made by Lin and BInc in Experiment 1 were mostly pairs of infrequent verbs such as technical terms. Thus, we conducted the acquisition of entailment pairs targeting more frequent verbs to see how their performance changed. The experimental conditions were the same as in Experiment 1, except that the templates ($\langle p, v \rangle$) used were all $Freq(\langle p, v \rangle) \geq 200$.

Table 3 shows the accuracy figures for each method with the changes in accuracy from those of the original methods in parentheses. The results show that the accuracies of $Score$ and Precision (the two best methods in Experiment 1) degraded, while the other two improved a little. We suspect that the performance difference between these methods would get smaller if we further restricted the target verbs to more frequent ones.

Method	Acc-1	Acc-2	Acc-3
$Score$	0.690 (−0.080)	0.520 (−0.140)	0.335 (−0.125)
BInc	0.455 (+0.005)	0.295 (+0.040)	0.160 (+0.035)
Precision	0.450 (−0.275)	0.355 (−0.190)	0.205 (−0.180)
Lin	0.635 (+0.045)	0.385 (+0.015)	0.205 (+0.045)

Table 3: Accuracy of frequent verb pairs.

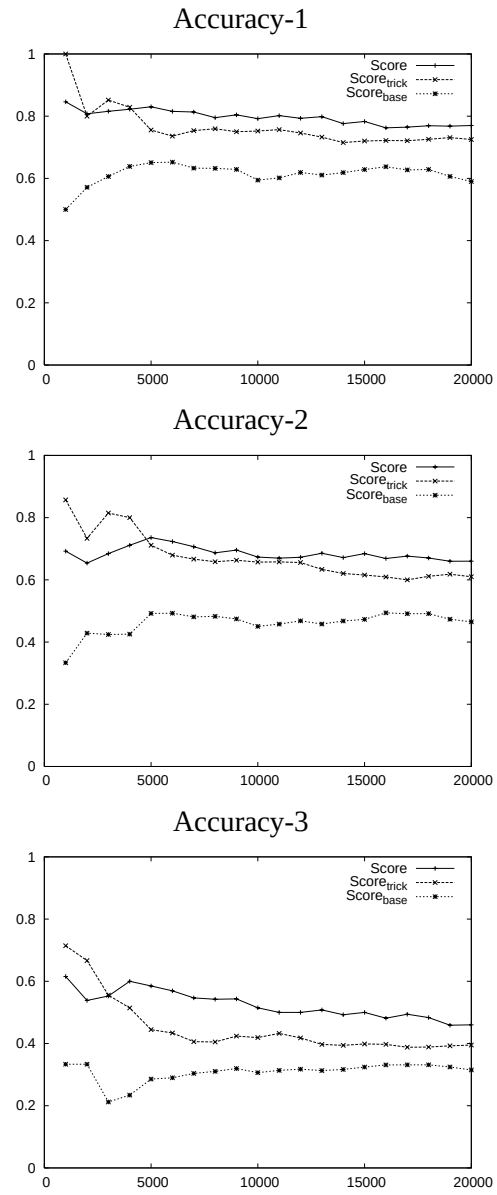

Figure 2: Accuracy of verb entailment pairs acquired by $Score$, $Score_{trick}$, and $Score_{base}$.

However, we believe that dealing with verbs comprehensively, including infrequent ones, is important, since, in the era of information explosion, the impact on applications is determined not only by frequent verbs but also infrequent ones that constitute the long tail of a verb-frequency graph. Thus, this tendency does not matter for our purpose.

4.4 Experiment 4: Template Pairs

This section presents the entailment acquisition accuracy for template pairs to show that our method can also perform the entailment acquisition of unary templates. We presented pairs of unary templates, obtained by the procedure in

§3.4, to the annotators. In doing so, we restricted the correct entailment pairs to those for which entailment always held regardless of what argument filled the two unary slots, and the two slots had to be filled with the same argument, as exemplified in (2). We evaluated $Score$ and Precision.

Table 4 shows the accuracy of the acquired pairs of unary templates. Compared to verb entailment

	Method	Acc-1	Acc-2	Acc-3
Scoring Slots	$Score$	**0.655** (−0.115)	**0.510** (−0.150)	**0.300** (−0.160)
	Precision	0.565 (−0.160)	0.430 (−0.115)	0.265 (−0.120)
Nom Slots	$Score$	**0.665** (−0.105)	**0.515** (−0.145)	**0.315** (−0.145)
	Precision	0.490 (−0.235)	0.325 (−0.220)	0.215 (−0.170)

Table 4: Accuracy of entailment pairs of templates whose slots were used for scoring.

acquisition, the accuracy of both methods dropped by about 10%. This was mainly due to the evaluation restriction exemplified in (2) which was not introduced in the previous experiments; the annotators ignored the argument correspondence between the verb pairs in Experiment 1. Also note that $Score$ outperformed Precision in this experiment, too.

(7) and (8) are examples of the Scoring Slots template entailment pairs and (9) is that of the Nom Slots acquired by our method.

(7) *X-wo tatigui-suru* → *X-wo taberu*
X-ACC standing.up.eating-do X-ACC eat
"eat X standing up" "eat X"

(8) *X-de marineedo-suru* → *X-wo ireru*
X-INS marinade-do X-ACC pour
"marinate with X" "pour X"

(9) *X-ga NBA-iri-suru* · · · (was *X-de* (INS))
X-NOM NBA-entering-do
'X joins an NBA team'
→ *X-ga nyuudan-suru* · · · (was *X-de*)
X-NOM enrollment-do
"X joins a team"

4.5 Experiment 5: Verb Pairs form the Top 100,000

Finally, we examined the accuracy of the top 100,000 verb pairs acquired by $Score$ and Precision. As Table 5 shows, $Score$ outperformed Precision. Note also that $Score$ kept a reasonable accuracy for the top 100,000 results (Acc-2: 48%). The accuracy is encouraging enough to consider human annotation for the top 100,000 results to produce a language resource for verb entailment, which we actually plan to do.

Method	Acc-1	Acc-2	Acc-3
$Score$	**0.610**	**0.480**	**0.300**
Precision	0.470	0.295	0.190

Table 5: Accuracy of the top 100,000 verb pairs.

Below are correct verb entailment examples from the top 100,000 results of our method.

(10) The **121**th pair
kaado-kessai-suru → *siharau*
card-payment-do pay
"pay by card" "pay"

(11) The **6,081**th pair
saitei-suru → *sadameru*
adjudicate-do settle
"adjudicate" "settle"

(12) The **15,464**th pair
eraa-syuuryou-suru → *jikkou-suru*
error-termination-do perform-do
"abend" "execute"

(13) The **30,044**th pair
ribuuto-suru → *kidou-suru*
reboot-do start-do
"reboot" "boot"

(14) The **57,653**th pair
rinin-suru → *syuunin-suru*
resignation-do accession-do
"resign" "accede"

(15) The **70,103**th pair
sijou-tounyuu-suru → *happyou-suru*
market-input-do publication-do
"bring to the market" "publicize"

Below are examples of erroneous pairs from our results. (16) is a causal relation but not an entailment. (17) is a contradictory pair.

(16) The **5,475**th pair
juken-suru → *goukaku-suru*
take.an.exam-do acceptance-do
"take an exam" "gain admission"

(17) The **40,504**th pair

ketujou-suru	→	*syutujou-suru*
not.take.part-do		take.part-do
"not take part"		"take part"

5 Conclusion

This paper addressed verb entailment acquisition from the Web, and proposed a novel directional similarity measure $Score$. Through a series of experiments, we showed **i)** that $Score$ outperforms the previously proposed measures, Lin, Precision, and BInc in large scale verb entailment acquisition, **ii)** that our proposed trick implemented in $Score_{trick}$ significantly improves the accuracy of verb entailment acquisition despite its simplicity, **iii)** that $Score$ worked better than the others even when we restricted the target verbs to more frequent ones, **iv)** that our method is also moderately successful at producing template-level entailment pairs, and **v)** that our method maintained reasonable accuracy (in terms of human annotation) for the top 100,000 results. As examples of the acquired verb entailment pairs illustrated, our method can acquire from an ocean of information, namely the Web, a variety of verb entailment pairs ranging from those that are used in daily life to those that are used in very specific fields.

Abstract

Recent syntactic extensions of statistical translation models work with a synchronous context-free or tree-substitution grammar extracted from an automatically parsed parallel corpus. The decoders accompanying these extensions typically exceed quadratic time complexity.

This paper extends the Direct Translation Model 2 (DTM2) with syntax while maintaining linear-time decoding. We employ a linear-time parsing algorithm based on an eager, incremental interpretation of Combinatory Categorial Grammar (CCG). As every input word is processed, the local parsing decisions resolve ambiguity eagerly, by selecting a single supertag–operator pair for extending the dependency parse incrementally. Alongside translation features extracted from the derived parse tree, we explore syntactic features extracted from the incremental derivation process. Our empirical experiments show that our model significantly outperforms the state-of-the art DTM2 system.

1 Introduction

Syntactic structure is gradually showing itself to constitute a promising enrichment of state-of-the-art Statistical Machine Translation (SMT) models. However, it would appear that the decoding algorithms are bearing the brunt of this improvement in terms of time and space complexity. Most recent extensions work with a synchronous context-free or tree-substitution grammar extracted from an automatically parsed parallel corpus. While attractive in many ways, the decoders that are needed for these types of grammars usually have time and space complexities that are far beyond linear. Leaving pruning aside, there is a genuine question as to whether syntactic structure necessarily implies more complex decoding algorithms. This paper shows that this need not necessarily be the case.

In this paper we extend the Direct Translation Model (DTM2) (Ittycheriah and Roukos, 2007) with target language syntax while maintaining linear-time decoding. With this extension we make three novel contributions to SMT. Our first contribution is to define a linear-time syntactic parser that works as incrementally as standard SMT decoders (Tillmann and Ney, 2003; Koehn, 2004a). At every word position in the target language string, this parser spans *at most a single parse-state* to augment the translation states in the decoder. The parse state summarizes previous parsing decisions and imposes constraints on the set of valid future extensions such that a well-formed sequence of parse states unambiguously defines a dependency structure. This approach is based on an *incremental interpretation* of the mechanisms of Combinatory Categorial Grammar (CCG) (Steedman, 2000).

Our second contribution lies in extending the DMT2 model with a novel set of syntactically-oriented feature functions. Crucially, these feature functions concern the derived (partial) dependency structure as well as local aspects of *the derivation process*, including such information as the CCG lexical categories (supertag), the CCG operators and the intermediate parse states. This accomplishment is interesting both from a linguistic and technical point of view.

Our third contribution is the extension of the standard phrase-based decoder with the syntactic structure and definition of new *grammar-specific pruning techniques* that control the size of the search space. Interestingly, because it is eager, the incremental parser used in this work is hard pushed to perform at a parsing level close to state-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1182–1191,
Singapore, 6-7 August 2009.

of-the-art cubic-time parsers. Nevertheless, the parsing information it provides allows for significant improvement in translation quality.

We test the new model, called the Dependency-based Direct Translation Model (DDTM), on standard Arabic–English translation tasks used in the community, including LDC and GALE data. We show that our DDTM system provides significant improvements in BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) scores over the already extremely competitive DTM2 system. We also provide results of manual, qualitative analysis of the system output to provide insight into the quantitative results.

This paper is organized as follows. Section 2 reviews the related work. Section 3 discusses the DTM2 baseline model. Section 4 presents the general workings of the incremental CCG parser laying the foundations for integrating it into DTM2. Section 5 details our own DDTM, the dependency-based extension of the DTM2 model. Section 6 reports on extensive experiments and their results. Section 7 provides translation output to shed further detailed insight into the characteristics of the systems. Finally, Section 8 concludes, and discusses future work.

2 Related Work

In (Marcu et al., 2006), it is demonstrated that 'syntactified' target language phrases can improve translation quality for Chinese–English. A stochastic, top-down transduction process is employed that assigns a joint probability to a source sentence and each of its alternative syntactified translations; this is done by specifying a rewriting process of the target parse-tree into a source sentence.

Likewise, the model in (Zollmann and Venugopal, 2006) extends (Chiang, 2005) by augmenting the hierarchical phrases with syntactic categories derived from parsing the target side of a parallel corpus. They use an existing parser to parse the target side of the parallel corpus in order to extract a syntactically motivated, bilingual synchronous grammar as in (Chiang, 2005).

The above-mentioned approaches for incorporating syntax into Phrase-based SMT (Marcu et al., 2006; Zollmann and Venugopal, 2006) share common drawbacks. Firstly, they are based on syntactic phrase-structure parse trees incorporated into a Synchronous CFG or Tree-Substitution Grammar, which makes for a difficult match with non-constituent phrases that are common within Phrase-based SMT. These approaches usually resort to ad hoc solutions to enrich the non-constituent phrases with syntactic structures. Secondly, they deploy chart-based decoders with a high computational cost compared with the phrase-based beam search decoders, e.g., (Tillmann and Ney, 2003; Koehn, 2004a). Thirdly, due to the large parse space, some of the proposed approaches are forced to employ small language models compared to what is usually used in phrase-based systems. To circumvent these computational limitations, various pruning techniques are usually needed, e.g., (Huang and Chiang, 2007).

Other recent approaches, e.g., (Birch et al., 2007; Hassan et al., 2007; Hassan et al., 2008a) incorporate a linear-time supertagger into SMT to take the role of a syntactic language model alongside the standard language model. While these approaches share with our work the use of lexicalized grammars, they never seek to build a full dependency tree or employ syntactic features in order to directly influence the reordering probabilities in the decoder. In the current work, we expand our previous work in (Hassan et al., 2007; Hassan et al., 2008a) to introduce the capabilities of building a full dependency structure and employing syntactic features to influence the decoding process.

Recently, (Shen et al., 2008) introduced an approach for incorporating a dependency-based language model into SMT. They proposed to extract String-to-Dependency trees from the parallel corpus. As the dependency trees are not constituents by nature, they handle non-constituent phrases as well. While this work is in the same general direction as our work, namely aiming at incorporating dependency parsing into SMT, there remain three major differences. Firstly, (Shen et al., 2008) resorted to heuristics to extract the String-to-Dependency trees, whereas our approach employs the well formalized CCG grammatical theory. Secondly, their decoder works bottom-up and uses a chart parser with a limited language model capability (3-grams), while we build on the efficient, linear-time decoder commonly used in phrase-based SMT. Thirdly, (Shen et al., 2008) deploys the dependency language model to augment the lexical language model probability be-

tween two head words but never seek a full dependency graph. In contrast, our approach integrates an incremental parsing capability, that produces the partial dependency structures incrementally while decoding, and thus provides for better guidance for the search of the decoder for more grammatical output. To the best of our knowledge, our approach is the first to incorporate incremental dependency parsing capabilities into SMT while maintaining the linear-time and -space decoder.

3 Baseline: Direct Translation Model 2

The Direct Translation Model (DTM) (Papineni et al., 1997) employs the *a posteriori* conditional distribution $P(T|S)$ of a target sentence T given a source sentence S, instead of the common inversion into $P(S|T)$ based on the source channel approach (Brown et al., 1990). DTM2, introduced in (Ittycheriah and Roukos, 2007), expresses the phrase-based translation task in a unified log-linear probabilistic framework consisting of three components: (i) a prior conditional distribution $P_0(.|S)$, (ii) a number of feature functions $\phi_i()$ that capture the translation and language model effects, and (iii) the weights of the features λ_i that are estimated under MaxEnt (Berger et al., 1996), as in (1):

$$P(T|S) = \frac{P_0(T,J|S)}{Z} \exp \sum_i \lambda_i \phi_i(T,J,S) \quad (1)$$

Here J is the skip reordering factor for the phrase pair captured by $\phi_i()$ and represents the jump from the previous source word, and Z is the per source sentence normalization term. The prior probability P_0 is the prior distribution for the phrase probability which is estimated using the phrase normalized counts commonly used in conventional Phrase–based SMT systems, e.g., (Koehn et al., 2003).

DTM2 differs from other Phrase–based SMT models in that it extracts from a word-aligned parallel corpus only a *non-redundant* set of *minimal phrases* in the sense that no two phrases overlap with each other.

Baseline DTM2 Features: The baseline employs the following five types of features (beside the language model):

- *Lexical Micro Features* examining source and target words of the phrases,
- *Lexical Context Features* encoding the source and target phrase context (i.e. previous and next source and previous target),
- *Source Morphological Features* encoding morphological and segmentation characteristics of source words.
- *Part-of-Speech Features* encoding source and target POS tags as well as the POS tags of the surrounding contexts of phrases.

The DTM2 approach based on MaxEnt provides a flexible framework for incorporating other available feature types as we demonstrate below.

DTM2 Decoder: The decoder for the baseline is a beam search decoder similar to decoders used in standard phrase-based log-linear systems such as (Tillmann and Ney, 2003) and (Koehn, 2004a). The main difference between the DTM2 decoder and the standard Phrase–based SMT decoders is that DTM2 deploys Maximum Entropy probabilistic models to obtain the translation costs and various feature costs by deploying the features described above in a discriminative MaxEnt fashion.

In the rest of this paper we adopt the DTM2 formalization of translation as a discriminative task, and we describe the CCG-based incremental dependency parser that we use for extending the DTM2 decoder, and then list a new set of syntactic dependency feature functions that extend the DTM2 feature set. We also discuss pruning and other details of the approach.

4 The Incremental Dependency Parser

As it processes an input sentence left-to-right word-by-word, the incremental dependency model builds—for each prefix of the input sentence—a partial parse that is a subgraph of the partial parse that it builds for a longer prefix. The dependency graph is constructed incrementally, in that the subgraph constructed at a preceding step is never altered or revised in any later steps. The following schematic view in (2) exhibits the general workings of this parser:

$$S_0 \xrightarrow[w_1,st_1]{o_1} S_1 \xrightarrow[w_2,st_2]{o_2} S_2 \cdots\cdots S_i \xrightarrow[w_i,st_i]{o_i} S_{i+1} \cdots\cdots S_n \quad (2)$$

The syntactic process is represented by a sequence of transitions between adjacent syntactic states S_i.

A transition from state S_{i-1} to S_i scans the current word w_i and stochastically selects a complex lexical descriptor/category st_i and an operator o_i given the local context in the transition sequence. The syntactic state S_i summarizes all the syntactic information about fragments that have already been processed and registers the syntactic arguments which are to be expected next. Only an impoverished deterministic procedure (called a 'State-Realizer') is needed in order to compose a state S_i with the previous states $S_0 \ldots S_{i-1}$ in order to obtain a *fully connected intermediate dependency structure* at every position in the input.

To implement the incremental parsing scheme described above we use the parser described in (Hassan et al., 2008b; Hassan et al., 2009), which is based on Combinatory Categorial Grammar (CCG) (Steedman, 2000). We only briefly describe this parser as its full description is beyond the scope of this paper. The notions of a *supertag* as a lexical category and the process of *supertagging* are both crucial here (Bangalore and Joshi, 1999). Fortunately, CCG specifies the desired kind of lexical categories (supertags) st_i for every word and a small set of combinatory operators o_i that combine the supertag st_i with a previous parse state S_{i-1} into the next parse state S_i. In terms of CCG representations, the parse state is a CCG composite category which specifies either a functor and the arguments it expects to the right of the current word, or is itself an argument for a functor that will follow it to the right. At the first word in the sentence, the parse state consists solely of the supertag of that word.

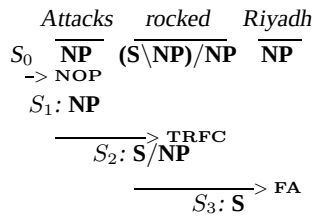

Figure 1: A sentence and possible supertag-, operator- and state-sequences. NOP: No Operation; TRFC: Type Raise-Forward Composition; FA: Forward Application. The CCG operators used show that `Attacks` *and* `Riyadh` *are both dependents of* `rocked`*.*

Figure 1 exhibits an example of the workings of this parser. Practically speaking, after POS tagging the input sentence, the parser employs two components:

- A Supertag-Operator Tagger which proposes a supertag–operator pair for the current word,
- A deterministic State-Realizer, which realizes the current state by applying the current operator to the previous state and the current supertag.

The Supertag-Operator Tagger is a probablistic component while the State-Realizer is a deterministic component. The generative model underlying this component concerns the probability $P(W, S)$ of a word sequence $W = w_1^n$ and a parse-state sequence $S = S_1^n$, with associated supertag sequence $ST = st_1^n$ and operator sequence $O = o_1^n$, which represents a possible derivation. Note that given the choice of supertags st_i and operator o_i, the state S_i is calculated deterministically by the State-Realizer.

A generative version of this model is described in (3):

$$P(W,S) = \prod_{i=1}^{n} \overbrace{P(w_i|W_{i-1}S_{i-1})}^{Word\ Predictor} \cdot \overbrace{P(st_i|W_i)}^{Supertagger} \cdot \overbrace{P(o_i|W_i, S_{i-1}, ST_i)}^{Operator\ Tagger} \quad (3)$$

In (3):

- $P(W, S)$ represents the product of the production probabilities at each parse-state and is similar to the structured language model representation introduced in (Chelba, 2000).
- $P(w_i|W_{i-1}S_{i-1})$ is the probability of w_i given the previous sequence of words W_{i-1} and the previous sequence of states S_{i-1},
- $P(st_i|W_i)$: is the supertag st_i probability given the word sequence W_i up to the current position. Basically, this represents a sequence tagger (a 'supertagger').
- $P(o_i|W_i, S_{i-1}, ST_i)$ represents the probability of the operator o_i given the previous words, supertags and state sequences up to the current position. This represents a CCG operator tagger.

The different local conditional components (for every i) in (3) are estimated as discriminative MaxEnt submodels trained on a corpus of *incremental CCG derivations*. This corpus was extracted from the CCGbank (Hockenmaier, 2003)

by transforming every normal form derivation into strictly left-to-right CCG derivations, with the CCG operators only slightly redesigned to allow incrementality while still satisfying the dependencies in the CCGbank (cf. (Hassan et al., 2008b; Hassan et al., 2009)).

As mentioned before, the State-Realizer is a deterministic function. Starting at the first word with (obviously) a null previous state, the realizer performs the following deterministic steps for each word in turn: (i) set the current supertag and operator to those of the current word; (ii) at the current state, apply the current operator to the previous state and current supertag; (iii) add edges to the dependency graphs between words that are linked as CCG arguments; and (iv) if not at the end of the sentence, set the previous state to the current one, then set the current word to the next one, and iterate from (i).

It is worth noting that the proposed dependency parser is deterministic in the sense that it maintains *only one parse state per word*. This characteristic is crucial for its incorporation into a large-scale SMT system to avoid explosion of the translation space during decoding.

5 Dependency-based DTM (DDTM)

In this section we extend the DTM2 model with incremental target dependency-based syntax. We call the resulting model the Dependency-based Direct Translation Model (DDTM). This extension takes place by (i) extracting syntactically enriched minimal phrase pairs, (ii) including a new set of syntactic feature functions among the exponential model features, and (iii) adapting the decoder for dealing with syntax, including various pruning strategies and enhancements. Next we describe each extension in turn.

5.1 Phrase Table: Incremental Syntax

The target-side sentences in the word-aligned parallel corpus used for training are parsed using the incremental dependency parser described in section 4. This results in a word-aligned parallel corpus where the words of the target sentences are tagged with supertags and operators. From this corpus we extract the set of minimal phrase pairs using the method described in (Ittycheriah and Roukos, 2007), extracting along with every target phrase the associated sequences of supertags and operators. As shown in (4), a source phrase $s_1, \ldots, s_n$ translates into a target phrase $w_1, \ldots, w_m$ where every word w_i is labeled with a supertag st_i, and a possible parsing operator o_i appearing with it in the parsed parallel corpus:

$$s_1 ... s_n \longrightarrow [w_1, st_1, o_1] ... [w_m, st_m, o_m] \quad (4)$$

Hence, our phrase table associates with every target phrase an *incremental parsing subgraph*. These subgraphs along with their probabilities represent our phrase table augmented with incremental dependency parsing structure.

This representation turns the complicated problem of MT with incremental parsing into a sequential classification problem in which the classifier deploys various features from the source sentence and the candidate target translations to specify a sequence of decisions that finally results in an output target string along with its associated dependency graph. The classification decisions are performed in sequence step-by-step while traversing the input string to provide decisions on possible words, supertags, operators and states. A beam search decoder simultaneously decides which sequence is the most probable.

5.2 DDTM Features

The exponential model and the MaxEnt framework used in DTM2 and DDTM enabled us to explore the utility of incremental syntactic parsing within a rich feature space. In our DDTM system, we implemented a set of features alongside the baseline DTM2 features that were discussed in Section 3. The features described here encode all the probabilistic components in (3) within a log linear interpretation along with some more empirically intuitive features.

- Supertag-Word features: these features examine the target phrase words with their associated supertags and is related to the Supertagger component in (3).
- Supertag sequence features: these features encode *n*-gram supertags (equivalent to the *n*-gram supertags Language Model). This feature is related to the supertagger component as well.
- Supertag-Operator features: these features encode supertags and associated operators which is related to the Operator Tagger component in (3).

- Supertag-State features: these features register state and supertag co-occurrences.
- State sequence features: these features encode *n*-gram state features and are equivalent to an *n*-gram Language Model over parse state sequences which is related to the multiplication in (3).
- Word-State sequence features: these features encode words and states co-occurrences which is related to the Word Predictor component in (3).

The exponential model and the MaxEnt framework used in DTM2 and DDTM enable us to explore the utility of incremental syntactic parsing with the use of minimal phrases within a rich feature space.

5.3 DDTM Decoder

In order to support incremental dependency parsing, we extend the DTM2 decoder in three ways: firstly, by constructing the syntactic states during decoding; secondly, by extending the hypothesis structures to incorporate the syntactic states and the partial dependency derivations; and thirdly, by modifying the pruning strategy to handle the large search space.

At decoding time, each hypothesis state is associated with a parse-state which is constructed while decoding using the incremental parsing approach introduced in ((Hassan et al., 2008b; Hassan et al., 2009)). The previous state, the sequences of supertags and CCG incremental operators are deployed in a deterministic manner to realize the parse-states as well as the intermediate dependency graphs between words.

Figure 2 shows the DDTM decoder while decoding a sentence with the English translation "Attacks rocked Riyadh". Each hypothesis is associated with a parse-state S_i and a partial dependency graph (shown for some states only). Moreover, each transition is associated with an operator o that combines the previous state and the current supertag st to construct the next state S_i. The decoder starts from a null state S_1 and then proceeds with a possible expansion with the word "attacks", supertag NP and operator NOP to produce the next hypothesis with state S_2 and category NP. Further expansion for that path with the verb "rocked", supertag '$(S\backslash NP)/NP$ and operator $TRFC$ will produce the state S_5 with category S/NP. The partial dependency graph for state S_5 is shown above the state where a dependency relation between the two words is established. Furthermore, another expansion with the word "Riyadh", supertag NP and operator FA produces state S_7 with category S and a completed dependency graph as shown above the state. Another path which spans the states S_1, S_3 , S_6 and S_8 ends with a state category S/NP and a partial dependency graph as shown under state S_8 where the dependency graph is still missing its object (e.g. "Riyadh attacks rocked the Saudi Govt.").

The addition of parse-states may result in a very large search space due to the fact that the same phrase/word may have many possible supertags and many possible operators. Moreover, the same word sequences may have many parse-state sequences and, therefore, many hypotheses that represent the same word sequence. The search space is definitely larger than the baseline search space. We adopt the following three pruning heuristics to limit the search space.

5.3.1 Grammatical Pruning

Any hypothesis which does not constitute a valid parse-state is discarded, i.e. if the previous parse-state and the current supertag sequence cannot construct a valid state using the associated operator sequence, then the expansion is discarded. Therefore, this pruning strategy maintains only fully connected graphs and discards any partially connected graphs that might result during the decoding process.

As shown in Figure 2, the expansion from state S_1 to state S_4 (with the dotted line) is pruned and not expanded further because the proposed expansion is the verb "attacks", supertag $(S\backslash NP)/NP$ and operator $TRFC$. Since the previous state is NULL, it cannot be combined with the verb using the $TRFC$ operator. This would produce an undefined state and thus the hypothesis is discarded.

5.3.2 Supertags and Operators Threshold

We limit the supertag and operator variants per target phrase to a predefined number of alternatives. We tuned this on the MT03 DevSet for the best accuracy while maintaining a manageable search space. The supertags limit was set to four alternatives while the operators limit was set to three.

As shown in Figure 2, each word can have many alternatives with different supertags. In this example the word "attacks" has two forms, namely a

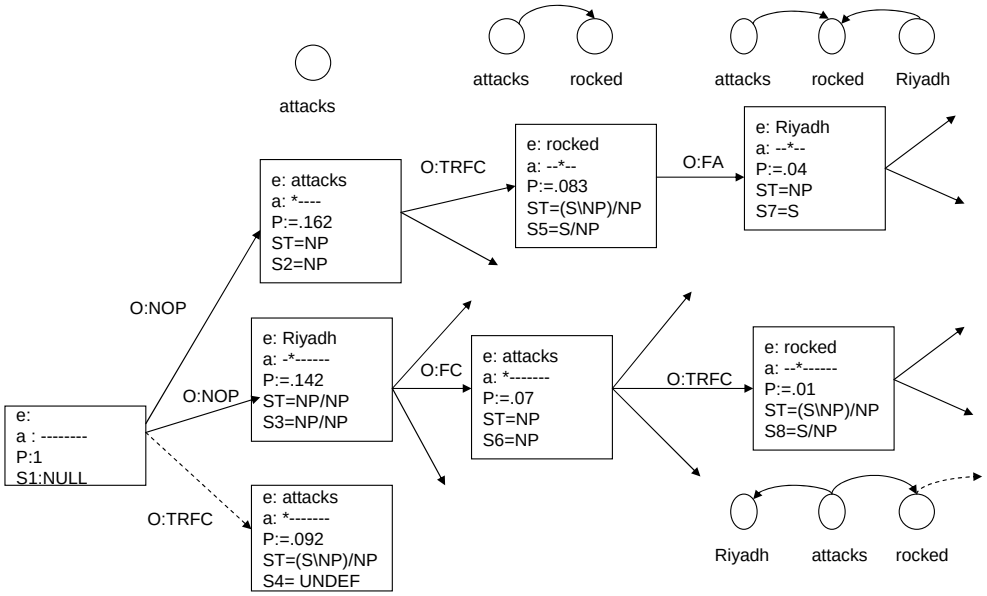

Figure 2: DDTM Decoder: each hypothesis has a parse state and a partial dependency structure.

noun and a verb, with different supertags and operators. The proposed thresholds limit the possible alternatives to a reasonable number.

5.3.3 Merging Hypotheses

Standard Phrase–based SMT decoders merge translation hypotheses if they cover the same source words and share the same *n*-gram language model history. Similarly, DDTM decoder merges translation hypotheses if they cover the same source words, share the same *n*-gram language model history and share the same parse-state history. This helps in reducing the search space by merging paths that will not constitute a part of the best path.

6 Experiments

We conducted experiments on an Arabic-to-English translation task using LDC parallel data and GALE parallel data. We used the UN parallel corpus and LDC news corpus together with the GALE parallel corpus, totaling 7.8M parallel sentences. The 5-gram Language Model was trained on the English Gigaword Corpus and the English part of the parallel corpus. Our baseline system is similar to the system described in (Ittycheriah and Roukos, 2007). We report results on NIST MT05 and NIST MT06 evaluations test sets using BLEU and TER as automatic evaluation metrics.

To train the DDTM model, we use the incremental parser introduced in (Hassan et al., 2008b; Hassan et al., 2009) to parse the target side of the parallel training data. Each sentence is associated with supertag, operator and parse-state sequences. We then train models with different feature sets.

Results: We compared the baseline DTM2 (Ittycheriah and Roukos, 2007) with our DDTM system with the features listed above. We examine the effect of all features on system performance. In this set of experiments we used LDC parallel data only which is composed of 3.7M sentences and the results are reported on MT05 test set. Each of the examined systems deploys DTM2 features in addition to a number of newly added syntactic features. The systems examined are:

- DTM2: Direct Translation model 2 baseline.
- D-SW: DTM2 + Supertag-Word features.
- D-SLM: DTM2 + Supertag-Word and supertag *n*-gram features.
- D-SO: DTM2+ Supertag-Operator features.
- D-SS : DTM2 + supertags and states features with parse-state construction.
- D-WS : DTM2 + words and states features with parse-state construction.
- D-STLM: DTM2 + state *n*-gram features with parse-state construction.
- DDTM: fully fledged system with all features that proved useful above which are: Supertag-Word features, supertag *n*-gram

features, supertags and states features and state *n*-gram features .

System	BLEU Score on MT05
DTM2-Baseline	52.24
D-SW	52.28
D-SLM	52.29
D-SO	52.01
D-SS	52.39
D-WS	52.03
D-STLM	52.53
DDTM	**52.61**

Table 1: DDTM Results with various features.

As shown in Table 1, the DTM baseline system demonstrates a very high BLEU score, unsurprisingly given its top-ranked performance in two recent major MT evaluation campaigns. Among the features we tried, supertags and *n*-gram supertags systems (D-SW and D-SLM systems) give slight yet statistically insignificant improvements. On the other hand, the states *n*-gram sequence features (D-SS and DDTM systems) give small yet statistically significant improvements (as calculated via bootstrap resampling (Koehn, 2004b)). The D-WS system shows a small degradation in performance, probably due to the fact that the states-words interactions are quite sparse and could not be estimated with good evidence. Similarly, the D-SO system shows a small degradation in performance. When we investigated the features types, we found out that all features that deploy the operators had bad effect on the model. We think this is due to the fact that the operator set is a small set with high evidence in many training instances such that it has low discriminative power on it is own. However, it implicitly helps in producing the state sequence which proved useful.

System	DTM2-Baseline	DDTM
MT05 (BLEU)	55.28	55.66
MT05 (*TER*)	38.79	38.48
MT06 (BLEU)	43.56	43.91
MT06 (*TER*)	49.08	48.65

Table 2: DDTM Results on MT05 and MT06.

We examined a combination of the best features in our DDTM system on a larger training data comprising 7.8M sentences from both NIST and GALE parallel corpora. Table 2 shows the results on both MT05 and MT06 test sets. As shown, DDTM significantly outperforms the state-of-the-art baseline system. It is worth noting that DDTM outperforms this baseline even when very large amounts of training data are used. Despite the fact that the actual scores are not so different, we found that the baseline translation output and the DDTM translation outout are significantly different. We measured this by calculating the TER between the baseline translation and the DDTM translation for the MT05 test set, and found this to be 25.9%. This large difference has not been realized by the BLEU or TER scores in comparison to the baseline. We believe that this is due to the fact that most changes that match the syntactic constraints do not bring about the best match where the automatic evaluation metrics are concerned. Accordingly, in the next section we describe the outcome of a detailed manual analysis of the output translations.

7 Manual Analysis of Results

Although the BLEU score does not mark a large improvement by the dependency-based system over the baseline system, human inspection of the data gives us important insights into the pros and cons of the dependency-based model. We analyzed a randomly selected set of 100 sentences from the MT05 test set. In this sample, the baseline and the DDTM system perform similarly in 68% of the sentences. The outputs of both system are similar though not identical. In these cases, the systems may choose equivalent paraphrases. However, the translations using syntactic structures are rather similar. It is worth noting that the DDTM system tends to produce more concise syntactic structures which may lead to less BLUE score due to penalizing the translation length although the translation might be equivelent to the baseline if not better.

In 28% of the sentences, the DDTM system produces remarkably better translations. The examples here illustrate the behaviour of the baseline and the DDTM systems which can be observed consistently throughout the test set. We only highlight some of the examples for illustration purposes. DDTM manages to insert verbs which are deleted by any standard phrase-based SMT system. DDTM prefers to deploy verbs since they have complex and more detailed syntactic structures which give better and more likely state se-

quences. Furthermore, the DDTM system avoids longer noun phrases and instead uses some prepositions in-between. Again, this is probably due to the fact that like verbs, prepositions have a complex syntactic description that give rise to more likely state sequences.

On the other hand, the baseline produced better translation in 8% of the analysis sample. We observed that the baseline is doing better mainly in two cases. The first when the produced translation is very poor and producing poor sysntatctic structure due to out of vocabularies or hard to translate sentences. The second case is with sentences with long noun phrases, in such cases the DDTM system prefres to introduce verbs or prepositions in the middle of long noun phrase and thus the baseline would produce better translations. This is maybe due to the fact that noun phrases have relatively simple structure in CCG such that it did not help in constructing long noun phrases.

Source: وخضع بعد ذلك لفحوصات اجراهَا احد اطباء الشرطة
Reference: *He then underwent medical examinations by a police doctor .*
Baseline: *He was subjected after that tests conducted by doctors of the police .*
DDTM: *Then he underwent tests conducted by doctors of the police .*

Source: وقد هز الرياض مساء اليوم هجومان بسيارتين مفخـختين
Reference: *Riyadh was rocked tonight by two car bomb attacks..*
Baseline: *Riyadh rocked today night attacks by two booby - trapped cars.*
DDTM: *Attacks rocked Riyadh today evening in two car bombs.*

Figure 3: DDTM provides better syntactic structure with more concise translations.

Figure 3 shows two examples where DDTM provides better and more concise syntactic structure. As we can see, there is not much agreement between the reference and the proposed translation. However, longer translations enhance the possibility of picking more common *n*-gram matches via the BLEU score and so increases the chance of better scores. This well-known bias does not favour the more concise output derived by our DDTM system, of course.

8 Conclusion and Future Work

In this paper, we presented a novel model of dependency phrase-based SMT which integrates incremental dependency parsing into the translation model while retaining the linear decoding assumed in conventional Phrase–based SMT systems. To the best of our knowledge, this model constitutes the first effective attempt at integrating a linear-time dependency parser that builds a connected tree incrementally into SMT systems with linear-time decoding. Crucially, it turns out that incremental dependency parsing based on lexicalized grammars such as CCG and LTAG can provide valuable incremental parsing information to the decoder even if their output is imperfect. We believe this robustness in the face of imperfect parser output to be a property of the probabilistic formulation and statistical estimation used in the Direct Translation Model. A noteworthy aspect of our proposed approach is that it integrates features from the derivation process as well as the derived tree. We think that this is possible due to the importance of the notion of a derivation in linguistic frameworks such as CCG and LTAG.

Future work will attempt further extensions of our DDTM system to allow for the exploitation of long-range aspects of the dependency structure. We will work on expanding the features set of DDTM system to leverage features from the constructed dependency structure itself. Finally, we will work on enabling the deployment of source side dependency structures to influence the construction of the target dependency structure based on a bilingually enabled dependency parsing mechanism using the discriminative modeling capabilities.

Acknowledgments

We would like to thank Salim Roukos, IBM TJ Watson Research Center, for fruitful, insightful discussions and for his support during this work. We also would like to thank Abe Ittycheriah, IBM TJ Watson Research Center, for providing the DTM2 baseline and for his support during developing this system. Finally, we would like to thank the anonymous reviewers for their helpful and constructive comments.

Cross-lingual Semantic Relatedness Using Encyclopedic Knowledge

Samer Hassan and **Rada Mihalcea**
Department of Computer Science
University of North Texas
samer@unt.edu, rada@cs.unt.edu

Abstract

In this paper, we address the task of cross-lingual semantic relatedness. We introduce a method that relies on the information extracted from Wikipedia, by exploiting the interlanguage links available between Wikipedia versions in multiple languages. Through experiments performed on several language pairs, we show that the method performs well, with a performance comparable to monolingual measures of relatedness.

1 Motivation

Given the accelerated growth of the number of multilingual documents on the Web and elsewhere, the need for effective multilingual and cross-lingual text processing techniques is becoming increasingly important. In this paper, we address the task of *cross-lingual semantic relatedness*, and introduce a method that relies on Wikipedia in order to calculate the relatedness of words across languages. For instance, given the word *factory* in English and the word *lavoratore* in Italian (En. *worker*), the method can measure the relatedness of these two words despite the fact that they belong to two different languages.

Measures of cross-language relatedness are useful for a large number of applications, including cross-language information retrieval (Nie et al., 1999; Monz and Dorr, 2005), cross-language text classification (Gliozzo and Strapparava, 2006), lexical choice in machine translation (Och and Ney, 2000; Bangalore et al., 2007), induction of translation lexicons (Schafer and Yarowsky, 2002), cross-language annotation and resource projections to a second language (Riloff et al., 2002; Hwa et al., 2002; Mohammad et al., 2007).

The method we propose is based on a measure of closeness between concept vectors automatically built from Wikipedia, which are mapped via the Wikipedia interlanguage links. Unlike previous methods for cross-language mapping, which are typically limited by the availability of bilingual dictionaries or parallel texts, the method proposed in this paper can be used to measure the relatedness of word pairs in any of the 250 languages for which a Wikipedia version exists.

The paper is organized as follows. We first provide a brief overview of Wikipedia, followed by a description of the method to build concept vectors based on this encyclopedic resource. We then show how these concept vectors can be mapped across languages for a cross-lingual measure of word relatedness. Through evaluations run on six language pairs, connecting English, Spanish, Arabic and Romanian, we show that the method is effective at capturing the cross-lingual relatedness of words, with results comparable to the monolingual measures of relatedness.

2 Wikipedia

Wikipedia is a free online encyclopedia, representing the outcome of a continuous collaborative effort of a large number of volunteer contributors. Virtually any Internet user can create or edit a Wikipedia webpage, and this "freedom of contribution" has a positive impact on both the quantity (fast-growing number of articles) and the quality (potential errors are quickly corrected within the collaborative environment) of this online resource.

The basic entry in Wikipedia is an *article* (or *page*), which defines and describes an entity or an event, and consists of a hypertext document with hyperlinks to other pages within or outside Wikipedia. The role of the hyperlinks is to guide the reader to pages that provide additional information about the entities or events mentioned in an article. Articles are organized into *categories*, which in turn are organized into hierarchies. For instance, the article *automobile* is included in the category *vehicle*, which in turn has a parent cate-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1192–1201,
Singapore, 6-7 August 2009.

Language	Articles	Users
English	2,221,980	8,944,947
German	864,049	700,980
French	765,350	546,009
Polish	579,170	251,608
Japanese	562,295	284,031
Italian	540,725	354,347
Dutch	519,334	216,938
Portuguese	458,967	503,854
Spanish	444,696	966,134
Russian	359,677	226,602

Table 1: Top ten largest Wikipedias

gory named *machine*, and so forth.

Each article in Wikipedia is uniquely referenced by an identifier, consisting of one or more words separated by spaces or underscores and occasionally a parenthetical explanation. For example, the article for *bar* with the meaning of *"counter for drinks"* has the unique identifier *bar (counter)*.

Wikipedia editions are available for more than 250 languages, with a number of entries varying from a few pages to two millions articles or more per language. Table 1 shows the ten largest Wikipedias (as of December 2008), along with the number of articles and approximate number of contributors.[1]

Relevant for the work described in this paper are the *interlanguage links*, which explicitly connect articles in different languages. For instance, the English article for *bar (unit)* is connected, among others, to the Italian article *bar (unitá di misura)* and the Polish article *bar (jednostka)*. On average, about half of the articles in a Wikipedia version include interlanguage links to articles in other languages. The number of interlanguage links per article varies from an average of five in the English Wikipedia, to ten in the Spanish Wikipedia, and as many as 23 in the Arabic Wikipedia.

3 Concept Vector Representations using Explicit Semantic Analysis

To calculate the cross-lingual relatedness of two words, we measure the closeness of their concept vector representations, which are built from Wikipedia using explicit semantic analysis (ESA).

Encyclopedic knowledge is typically organized into concepts (or topics), each concept being further described using definitions, examples, and possibly links to other concepts. ESA (Gabrilovich and Markovitch, 2007) relies on the distribution of words inside the encyclopedic descriptions, and builds semantic representations for a given word in the form of a vector of the encyclopedic concepts in which the word appears. In this vector representation, each encyclopedic concept is assigned with a weight, calculated as the term frequency of the given word inside the concept's article.

Formally, let C be the set of all the Wikipedia concepts, and let a be any content word. We define $\vec{a}$ as the ESA concept vector of term a:

$$\vec{a} = \{w_{c_1}, w_{c_2} ... w_{c_n}\}, \quad (1)$$

where w_{c_i} is the weight of the concept c_i with respect to a. ESA assumes the weight w_{c_i} to be the term frequency tf_i of the word a in the article corresponding to concept c_i.

We use a revised version of the ESA algorithm. The original ESA semantic relatedness between the words in a given word pair $a - b$ is defined as the cosine similarity between their corresponding vectors:

$$Relatedness(a, b) = \frac{\vec{a} \cdot \vec{b}}{\|\vec{a}\| \left\|\vec{b}\right\|}. \quad (2)$$

To illustrate, consider for example the construction of the ESA concept vector for the word *bird*. The top ten concepts containing this word, along with the associated weight (calculated using equation 7), are listed in table 2. Note that the the ESA vector considers all the possible senses of *bird*, including *Bird* as a surname as in e.g., *"Larry Bird."*

Weight	Wikipedia concept
51.4	Lists Of Birds By Region
44.8	Bird
40.3	British Birds Rarities Committee
32.8	Origin Of Birds
31.5	Ornithology
30.1	List Of Years In Birding And Ornithology
29.8	Bird Vocalization
27.4	Global Spread Of H5n1 In 2006
26.5	Larry Bird
22.3	Birdwatching

Table 2: Top ten Wikipedia concepts for the word "bird"

In our ESA implementation, we make three changes with respect to the original ESA algorithm. First, we replace the cosine similarity with

[1] http://meta.wikimedia.org/wiki/List_of_Wikipedias#Grand_Total

a Lesk-like metric (Lesk, 1986), which places less emphasis on the distributional differences between the vector weights and more emphasis on the overlap (mutual coverage) between the vector features, and thus it is likely to be more appropriate for the sparse ESA vectors, and for the possible asymmetry between languages. Let a and b be two terms with the corresponding ESA concept vectors $\vec{A}$ and $\vec{B}$ respectively. Let A and B represent the sets of concepts with a non-zero weight encountered in $\vec{A}$ and $\vec{B}$ respectively. The coverage of $\vec{A}$ by $\vec{B}$ is defined as:

$$G(\vec{B}|\vec{A}) = \sum_{i \in B} w_{a_i} \quad (3)$$

and similarly, the coverage of $\vec{B}$ by $\vec{A}$ is:

$$G(\vec{A}|\vec{B}) = \sum_{i \in A} w_{b_i} \quad (4)$$

where wa_i and wb_i represent the weight associated with concept c_i in vectors $\vec{A}$ and $\vec{B}$ respectively. By averaging these two asymmetric scores, we redefine the relatedness as:

$$Relatedness(a,b) = \frac{G(\vec{B}|\vec{A}) + G(\vec{A}|\vec{B})}{2} \quad (5)$$

Second, we refine the ESA weighting schema to account for the length of the articles describing the concept. Since some concepts have lengthy descriptions, they may be favored due to their high term frequencies when compared to more compact descriptions. To eliminate this bias, we calculate the weight associated with a concept c_i as follows:

$$w_{c_i} = tf_i \times log(M/\,|c_i|), \quad (6)$$

where tf_i represents the term frequency of the word a in concept c_i, M is a constant representing the maximum vocabulary size of Wikipedia concepts, and $|c_i|$ is the size of the vocabulary used in the description of concept c_i.

Finally, we use the Wikipedia category graph to promote category-type concepts in our feature vectors. This is done by scaling the concept's weight by the inverse of the distance d_i to the root category. The concepts that are not categories are treated as leaves, and therefore their weight is scaled down by the inverse of the maximum depth in the category graph. The resulting weighting scheme is:

$$w_{c_i} = tf_i \times log(M/\,|c_i|)/d_i \quad (7)$$

4 Cross-lingual Relatedness

We measure the relatedness of concepts in different languages by using their ESA concept vector representations in their own languages, along with the Wikipedia interlanguage links that connect articles written in a given language to their corresponding Wikipedia articles in other languages. For example, the English Wikipedia article *moon* contains interlanguage links to قمر in the Arabic Wikipedia, *luna* in the Spanish Wikipedia, and *lună* in the Romanian Wikipedia. The interlanguage links can map concepts across languages, and correspondingly map concept vector representations in different languages.

Formally, let C_x and C_y be the sets of all Wikipedia concepts in languages x and y, with corresponding translations in the y and x languages, respectively. If $tr_{xy}()$ is a translation function that maps a concept $c_i \in C_x$ into the concept $c_i^{'} \in C_y$ via the interlanguage links, we can write:

$$tr_{xy}(c_i) = c_i^{'}, \quad (8)$$

The projection of the ESA vector $\vec{t}$ from language x onto y can be written as:

$$tr_{xy}(\vec{t}) = \left\{ w_{tr_{xy}(c_1)} ... w_{tr_{xy}(c_n)} \right\}. \quad (9)$$

Using equations 5, 7, and 9, we can calculate the cross-lingual semantic relatedness between any two content terms a_x and b_y in given languages x and y as:

$$sim(a_x, b_y) = \frac{G(tr_{yx}(\vec{B})|\vec{A}) + G(\vec{A}|tr_{yx}(\vec{B}))}{2}. \quad (10)$$

Note that the weights assigned to Wikipedia concepts inside the concept vectors are language specific. That is, two Wikipedia concepts from different languages, mapped via an interlanguage link, can, and often do have different weights.

Intuitively, the relation described by the interlanguage links should be reflective and transitive. However, due to Wikipedia's editorial policy, which accredits users with the responsibility

of maintaining the articles, these properties are not always met. Table 3 shows real cases where the transitive and the reflective properties fail due to missing interlanguage links.

Relation	Exists
Reflectivity	
Kafr-El-Dawwar Battle(en) ↦ معركة كفر الدوّار(ar)	Yes
معركة كفر الدوّار(ar) ↦ Kafr-El-Dawwar Battle(en)	No
Transitivity	
Intifada(en) ↦ Intifada(es)	Yes
Intifada(es) ↦ انتفَاضة(ar)	Yes
Intifada(en) ↦ انتفَاضة(ar)	No

Table 3: Reflectivity and transitivity in Wikipedia

We solve this problem by iterating over the translation tables and extracting all the missing links by enforcing the reflectivity and the transitivity properties. Table 4 shows the initial number of interlanguage links and the discovered links for the four languages used in our experiments. The table also shows the coverage of the interlanguage links, measured as the ratio between the total number of interlanguage links (initial plus discovered) originating in the source language towards the target language, divided by the total number of articles in the source language.

	Interlanguage links		
Language pair	Initial	Discov.	Cover.
English → Spanish	293,957	12,659	0.14
English → Romanian	86,719	4,641	0.04
English → Arabic	56,233	3,916	0.03
Spanish → English	294,266	7,328	0.58
Spanish → Romanian	39,830	3,281	0.08
Spanish → Arabic	33,889	3,319	0.07
Romanian → English	75,685	6,783	0.46
Romanian → Spanish	36,002	3,546	0.22
Romanian → Arabic	15,777	1,698	0.10
Arabic → English	46,072	3,170	0.33
Arabic → Spanish	28,142	3,109	0.21
Arabic → Romanian	15,965	1,970	0.12

Table 4: Interlanguage links (initial and discovered) and their coverage in Wikipedia versions in four languages.

5 Experiments and Evaluations

We run our experiments on four languages: English, Spanish, Romanian and Arabic. For each of these languages, we use a Wikipedia download from October 2008. The articles were preprocessed using Wikipedia Miner (Milne, 2007) to extract structural information such as generality, and interlanguage links. Furthermore, articles were also processed to remove numerical content, as well as any characters not included in the given language's alphabet. The content words are stemmed, and words shorter than three characters are removed (a heuristic which we use as an approximation for stopword removal). Table 5 shows the number of articles in each Wikipedia version and the size of their vocabularies, as obtained after the pre-processing step.

	Articles	Vocabulary
English	2,221,980	1,231,609
Spanish	520,154	406,134
Arabic	149,340	216,317
Romanian	179,440	623,358

Table 5: Number of articles and size of vocabulary for the four Wikipedia versions

After pre-processing, the articles are indexed to generate the ESA concept vectors. From each Wikipedia version, we also extract other features including article titles, interlanguage links, and Wikipedia category graphs. The interlanguage links are further processed to recover any missing links, as described in the previous section.

5.1 Data

For the evaluation, we build several cross-lingual datasets based on the standard Miller-Charles (Miller and Charles, 1998) and WordSimilarity-353 (Finkelstein et al., 2001) English word relatedness datasets.

The Miller-Charles dataset (Miller and Charles, 1998) consists of 30-word pairs ranging from synonymy pairs (e.g., *car - automobile*) to completely unrelated terms (e.g., *noon - string*). The relatedness of each word pair was rated by 38 human subjects, using a scale from 0 (not-related) to 4 (perfect synonymy). The dataset is available only in English and has been widely used in previous semantic relatedness evaluations (e.g., (Resnik, 1995; Hughes and Ramage, 2007; Zesch et al., 2008)).

The WordSimilarity-353 dataset (also known as Finkelstein-353) (Finkelstein et al., 2001) consists of 353 word pairs annotated by 13 human experts, on a scale from 0 (unrelated) to 10 (very closely related or identical). The Miller-Charles set is a subset in the WordSimilarity-353 data set. Unlike the Miller-Charles data set, which consists only of

	Word pair		
English	coast - shore	car - automobile	brother - monk
Spanish	costa - orilla	coche - automovil	hermano - monje
Arabic	شَاطيء - سَاحل	عربه - سيَارة	رَاهب - شقيق
Romanian	ţărm - mal	maşfină - automobil	frate - călugăr

Table 6: Word pair translation examples

single words, the WordSimilarity-353 set also features phrases (e.g., *"Wednesday news"*), therefore posing an additional degree of difficulty for a relatedness metric applied on this data.

Native speakers of Spanish, Romanian and Arabic, who were also highly proficient in English, were asked to translate the words in the two data sets. The annotators were provided one word pair at a time, and asked to provide the appropriate translation for each word while taking into account their relatedness within the word pair. The relatedness was meant as a hint to disambiguate the words, when multiple translations were possible.

The annotators were also instructed not to use multi-word expressions in their translations. They were also allowed to use replacement words to overcome slang or culturally-biased terms. For example, in the case of the word pair *dollar-buck*, annotators were allowed to use دينَار[2] as a translation for *buck*.

To test the ability of the bilingual judges to provide correct translations by using this annotation setting, we carried out the following experiment. We collected Spanish translations from five different human judges, which were then merged into a single selection based on the annotators' translation agreement; the merge was done by a sixth human judge, who also played the role of adjudicator when no agreement was reached between the initial annotators.

Subsequently, five additional human experts rescored the word-pair Spanish translations by using the same scale that was used in the construction of the English data set. The correlation between the relatedness scores assigned during this experiment and the scores assigned in the original English experiment was 0.86, indicating that the translations provided by the bilingual judges were correct and preserved the word relatedness.

For the translations provided by the five human judges, in more than 74% of the cases at least three human judges agreed on the same translation for a word pair. When the judges did not provide identical translations, they typically used a close synonym. The high agreement between their translations indicates that the annotation setting was effective in pinpointing the correct translation for each word, even in the case of ambiguous words.

Motivated by the validation of the annotation setting obtained for Spanish, we used only one human annotator to collect the translations for Arabic and Romanian. Table 6 shows examples of translations in the three languages for three word pairs from our data sets.

Using these translations, we create six cross-lingual data sets, one for each possible language pair (English-Spanish, English-Arabic, English-Romanian, Spanish-Arabic, Spanish-Romanian, Arabic-Romanian). Given a source-target language pair, a data set is created by first using the source language for the first word and the target language for the second word, and then reversing the order, i.e., using the source language for the second word and the target language for the first word. The size of the data sets is thus doubled in this way (e.g., the 30 word pairs in the English Miller-Charles set are transformed into 60 word pairs in the English-Spanish Miller-Charles set).

5.2 Results

We evaluate the cross-lingual measure of relatedness on each of the six language pairs. For comparison purposes, we also evaluate the monolingual relatedness on the four languages.

For the evaluation, we use the Pearson (r) and Spearman (ρ) correlation coefficients, which are the standard metrics used in the past for the evaluation of semantic relatedness (Finkelstein et

[2] Arabic for dinars – the commonly used currency in the Middle East.

al., 2001; Zesch et al., 2008; Gabrilovich and Markovitch, 2007). While the Pearson correlation is highly dependent on the linear relationship between the distributions in question, Spearman mainly emphasizes the ability of the distributions to maintain their relative ranking.

Tables 7 and 8 show the results of the evaluations of the cross-lingual relatedness, when using an ESA concept vector with a size of maximum 10,000 concepts.[3]

	English	Spanish	Arabic	Romanian
Miller-Charles				
English	0.58	0.43	0.32	0.50
Spanish		0.44	0.20	0.38
Arabic			0.36	0.32
Romanian				0.58
WordSimilarity-353				
English	0.55	0.32	0.31	0.29
Spanish		0.45	0.32	0.28
Arabic			0.28	0.25
Romanian				0.30

Table 7: Pearson correlation for cross-lingual relatedness on the Miller-Charles and WordSimilarity-353 data sets

	English	Spanish	Arabic	Romanian
Miller-Charles				
English	0.75	0.56	0.27	0.55
Spanish		0.64	0.17	0.32
Arabic			0.33	0.21
Romanian				0.61
WordSimilarity-353				
English	0.71	0.55	0.35	0.38
Spanish		0.50	0.29	0.30
Arabic			0.26	0.20
Romanian				0.28

Table 8: Spearman correlation for cross-lingual relatedness on the Miller-Charles and WordSimilarity-353 data sets

As a validation of our ESA implementation, we compared the results obtained for the monolingual English relatedness with other results reported in the past for the same data sets. Gabrilovich and Markovitch (2007) reported a Spearman correlation of 0.72 for the Miller-Charles data set and 0.75 for the WordSimilarity-353 data set, respectively. Zesch et al. (2008) reported a Spearman correlation of 0.67 for the Miller-Charles set. These values are comparable to the Spearman correlation scores obtained in our experiments for the English data sets (see Table 8), with a fairly large improvement obtained on the Miller-Charles data set when using our implementation.

6 Discussion

Overall, our method succeeds in capturing the cross-lingual semantic relatedness between words. As a point of comparison, one can use the monolingual measures of relatedness as reflected by the diagonals in Tables 7 and 8.

Looking at the monolingual evaluations, the results seem to be correlated with the Wikipedia size for the corresponding language, with the English measure scoring the highest. These results are not surprising, given the direct relation between the Wikipedia size and the sparseness of the ESA concept vectors. A similar trend is observed for the cross-lingual relatedness, with higher results obtained for the languages with large Wikipedia versions (e.g., English-Spanish), and lower results for the languages with a smaller size Wikipedia (e.g., Arabic-Spanish).

For comparison, we ran two additional experiments. In the first experiment, we compared the coverage of our cross-lingual relatedness method to a direct use of the translation links available in Wikipedia. The cross-lingual relatedness is turned into a monolingual relatedness by using the interlanguage Wikipedia links to translate the first of the two words in a cross-lingual pair into the language of the second word in the pair.[4] From the total of 433 word pairs available in the two data sets, this method can produce translations for an average of 103 word pairs per language pair. This means that the direct Wikipedia interlanguage links allow the cross-lingual relatedness measure to be transformed into a monolingual relatedness in about 24% of the cases, which is a low coverage compared to the full coverage that can be obtained with our cross-lingual method of relatedness.

In an attempt to raise the coverage of the translation, we ran a second experiment where we used a state-of-the-art translation engine to translate the first word in a pair into the language of the sec-

[3]The concepts are selected in reversed order of their weight inside the vector in the respective language. Note that the cross-lingual mapping between the concepts in the ESA vectors is done after the selection of the top 10,000 concepts in each language.

[4]We use all the interlanguage links obtained by combining the initial and the discovered links, as described in Section 4.

ond word in the pair. We use Google Translate, which is a statistical machine translation engine that relies on large parallel corpora, to find the most likely translation for a given word. Unlike the previous experiment, this time we can achieve full translation coverage, and thus we are able to produce data sets of equal size that can be used for a comparison between relatedness measures. Specifically, using the translation produced by the machine translation engine for the first word in a pair, we calculate the relatedness within the space of the language of the second word using a monolingual ESA also based on Wikipedia. The results obtained with this method are compared against the results obtained with our cross-lingual ESA relatedness.

Using a Pearson correlation, our cross-lingual relatedness method achieves an average score across all six language pairs of 0.36 for the Miller-Charles data set and 0.30 for the WordSimilarity-353 data set,[5] which is higher than the 0.33 and 0.28 scores achieved for the same data sets when using a translation obtained with Google Translate followed by a monolingual measure of relatedness. These results are encouraging, also given that the translation-based method is limited to those language pairs for which a translation engine exists (e.g., Google Translate covers 40 languages), whereas our method can be applied to any language pair from the set of 250 languages for which a Wikipedia version exists.

To gain further insights, we also determined the impact of the vector length in the ESA concept vector representation, by calculating the Pearson correlation for vectors of different lengths. Figures 1 and 2 show the Pearson score as a function of the vector length for the Miller-Charles and WordSimilarity-353 data sets. The plots show that the cross-lingual measure of relatedness is not significantly affected by the reduction or increase of the vector length. Thus, the use of vectors of length 10,000 (as used in most of our experiments) appears as a reasonable tradeoff between accuracy and performance.

Furthermore, by comparing the performance of the proposed Lesk-like model to the traditional cosine-similarity (Figures 3 and 4), we note that the Lesk-like model outperforms the cosine model on most language pairs. We believe that this is due to the stricter correlation conditions imposed by the cosine-metric in such sparse vector-based representations, as compared to the more relaxed hypothesis used by the Lesk model.

[5]This average considers all the cross-lingual relatedness scores listed in Table 7; it does not include the monolingual scores listed on the table diagonal.

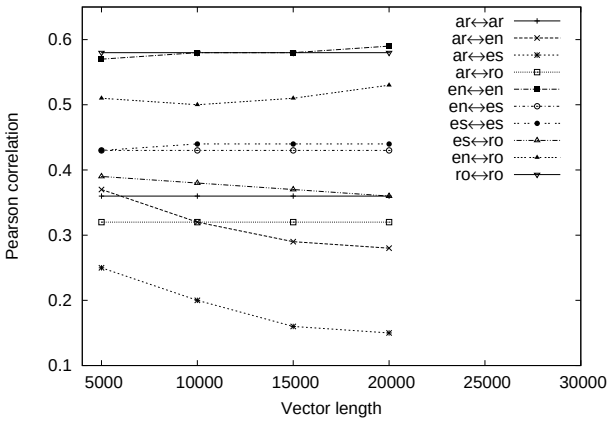

Figure 1: Pearson correlation vs. ESA vector length on the Miller-Charles data set

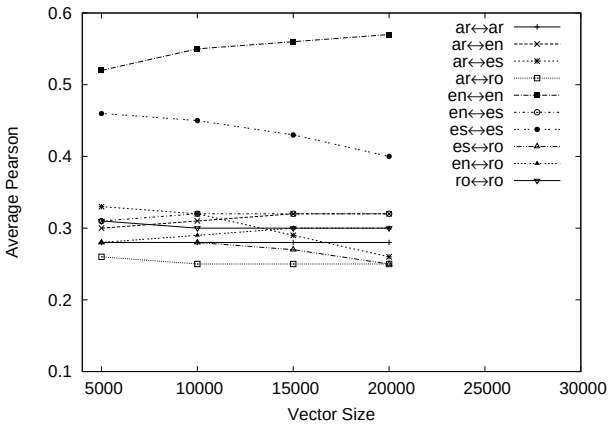

Figure 2: Pearson correlation vs. ESA vector length on the WordSimilarity-353 data set

Finally, we also looked at the relation between the number of interlanguage links found for the concepts in a vector and the length of the vector. Figures 5 and 6 display the average number of interlanguage links as a function of the concept vector length.

By analyzing the effect of the average number of interlanguage links found per word in the given datasets (Figures 5 and 6), we notice that these links increase proportionally with the vector size, as expected. However, this increase does not lead to any significant improvements in accuracy (Figures 1 and 2). This implies that while the presence of interlanguage links is a prerequisite for the mea-

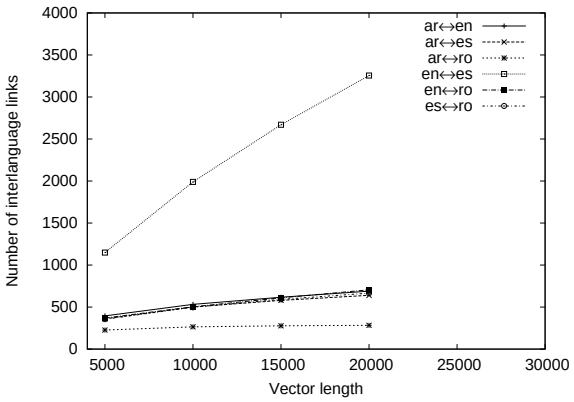

Figure 6: Number of interlanguage links vs. vector length for the WordSimilarity-353 data set

sure of relatedness,[6] their effect is only significant for the top ranked concepts in a vector. Therefore, increasing the vectors size to maximize the matching of the projected dimensions does not necessarily lead to accuracy improvements.

7 Related Work

Measures of word relatedness were found useful in a large number of natural language processing applications, including word sense disambiguation (Patwardhan et al., 2003), synonym identification (Turney, 2001), automated essay scoring (Foltz et al., 1999), malapropism detection (Budanitsky and Hirst, 2001), coreference resolution (Strube and Ponzetto, 2006), and others. Most of the work to date has focused on measures of word relatedness for English, by using methods applied on knowledge bases (Lesk, 1986; Wu and Palmer, 1994; Resnik, 1995; Jiang and Conrath, 1997; Hughes and Ramage, 2007) or on large corpora (Salton et al., 1997; Landauer et al., 1998; Turney, 2001; Gabrilovich and Markovitch, 2007).

Although to a lesser extent, measures of word relatedness have also been applied on other languages, including German (Zesch et al., 2007; Zesch et al., 2008; Mohammad et al., 2007), Chinese (Wang et al., 2008), Dutch (Heylen et al., 2008) and others. Moreover, assuming resources similar to those available for English, e.g., WordNet structures or large corpora, the measures of relatedness developed for English can be in principle applied to other languages as well.

All these methods proposed in the past have been concerned with *monolingual* word relatedness calculated within the boundaries of one language, as opposed to *cross-lingual* relatedness, which is the focus of our work.

The research area closest to the task of cross-

[6] Two languages with no interlanguage links between them will lead to a relatedness score of zero for any word pair across these languages, no matter how strongly related the words are.

lingual relatedness is perhaps cross-language information retrieval, which is concerned with matching queries posed in one language to document collections in a second language. Note however that most of the approaches to date for cross-language information retrieval have been based on direct translations obtained for words in the query or in the documents, by using bilingual dictionaries (Monz and Dorr, 2005) or parallel corpora (Nie et al., 1999). Such explicit translations can identify a direct correspondence between words in two languages (e.g., they will find that *fabbrica* (It.) and *factory* (En.) are translations of each other), but will not capture similarities of a different degree (e.g., they will not find that *lavoratore* (It.; worker in En.) is similar to *factory* (En.).

Also related are the areas of word alignment for machine translation (Och and Ney, 2000), induction of translation lexicons (Schafer and Yarowsky, 2002), and cross-language annotation projections to a second language (Riloff et al., 2002; Hwa et al., 2002; Mohammad et al., 2007). As with cross-language information retrieval, these areas have primarily considered direct translations between words, rather than an entire spectrum of relatedness, as we do in our work.

8 Conclusions

In this paper, we addressed the problem of cross-lingual semantic relatedness, which is a core task for a number of applications, including cross-language information retrieval, cross-language text classification, lexical choice for machine translation, cross-language projections of resources and annotations, and others.

We introduced a method based on concept vectors built from Wikipedia, which are mapped across the interlanguage links available between Wikipedia versions in multiple languages. Experiments performed on six language pairs, connecting English, Spanish, Arabic and Romanian, showed that the method is effective at capturing the cross-lingual relatedness of words. The method was shown to be competitive when compared to methods based on a translation using the direct Wikipedia links or using a statistical translation engine. Moreover, our method has wide applicability across languages, as it can be used for any language pair from the set of 250 languages for which a Wikipedia version exists.

The cross-lingual data sets introduced in this paper can be downloaded from http://lit.csci.unt.edu/index.php/Downloads.

Joint Optimization for Machine Translation System Combination

Abstract

System combination has emerged as a powerful method for machine translation (MT). This paper pursues a joint optimization strategy for combining outputs from multiple MT systems, where word alignment, ordering, and lexical selection decisions are made jointly according to a set of feature functions combined in a single log-linear model. The decoding algorithm is described in detail and a set of new features that support this joint decoding approach is proposed. The approach is evaluated in comparison to state-of-the-art confusion-network-based system combination methods using equivalent features and shown to outperform them significantly.

1 Introduction

System combination for machine translation (MT) has emerged as a powerful method of combining the strengths of multiple MT systems and achieving results which surpass those of each individual system (e.g. Bangalore, et. al., 2001, Matusov, et. al., 2006, Rosti, et. al., 2007a). Most state-of-the-art system combination methods are based on constructing a confusion network (CN) from several input translation hypotheses, and choosing the best output from the CN based on several scoring functions (e.g. Rosti et. al., 2007a, He et. al., 2008, Matusov et al. 2008). Confusion networks allow word-level system combination, which was shown to outperform sentence re-ranking methods and phrase-level combination (Rosti, et. al. 2007a).

We will review confusion-network-based system combination with the help of the examples in Figures 1 and 2. Figure 1 shows translation hypotheses from three Chinese-to-English MT systems. The general idea is to combine hypotheses in a representation such as the ones in Figure 2, where for each word position there is a set of possible words, shown in columns.[1] The final output is determined by choosing one word from each column, which can be a real word or the empty word ε. For example, the CN in Figure 2a) can generate eight distinct sequences of words, including e.g. "she bought the Jeep" and "she bought the SUV Jeep". The choice is performed to maximize a scoring function using a set of features and a log-linear model (Matusov, et. al 2006, Rosti, et al. 2007a).

We can view a confusion network as an ordered sequence of columns (*correspondence sets*). Each word from each input hypothesis belongs to exactly one correspondence set. Each correspondence set contains at most one word from each input hypothesis and contributes exactly one of its words (including the possible ε) to the final output. Final words are output in the order of correspondence sets. In order to construct such a representation, we need to solve the following two sub-problems: arrange words from all input hypotheses into correspondence sets (alignment problem) and order correspondence sets (ordering problem). After constructing the confusion network we need to solve a third sub-problem: decide which words to output from each correspondence set (lexical choice problem).

In current state-of-the-art approaches, the construction of the confusion network is performed as follows: first, a backbone hypothesis is selected. The backbone hypothesis determines the order of words in the final system output, and guides word-level alignments for construction of columns of possible words at each position. Let us assume that for our example in Figure 1, the second hypothesis is selected as a backbone. All other hypotheses are aligned to the backbone such that these alignments are one-to-one; empty words are inserted where necessary to make one-to-one

[1] This representation is alternative to directed acyclic graph representations of confusion networks.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1202–1211,
Singapore, 6-7 August 2009.

alignment possible. Words in all hypotheses are sorted by the position of the backbone word they align to and the confusion network is determined.

It is clear that the quality of selection of the backbone and alignments has a large impact on the performance, because the word order is determined by the backbone, and the set of possible words at each position is determined by alignment. Since the space of possible alignments is extremely large, approximate and heuristic techniques have been employed to derive them. In pair-wise alignment, each hypothesis is aligned to the backbone in turn, with separate processing to combine the multiple alignments. Several models have been used for pair-wise alignment, starting with TER and proceeding with more sophisticated techniques such as HMM models, ITG, and IHMM (Rosti et. al 2007a, Matusov et al 2008, Krakos et al. 2008, He et al. 2008). A major problem with such methods is that each hypothesis is aligned to the backbone independently, leading to sub-optimal behavior. For example, suppose that we use a state-of-the-art word alignment model for pairs of hypotheses, such as the IHMM. Figure 1 shows likely alignment links between every pair of hypotheses. If Hypothesis 1 is aligned to Hypothesis 2 (the backbone), *Jeep* is likely to align to *SUV* because they express similar Chinese content. Hypothesis 3 is separately aligned to the backbone and since the alignment is constrained to be one-to-one, *SUV* is aligned to *SUV* and *Jeep* to an empty word which is inserted after *SUV*. The network in Figure 2a) is the result of this process. An undesirable property of this CN is that the two instances of Jeep are placed in separate columns and cannot vote to reinforce each other.

Incremental alignment methods have been proposed to relax the independence assumption of pair-wise alignment (Rosti et al. 2008, Li et al. 2009). Such methods align hypotheses to a partially constructed CN in some order. For example, if in such method, Hypothesis 3 is first aligned to the backbone, followed by Hypothesis 1, we are likely to arrive at the CN in Figure 2b) in which the two instances of Jeep are aligned. However, if Hypothesis 1 is aligned to the backbone first, we would still get the CN in Figure 2a). Notice that the desirable output "*She bought the Jeep SUV*" cannot be generated from either of the confusion networks because a re-reordering of columns would be required.

A common characteristic of CN-based approaches is that the order of words (backbone) and the alignment of words (correspondence sets) are decided as greedy steps independently of the lexical choice for the final output. The backbone and alignment are optimized according to auxiliary scoring functions and heuristics which may or may not be optimal with respect to producing CNs leading to good translations. In some recent approaches, these assumptions are relaxed to allow each input hypothesis as a backbone. Each backbone produces a separate CN and the decision of which CN to choose is taken at a later decoding stage, but this still restricts the possible orders and alignments greatly (Rosti et al. 2008, Matusov et al. 2008).

In this paper, we present a joint optimization method for system combination. In this method, the alignment, ordering and lexical selection sub-problems are solved jointly in a single decoding framework based on a log-linear model.

2 Related Work

There has been a large body of work on MT system combination. Among confusion-network-based algorithms, most relevant to our work are state-of-the-art methods for constructing word alignments (correspondence sets) and methods for improving the selection of a backbone hypothesis. We have already reviewed such work in the introduction and will note relation to

specific models throughout the paper as we discuss specifics of our scoring functions.

In confusion network algorithms which use pair-wise (or incremental) word-level alignment algorithms for correspondence set construction, problems of converting many-to-many alignments and handling multiple insertions and deletions need to be addressed. Prior work has used a number of heuristics to deal with these problems (Matusov, et. al., 2006, He et al 08). Some work has made such decisions in a more principled fashion by computing model-based scores (Matusov et al. 2008), but still special-purpose algorithms and heuristics are needed and a single alignment is fixed.

In our approach, no heuristics are used to convert alignments and no concept of a backbone is used. Instead, the globally highest scoring combination of alignment, order, and lexical choice is selected (subject to search error).

Other than confusion-network-based algorithms, work most closely related to ours is the method of MT system combination proposed in (Jayaraman and Lavie 2005), which we will refer to as J&L. Like our method, this approach performs word-level system combination and is not limited to following the word order of a single backbone hypothesis; it also allows more flexibility in the selection of correspondence sets during decoding, compared to a confusion-network-based approach. Even though their algorithm and ours are broadly similar, there are several important differences.

Firstly, the J&L approach is based on pair-wise alignments between words in different hypotheses, which are hard and do not have associated probabilities. Every word in every hypothesis is aligned to at most one word from each of the remaining hypotheses. Thus there is no uncertainty about which words should belong to the correspondence set of an aligned word *w*, once that word is selected to extend a partial hypothesis during search. If words do not have corresponding matching words in some hypotheses, heuristic matching to currently unused words is attempted.

In contrast, our algorithm is based on the definition of a joint scoring model, which takes into account alignment uncertainty and combines information from word-level alignment models, ordering and lexical selection models, to address the three sub-problems of word-level system combination. In addition to the language model and word-voting features used by the J&L model, we incorporate features which measure alignment confidence via word-level alignment models and features which evaluate re-ordering via distortion models with respect to original hypotheses. While the J&L search algorithm incorporates a number of special-purpose heuristics to address phenomena of unused words lagging behind the last used words, the goal in our work is to minimize heuristics and perform search to jointly optimize the assignment of hidden variables (ordered correspondence sets) and observed output variables (words in final translations).

Finally, the J&L method has not been evaluated in comparison to confusion-network-based methods to study the impact of performing joint decoding for the three sub-problems.

3 Notation

Before elaborating the models and decoding algorithms, we first clarify the notation that will be used in the paper.

We denote by $\boldsymbol{H} = \{h_1, \ldots, h_N\}$ the set of hypotheses from multiple MT systems, where h_i is the hypothesis from the *i*-th system and h_i is a word sequence $w_{i,1}, \ldots, w_{i,L(i)}$ with length $L(i)$. For simplicity, we assume that each system contributes only its 1-best hypothesis for combination. Accordingly, the *i*-th hypothesis h_i will be associated with a weight $W(i)$ which is the weight of the *i*-th system. In the scenario that N-best lists are available from individual systems for combination, the weight of each hypothesis can be computed based on its rank in the N-best list (Rosti et. al. 2007a).

Like in CN-based system combination, we construct a set of ordered correspondence sets (CS) from input hypotheses, and select one word from each CS to form the final output. A CS is defined as a set of (possibly empty) words, one from each hypothesis, that implicitly align to each other and that contributes exactly one of its words to the final output. A valid complete set of CS includes each non-empty word from each hypothesis in exactly one CS. As opposed to CN-based algorithms, our ordered correspondence sets are constructed during a joint decoding process which performs lexical selection at the same time.

To facilitate the presentation of our features, we define notation for ordered CS. A sequence of correspondence sets is denoted by $C = CS_1, \ldots, CS_m$. Each correspondence set is specified by listing the positions of each of the words in the CS in their respective input

hypotheses. Each input hypothesis is assumed to have one special empty word ε at position 0. A CS is denoted by $CS(l_1, \dots, l_N) = \{w_{1,l_1}, \dots, w_{N,l_N}\}$, where w_{i,l_i} is the l_i-th word in the i-th hypothesis and the word position vector $v = [l_1, \dots, l_N]^T$ specifies the position of each word in its original hypothesis. Correspondingly, word w_{i,l_i} has the same weight $W(i)$ as its original hypothesis h_i. As an example, the last two correspondence sets specified by the CN in Figure 2a) would be specified as $CS_4 = CS(4,4,4) = \{Jeep, SUV, SUV\}$ and $CS_5 = CS(0,0,5) = \{\varepsilon, \varepsilon, Jeep\}$.

As opposed to the CS defined in a conventional CN, words that have the same surface form but come from different hypotheses are not collapsed to be one single candidate since they have different original word positions. We need to trace each of them separately during the decoding process.

4 A Joint Optimization Framework For System Combination

The joint decoding framework chooses optimal output according to the following log-linear model:

$$w^* = \underset{w \in \boldsymbol{W}, O \in \boldsymbol{O}, C \in \boldsymbol{C}}{\operatorname{argmax}} \; exp\left\{\sum_{i=1}^{F} \alpha_i \cdot f_i(w, O, C, \boldsymbol{H})\right\}$$

where we denote by $\boldsymbol{C}$ the set of all possible valid arrangements of CS, $\boldsymbol{O}$ the set of all possible orders of CS, $\boldsymbol{W}$ the set of all possible word sequences, consisting of words from the input hypotheses. $\{f_i(w, O, C, \boldsymbol{H})\}$ are the features and $\{\alpha_i\}$ are the feature weights in the log-linear model, respectively.

4.1 Features

A set of features are used in this framework. Each of them models one or more of the alignment, ordering, and lexical selection sub-problems. Features are defined as follows.

Word posterior model:

The word posterior feature is the same as the one proposed by Rosti et. al. (2007a). i.e.,

$$f_{wp}(w, O, C, \boldsymbol{H}) = \sum_{m=1}^{M} log\big(P(w_m | CS_m)\big)$$

where the posterior of a single word in a CS is computed based on a weighted voting score:

$$P\big(w_{i,l_i} | CS\big) = P\left(w_{i,l_i} \middle| CS(l_1, \dots, l_N)\right) = \sum_{k=1}^{N} W(k)\, \delta(w_{k,l_k} = w_{i,l_i})$$

and M is the number of CS generated. Note that M may be larger than the length of the output word sequence w since some CS may generate empty words.

Bi-gram voting model:

The second feature we used is a bi-gram voting feature proposed by Zhao and He (2009), i.e., for each bi-gram $\langle w_i, w_{i+1} \rangle$, a weighted position-independent voting score is computed:

$$P(\langle w_i, w_{i+1} \rangle | \boldsymbol{H}) = \sum_{k=1}^{N} W(k)\, \delta(\langle w_i, w_{i+1} \rangle \in h_i)$$

And the global bi-gram voting feature is defined as:

$$f_{bgv}(w, O, C, \boldsymbol{H}) = \sum_{i=1}^{|w|-1} log\big(P(\langle w_i, w_{i+1} \rangle | \boldsymbol{H})\big)$$

Distortion model:

Unlike in the conventional CN-based system combination, flexible orders of CS are allowed in this joint decoding framework. In order to model the distortion of different orderings, a distortion model between two CS is defined as follows:

First we define the distortion cost between two words at a single hypothesis. Similarly to the distortion penalty in the conventional phrase-based decoder (Koehn 2004b), the distortion cost of jumping from a word at position i to another word at position j, $d(i,j)$, is proportional to the distance between i and j, e.g., $|i-j|$. Then, the distortion cost of jumping from one CS, which has a position vector recording the original position of each word in that CS, to another CS is a weighted sum of single-hypothesis-based distortion costs:

$$d(CS_m, CS_{m+1}) = \sum_{k=1}^{N} W(k) \cdot |l_{m,k} - l_{m+1,k}|$$

where $l_{m,k}$ and $l_{m+1,k}$ are the k-th element of the word position vector of CS_m and CS_{m+1}, respectively. For the purpose of computing the distortion feature, the position of an empty word is taken to be the same as the position of

the last visited non-empty word from the same hypothesis.

The overall ordering feature can then be computed based on $d(CS_m, CS_{m+1})$:

$$f_{dis}(w, O, C, \boldsymbol{H}) = -\sum_{m=1}^{M-1} d(CS_m, CS_{m+1})$$

It is worth noting that this is not the only feature modeling the re-ordering behavior. Under the joint decoding framework, other features such as the language model and bi-gram voting affect the ordering as well.

Alignment model:

Each CS consists of a set of words, one from each hypothesis, that are implicitly aligned to each other. Therefore, a valid complete set of CS defines the word alignment among different hypotheses. In this paper, we derive an alignment score of a CS based on alignment scores of word pairs in that CS. To compute scores for word pairs, we perform pair-wise hypothesis alignment using the indirect HMM (He et al. 2008) for every pair of input hypotheses. Note that this involves a total of *N* by (*N*-1)/2 bi-directional hypothesis alignments. The alignment score for a pair of words w_{j,l_j} and w_{k,l_k} is defined as the average of posterior probabilities of alignment links in both directions and is thus direction independent:

$$p\left(w_{j,l_j}, w_{k,l_k}\right) = \frac{1}{2}\left(p(a_{l_j} = l_k | h_j, h_k) + p(a_{l_k} = l_j | h_k, h_j)\right)$$

If one of the two words is ε, the posterior of aligning word ε to state j is computed as suggested by Liang et al. (2006), i.e.,

$$p(a_0 = l_j | h_k, h_j) = \prod_{i=1}^{L(k)} \left(1 - p(a_i = l_j | h_k, h_j)\right)$$

And $p(a_{l_j} = 0 | h_j, h_k)$ can be computed by the HMM directly.

If both words are ε, then a pre-defined $p_{\varepsilon\varepsilon}$ is assigned, i.e., $p(a_0 = 0 | h_k, h_j) = p_{\varepsilon\varepsilon}$, where $p_{\varepsilon\varepsilon}$ can be optimized on a held-out validation set.

For a CS of words, if we set the *j*-th word as an anchor word, the probability that all other words align to that word is:

$$p(j|CS) = \prod_{\substack{k=1 \\ k \neq j}}^{N} p\left(w_{j,l_j}, w_{k,l_k}\right)$$

The alignment score of the whole CS is a weighted sum of the logarithm of the above alignment probabilities, i.e.,

$$S_{aln}(CS) = \sum_{j=1}^{N} W(j)\, log(P(j|CS))$$

and the global alignment score is computed as:

$$f_{aln}(w, O, C, \boldsymbol{H}) = \sum_{m=1}^{M} S_{aln}(CS_m)$$

Entropy model:

In general, it is preferable to align the same word from different hypotheses into a common CS. Therefore, we use entropy to model the purity of a CS. The entropy of a CS is defined as:

$$Ent(CS) = Ent(CS(l_1, \ldots, l_N)) = \sum_{i=1}^{N'} P(w_{i,l_i}|CS) logP(w_{i,l_i}|CS)$$

where the sum is taken over all distinct words in the CS. Then the global entropy score is computed as:

$$f_{ent}(w, O, C, \boldsymbol{H}) = \sum_{m=1}^{M} Ent(CS_m)$$

Other features used in our log-linear model include the count of real words |*w*|, a n-gram language model, and the count *M* of CS sets.

These features address one or more of the three sub-problems of MT system combination. By performing joint decoding with all these features working together, we hope to derive better decisions on alignment, ordering and lexical selection.

5 Joint Decoding

5.1 Core algorithm

Decoding is based on a beam search algorithm similar to that of the phrase-based MT decoder (Koehn 2004b). The input is a set of translation hypotheses to be combined, and the final output

sentence is generated left to right. Figure 3 illustrates the decoding process, using the example input hypotheses from Figure 1. Each decoding state represents a partial sequence of correspondence sets covering some of the words in the input hypotheses and a sequence of words selected from the CS to form a partial output hypothesis. The initial decoding state has an empty sequence of CS and an empty output sequence. A state corresponds to a complete output candidate if its CS covers all input words.

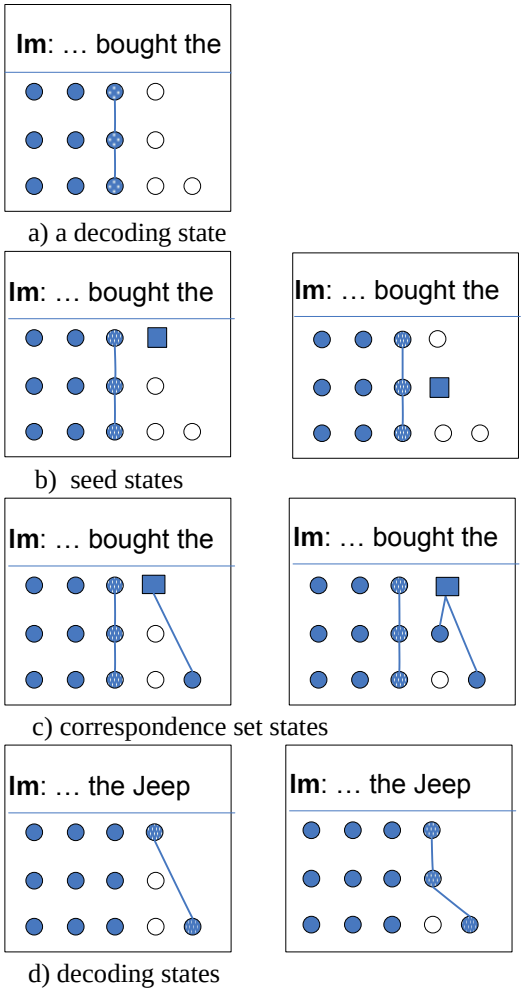

Figure 3. Illustration of the decoding process.

In practice, because the features over hypotheses can be decomposed, we do not need to encode all of this information in a decoding state. It suffices to store a few attributes. They include positions of words from each input hypothesis that have been visited, the last two non-empty words generated (if a tri-gram LM is used), and an "end position vector (EPV)" recording positions of words in the last CS, which were just visited. In the figure, the visited words are shown with filled circles and the EPV is shown with a dotted pattern in the filled circles. Words specified by the EPV are implicitly aligned. In the state in Figure 3 a) the first three words of each hypothesis have been visited, the third word of each hypothesis is the last word visited (in the EPV), and the last two words produced are "*bought the*". The states also record the decoding score accumulated so far and an estimated future score to cover words that have not been visited yet (not shown).

The expansion from one decoding state to a set of new decoding states is illustrated in Figure 3. The expansion is done in three steps with the help of intermediate states. Starting from a decoding state as shown in Figure 3a), first a set of "seed states" as shown in Figure 3b) are generated. Each seed state represents a choice of one of unvisited words, called a "seed word" which is selected and marked as visited. For example, the word *Jeep* from the first hypothesis and the word *SUV* from the second hypothesis are selected in the two seed states shown in Figure 3b), respectively. These seed states further expand into a set of "CS states" as shown in Figure 3c). I.e., a CS is formed by picking one word from each of the other hypotheses which is unvisited and has a valid alignment link to the seed word. Figure 3c) shows two CS states expanded from the first seed state of Figure 3b), using *Jeep* from the first hypothesis as a seed word. In one of them the empty word from the second hypothesis is chosen, and in the other, the word *SUV* is chosen. Both are allowed by the alignments illustrated in Figure 1. Finally, each CS state generates one or more complete decoding states, in which a word is chosen from the current CS and the EPV vector is advanced to reflect the last newly visited words. Figure 3d) shows two such states, descending from the corresponding CS states in 3c). After one more expansion the state in 3d) on the left can generate the translation "*She bought the Jeep SUV*", which cannot be produced by either confusion network in Figure 2.

5.2 Pruning

The full search space of joint decoding is a product of the alignment, ordering, and lexical selection spaces. Its size is exponential in the length of the sentence and the number of hypotheses involved in combination. Therefore, pruning techniques are necessary to reduce the search space.

First we will prune down the alignment space. Instead of allowing any alignment link between

arbitrary words of two hypotheses, only links that have alignment score higher than a threshold are allowed, plus links in the union of the Viterbi alignments in both directions. In order to prevent the garbage collection problem where many words align to a rare word at the other side (Moore, 2004), we further impose the limit that if one word is aligned to more than *T* words, these links are sorted by their alignment score and only the top *T* links are kept. Meanwhile, alignments between a real word and ε are always allowed.

We then prune down the ordering space by limiting the expansion of new states. Only states that are *adjacent* to their preceding states are created. Two states are called *adjacent* if their EPVs are adjacent, i.e., given the EPV of the preceding state m as $[l_{m,1}, \ldots, l_{m,N}]^T$ and the EPV of the next state m+1 as $[l_{m+1,1}, \ldots, l_{m+1,N}]^T$, if at least at one dimension k, $l_{m+1,k} = l_{m,k}+1$, then these two states are *adjacent*. When checking the adjacency of two states, the position of an empty word is taken to be the same as the position of the last visited non-empty word from the same hypothesis.

The number of possible CS states expanded from a decoding state is exponential in the number of hypotheses. In decoding, these CS states are sorted by their alignment scores and only the top *K* CS states are kept.

The search space can be further pruned down by the widely used technique of path recombination and by best-first pruning.

Path recombination is a risk-free pruning method. Two paths can be recombined if they agree on a) words from each hypothesis that have been visited so far, b) the last two real words generated, and c) their EPVs. In such case, we only need to keep the path with the higher score.

Best-first pruning can help to reduce the search space even further. In the decoding process we compare paths that have generated the same number of words (both real and empty words) and only keep a certain number of most promising paths. Pruning is based on an estimated overall score of each path, which is the sum of the decoding score accumulated so far and an estimated future score to cover the words that have not been visited. Next we discuss the future score computation.

5.3 Computing the future score

In order to estimate the future cost of an unfinished path, we treat the unvisited words of one input hypothesis as a backbone, and apply a greedy search for alignment based on it; i.e., for each word of this backbone, the most likely words (based on the alignment link scores) from other hypotheses, one word from each hypothesis, are collected to form a CS. These CS are ordered according to the word order of the backbone and form a CN. Then, a light decoding process with a search beam of size one is applied to decode this CN and find the approximate future path, with future feature scores computed during the decoding process. If there are leftover words not included in this CN, they are treated in the way described in section 5.4. Additionally, caching techniques are applied to speed up the computation of future scores further.

Given the method discussed above, we can estimate a future score based on each input hypothesis, and the final future score is estimated as the best of these hypothesis-dependent scores.

5.4 Dealing with leftover input words

At a certain point a path will reach the end, i.e., no more states can be generated from it according to the state expansion requirement. Then it is marked as a finished path. However, sometimes the state may contain a few input words that have not been visited. An example of this situation is the second state in Figure 3d). The word *SUV* in the third input hypothesis is left unvisited and it cannot be selected next because there is no adjacent state that can be generated. For such cases, we need to compute an extra score of covering these leftover words. Our approach is to create a state that produces the same output translation, but also covers all remaining words. For each leftover word, we create a pseudo CS that contains just that word plus ε's from all other hypotheses, and let it output ε. Moreover, that CS is inserted at a place such that no extra distortion cost is incurred. Figure 4 shows an example using the second state in Figure 3d). The last two words from the first two MT hypotheses "*the Jeep*" and "*the SUV*" align to the third and fifth words of the third hypothesis "*the Jeep*"; the word $w_{3,4}$ from the third hypothesis is left unvisited. The original path has two CS and one left-over word $w_{3,4}$. It is expanded to have three CS, with a pseudo CS inserted between the two CS.

It is worth noting that the new inserted pseudo CS will not affect the word count feature and contextually dependent feature scores such as the LM and bi-gram voting, since it only generates an empty word. Moreover, it will not affect the

distortion score either. For example, as shown in Figure 4, the distortion cost of jumping from word $w_{2,3}$ to ε_2 and then to $w_{2,4}$ is the same as the cost of jumping from $w_{2,3}$ to $w_{2,4}$ given the way we assign position to empty word and the fact that the distortion cost is proportional to the difference between word positions.

Scores of other features for this pseudo CS such as word posterior (of ε), alignment score, CS entropy, and CS count are all local scores and can be computed easily. Unlike future scores which are approximate, the score computed in this process is exact. Adding this extra score to the existing score accumulated in the final state gives the complete score of this finished path. When all paths are finished, the one with the best complete score is returned as the final output sentence.

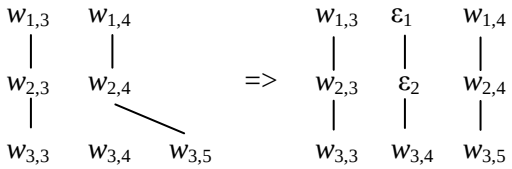

Figure 4. Expanding a leftover word to a pseudo correspondence set.

6 Evaluation

6.1 Experimental conditions

For the joint decoding method, the threshold for alignment-score-based pruning is set to 0.25 and the maximum number of words that can align to the same word is limited to 3. We call this the *standard setting*. The joint decoding approach is evaluated on the Chinese-to-English (C2E) test set of the 2008 NIST Open MT Evaluation (NIST 2008). Results are reported in case insensitive BLEU score in percentages (Papineni et. al., 2002).

The NIST MT08 C2E test set contains 691 and 666 sentences of data from two genres, newswire and web-data, respectively. Each test sentence has four references provided by human translators. Individual systems in our experiments belong to the official submissions of the MT08 C2E constraint-training track. Each submission provides 1-best translation of the whole test set. In order to train feature weights, the original test set is divided into two parts, called the dev and test set, respectively. The dev set consists of the first half of both newswire and web-data, and the test set consists of the second half of data of both genres.

There are 20 individual systems available. We ranked them by their BLEU score results on the dev set and picked the top five systems, excluding systems ranked 5th and 6th since they are subsets of the first entry (NIST 2008). Performance of these systems on the dev and test sets is shown in Table 1.

The baselines include a pair-wise hypothesis alignment approach using the indirect HMM (IHMM) proposed by He et al. (2008), and an incremental hypothesis alignment approach using the incremental HMM (IncHMM) proposed by Li et al. (2009). The lexical translation model used to compute the semantic similarity is estimated from two million parallel sentence-pairs selected from the training corpus of MT08. The backbone for the IHMM-based approach is selected based on Minimum Bayes Risk (MBR) using a BLEU-based loss function. The various parameters of the IHMM and the IncHMM are tuned on the dev set. The same IHMM is used to compute the alignment feature score for the joint decoding approach.

The final combination output can be obtained by decoding the CN with a set of features. The features used for the baseline systems are the same as the features used by the joint decoding approach. Some of these features are constant across decoding hypotheses and can be ignored. The non-constant features are word posterior, bi-gram voting, language model score, and word count. They are computed in the same way as for the joint decoding approach.

System weights and feature weights are trained together using Powell's search for the IHMM-based approach. Then the same system weights are applied to both IncHMM and Joint Decoding -based approaches, and the feature weights of them are trained using the max-BLEU training method proposed by Och (2003) and refined by Moore and Quirk (2008).

Table 1: Performance of individual systems on the dev and test set

System ID	dev	test
System A	32.88	31.81
System B	32.82	32.03
System C	32.16	31.87
System D	31.40	31.32
System E	27.44	27.67

6.2 Comparison against baselines

Table 2 lists the BLEU scores achieved by the two baselines and the joint decoding approach. Both baselines surpass the best individual system

significantly. However, the gain of incremental HMM over IHMM is smaller than that reported in Li et al. (2009). One possible reason of such discrepancy could be that fewer hypotheses are used for combination in this experiment compared to that of Li et al. (2009), so the performance difference between them is narrowed accordingly. Despite that, the proposed joint decoding method outperforms both IHMM and IncHMM baselines significantly.

Table 2: Comparison between the joint decoding approach and the two baselines

method	dev	test
IHMM	36.91	35.85
IncHMM	37.32	36.38
Joint Decoding	37.94	37.20*

* The gains of Joint Decoding over IHMM and IncHMM are both with a statistical significance level > 99%, measured based on the paired bootstrap re-sampling method (Koehn 2004a)

6.3 Comparison of alignment pruning

The effect of alignment pruning is also studied. We tested with limiting the allowable links to just those that in the union of bi-directional Viterbi alignments.

The results are presented in Table 3. Compared to the standard setting, allowing only links in the union of the bi-directional Viterbi alignments causes slight performance degradation. On the other hand, it still outperforms the IHMM baseline by a fair margin. This is because the joint decoding approach is effectively resolving the ambiguous 1-to-many alignments and deciding proper places to insert empty words during decoding.

Table 3: Comparison between different settings of alignment pruning

Setting	Test
standard settings	37.20
union of Viterbi	36.88

6.4 Comparison of ordering constraints

In order to investigate the effect of allowing flexible word ordering, we conducted experiments using different constraints on the ordering of CS in the decoding process. In the first case, we restrict the order of CS to follow the word order of a backbone, which is one of the input hypotheses selected by MBR-BLEU. In the second case, the order of CS is constrained to follow the word order of at least one of the input hypotheses. As shown in Table 4, in comparison to the standard setting that allows backbone-free word ordering, the constrained settings did not lead to significant performance degradation. This indicates that most of the gain due to the joint decoding approach comes from the joint optimization of alignment and word selection. It is possible, though, that if we lift the CS *adjacency* constraint during search, we might derive more benefit from flexible word ordering.

7 Discussion

This paper proposed a joint optimization approach for word-level combination of translation hypotheses from multiple machine translation systems. Unlike conventional confusion-network-based methods, alignments between words from different hypotheses are not pre-determined and flexible word orderings are allowed. Decisions on word alignment between hypotheses, word ordering, and the lexical choice of the final output are made jointly according to a set of features in the decoding process. A new set of features to model alignment and re-ordering behavior is also proposed. The method is evaluated against state-of-the-art baselines on the NIST MT08 C2E task. The joint decoding approach is shown to outperform baselines significantly.

Because of the complexity of search, a challenge for our approach is combining a large number of input hypotheses. When N-best hypotheses from the same system are added, it is possible to pre-compute and fix the one-to-one word alignment among the same-system hypotheses; such pre-computation is reasonable given our observation that the disagreement among hypotheses from different systems is larger than that among hypotheses from the same system. This will reduce the alignment search space to be the same as that for 1-best case. We plan to study this setting in future work.

To further improve the performance of our approach we see the biggest opportunity in developing better estimates of future scores and incorporating additional features. Beside potential performance improvement, they may help on more effective pruning and speed up the overall decoding process as well.

Fully Lexicalising CCGbank with Hat Categories

Matthew Honnibal and **James R. Curran**

{mhonn,james}@it.usyd.edu.au

Abstract

We introduce an extension to CCG that allows form and function to be represented simultaneously, reducing the proliferation of modifier categories seen in standard CCG analyses.

We can then remove the non-combinatory rules CCGbank uses to address this problem, producing a grammar that is fully lexicalised and far less ambiguous.

There are intrinsic benefits to full lexicalisation, such as semantic transparency and simpler domain adaptation. The clearest advantage is a 52-88% improvement in parse speeds, which comes with only a small reduction in accuracy.

1 Introduction

Deep grammars return parses that map transparently to semantic analyses, allowing information extraction systems to deal directly with content representations. Usually, this mapping is lexically specified, by linking lexical entries to semantic analyses. This property, lexicalisation, is central to some of the linguistic theories behind deep grammars, particularly Combinatory Categorial Grammar (Steedman, 2000) and Lexicalised Tree Adjoining Grammar (Joshi, 1999).

Lexicalisation can also help deep grammars achieve satisfactory parse times. Lexicalised grammars use few rules, which simply manipulate the lexical categories. The categories can be quickly assigned in a supertagging pre-process, dramatically reducing the search space the parser must explore (Bangalore and Joshi, 1999).

Combinatory Categorial Grammar (CCG) is well suited to this strategy, and Clark and Curran (2007) have highlighted the division of labour between the parser and the supertagger as one of the critical aspects of their approach to statistical CCG parsing. In their system, the division is managed with parameters that control how many categories the parser's chart is seeded with. But even if the parser is only given one category per word, it still has a lot of freedom — because the grammar it uses is not fully lexicalised.

In a fully lexicalised CCG grammar, modifier categories refer to the category of their head. This category does not necessarily represent the head's constituent type. For instance, the category of an adverb like *still* depends on whether it is modifying a predicate verb (1), or a clausal adjunct (2):

(1)	*The lion*	*was*	*lying*	*still*
	NP	VP/VP	*VP*	$VP\backslash VP$
(2)	*The lion*	*waited,*	*lying*	*still*
	NP	*VP*	$VP\backslash VP$	$(VP\backslash VP)\backslash(VP\backslash VP)$

Analyses like these are problematic because the training data is unlikely to include examples of each word in every syntactic environment that requires a new category. Hockenmaier and Steedman's (2007) solution was to add category specific phrase-structure rules to the grammar, which disrupts the linguistic principles of the formalism, and introduces over-generation and ambiguity as shown in Figure 1.

This paper proposes a new way to balance lexical and grammatical ambiguity in CCG. We introduce an extension to the formalism that allows type-changing rules to be lexically specified. The extension adds a new field to the category objects, and one additional rule to utilise it. This allows the formalism to express type-changing operations in a theoretically desirable way.

Lexically specifying the type-changing rules reduces the ambiguity in the grammar substantially, which leads to substantial improvements in parsing efficiency. After modifying the C&C parser and CCGbank, the parser runs almost twice as quickly, with only a 0.5% reduction in accuracy.

Singapore, 6-7 August 2009.

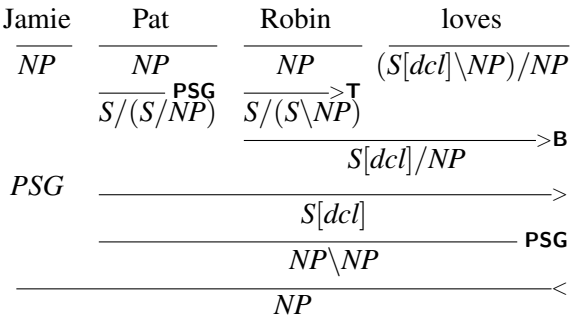

Figure 1: Over-generation by CCGbank rules.

2 Combinatory Categorial Grammar

Combinatory Categorial Grammar (CCG) (Steedman, 2000) is a lexicalised grammar formalism based on categorial grammar (Bar-Hillel, 1953). CCG can be distinguished from other CG extensions, such as categorial type-logic (Moortgat, 1997) by its attention to linguistic minimalism. One aim of the theory is to explain universal constraints on natural language syntax, so the generative power of the formalism is intended to closely match what natural language seems to require.

Steedman and Baldridge (2007) argue that the requirements can be fulfilled almost entirely by two basic rule types: application and composition. Direction specific instances of these types yields a grammar that consists of just six rules.

Initially, it seemed that some of the rules had to be restricted to certain contexts, particularly in languages that did not allow scrambling. Baldridge and Kruijff (2003) have since shown that rules could be restricted lexically, using a hierarchy of slash subtypes. This relieved the need for any language specific meta-rules, allowing CCG to offer a completely universal grammar, and therefore a theory of the innate human language faculty.

With a universal grammar, language specific variation is confined to the lexicon. A CCG lexical category is either an atomic type, like N, or a function that specifies an argument in a particular direction, and a result, like $S\backslash NP$ (where S is the result, NP the argument, and $\backslash$ indicates the argument must be found to the left).

Hockenmaier and Steedman (2007) showed that a CCG corpus could be created by adapting the Penn Treebank (Marcus et al., 1993). CCGbank has since been used to train fast and accurate CCG parsers (Clark and Curran, 2007).

3 The Need for Type-changing in CCG

We argue that there is a clear need for some sort of type-changing mechanism in CCG. The practical need for this has been known since at least Hockenmaier (2003), who introduced a type-changing mechanism into CCGbank in order to control the problem referred to as *modifier category proliferation*. We briefly describe the problem, and then the prominent solutions that have been proposed.

Unlike formalisms like LTAG and HPSG, CCG does not use different grammatical rules for arguments and adjuncts. Instead, modifier categories take the form $X_1|X_1$, where X is the category of the constituent being modified, and the subscript indicates that the result should inherit from the argument via unification. The modifier can then use the application rule to attach to its head, and return the head unchanged:

(3) *unusually* $(S[adj]\backslash NP)/(S[adj]\backslash NP)$ *resilient* $S[adj]\backslash NP$

unusually here modifies the predicative adjective *resilient*, attaching it as an argument using forward application. This prevents *resilient* from having to subcategorise for adjuncts, since they are optional. The problem is that *unusually* must subcategorise for the function of its head. If *resilient* changes function and becomes a noun modifier, its modifiers must change category too:

(4) *an* NP/N *unusually* $(N/N)/(N/N)$ *resilient* N/N *strain* N

There is often a way to analyse around the need for type-changing operations in CCG. However, these solutions tend to cause new difficulties, and the resulting category ambiguity is quite problematic (Hockenmaier and Steedman, 2002). The fact is that form-to-function coercions are quite common in English, so the grammar needs a way to have a constituent be modified according to its form, before undergoing a type-change to its function category.

One way to describe the problem is to say that CCG categories have an over-extended *domain of locality* (Joshi, 1999), the part of the derivation that it describes. A category should specify all and only the dependencies it governs, but CCG modifier categories are often forced to specify their heads' dependencies as well. These undesirable notational dependencies can also prevent modifier categories from factoring recursion away from their domain of locality.

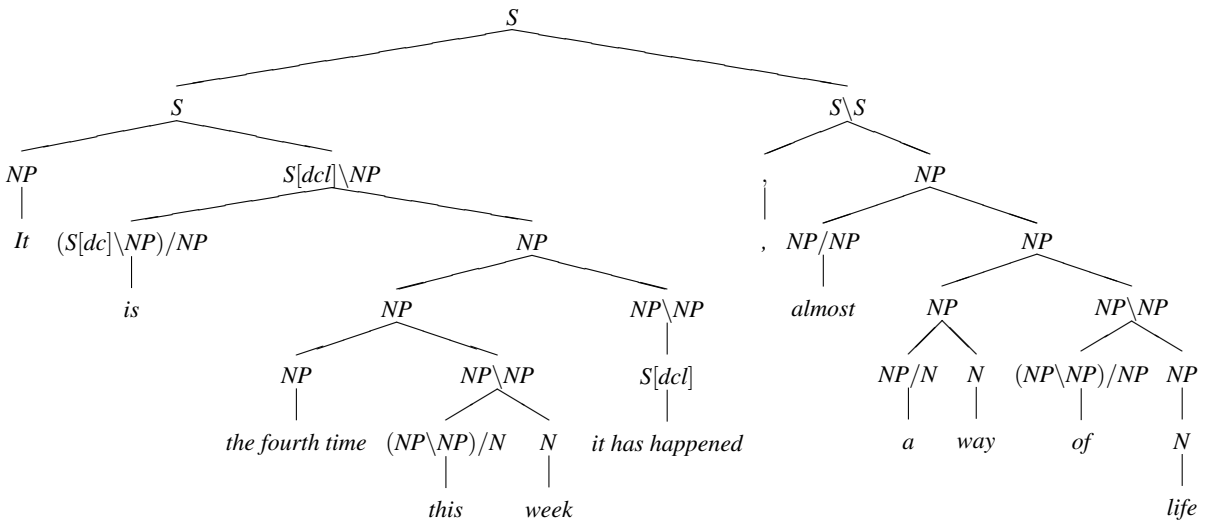

Figure 2: CCGbank derivation showing PSG rules.

4 Problems with Existing Proposals

This section completes the motivation of the paper by arguing that the existing proposals for type-changing are linguistically unsatisfactory, practically difficult, or a combination of the two.

4.1 Problems with PSG Rules

Hockenmaier and Steedman (2002) includes a brief discussion of the modifier category proliferation problem, and introduces unary phrase-structure rules to address the situation. Figure 2 shows two such rules. The $<S[dcl] \rightarrow NP\backslash NP>$[1] rule allows the reduced relative clause, *it has happened*, to be analysed as a modifier without affecting the category any modifiers that might attach to it. The other PSG type-changing rule in the derivation, $<, NP \rightarrow S\backslash S>$ enables the extraposition, using the punctuation to make the rule more precise.

One alternative to type-changing rules here would be to have *time* subcategorise for the clause, with a category like $NP/S[dcl]$. This would capture the constraint that only a restricted subset of nouns can be extracted as adjuncts in this way. The problem is that the extra argument would interfere with the attachment of adjuncts like *this week* to the *NP*, because the $NP\backslash NP$ category cannot be allowed to participate in backwards cross-composition rules (Baldridge and Kruijff, 2003).

There are 204 type-changing PSG rules in the training partition of CCGbank. 53 of the frequent rules transform produce modifier categories, 48 of them transforming verbal categories. The PSG rules also handle a variety of other constructions, such as form/function discrepancies like gerund nominals. By far the most frequent rule, with 115,333 occurrences, is $<N \rightarrow NP>$, which transforms bare nominals into noun phrases.

Steedman and Baldridge (2007) describes the CCG grammar as consisting of just 6 language universal combinatory rules, plus two lexical operations (type raising). Not only do the 204 category specific type-changing rules in CCGbank make the grammar ambiguous, they also run contrary to the design principles of the formalism.

CCG is a linguistically motivated formalism, which means it is not only interested in providing a convenient, computable notation for grammar development. In addition, it constitutes a hypothesis about the nature of the human language faculty. Like other lexicalised formalisms, part of the theory is that it is the grammar that is innate, and the lexicon is acquired.

If the grammar is innate, it must be language universal, confining all language specific variation to the lexicon. Baldridge and Kruijff (2003) described how the remaining language specific grammatical constraints described by Steedman (2000) could be controlled in the lexicon, using multi-modal slashes that have since become integrated into the main body of the theory (Steedman and Baldridge, 2007).

In addition to being linguistically undesirable, the PSG rules in CCGbank produce practical difficulties. Every additional rule increases ambiguity, motivating the C&C system to choose to implement only the most frequent. This decreases

[1] Phrase-structure rules are presented in bottom-up notation.

the parser's coverage, and introduces another dimension of domain sensitivity. For instance, the type-changing rule that allows gerund nominals, $<S[ng]\backslash NP \rightarrow NP>$, occurs roughly 300 times in the training data. The parser does not implement this rule, so if it is ported to a new domain, where the construction is frequent, the rule will have to be added. Presumably, the parser would also benefit from the removal of rules which are infrequent in some new, target domain.

The restricted set of PSG rules the parser does implement results in considerable added ambiguity to the grammar. Figure 1 shows how the rules interact to produce over-generation.

The PSG rules are also a barrier to the semantic transparency of the theory, one of its most attractive properties for natural language engineering. CCG derivations are isomorphic to semantic analyses, because the derivation instantiates dependencies between CCG categories that can be paired with semantic categories. This isomorphism is disrupted by the addition of PSG rules, since the grammar is no longer lexicalised. Often, the rules can be semantically annotated, restoring the isomorphism; but sometimes, this cannot be done.

For instance, the extraposition rule in Figure 2 transforms the *NP* category into $S\backslash S$. There is no syntactic argument on the *NP* category to map the dependency to, so the dependency cannot be created (and is in fact missing from CCGbank).

4.2 Lexical Rules and Zero Morphemes

The CCGbank PSG extension is closely related to the zero morpheme categories proposed by Aone and Wittenburg (1990), which they suggest be compiled into unary type-changing rules for processing. At first glance, it seems that conceptualising the rules as zero morphemes offers a way to locate them in the lexicon, avoiding the linguistic difficulties of having a language-specific grammar. However, CCG aims to provide a transparent interface between the surface form and the semantic analysis, so epsilon categories, traces, movement rules and other unrealised structures are explicitly banned (Steedman, 2000).

From a processing standpoint, if zero morpheme categories are not compiled into phrase-structure rules, then they will complicate the category assignment phase considerably, since we can no longer assume that exactly one category will be assigned per word. We are not aware of any proposal for how this difficulty might be overcome.

Carpenter (1992) provides a different suggestion for how sparse modifier categories can be accommodated. His solution is to use meta-rules that systematically expand the lexicon, much like the lexical rules used in HPSG (Flickinger, 1987), which exploit structural regularities to ensure that the lexicon is more complete.

The problem with this is that it does not actually make the category set less sparse, so the supertagger's task is just as difficult. The only advantage is that its dictionary will be more complete. This is important, but does not solve the underlying inefficiency in the grammar: CCG categories have an over-extended domain of locality, because they cannot represent form and function simultaneously. This is why some type-changing mechanism is required.

5 Lexically Specified Type-Changing

This section describes our mechanism for lexically specifying the PSG rules in CCGbank. Figure 3 shows an example of a reduced relative clause analysed using our extension, *hat categories*.

CCGbank deploys a solution that achieves *form transparency* at the expense of *type transparency*, by allowing type-changing rules that are not lexically specified. One way to recover the lost type transparency would be to demand that lexical categories specify what type changing rule (if any) the category can eventually undergo. For instance, imagine we have two type-changing rules we wish to include in our grammar:

a) $S[ng]\backslash NP \Rightarrow NP\backslash NP$

b) $S[ng]\backslash NP \Rightarrow VP\backslash VP$[2]

With these two rules, there will be three ways the $S[ng]\backslash NP$ category might behave in a derivation. What we need are two extra categories to control this:

1. $S[ng]\backslash NP$ only allows combinatory rules.
2. $(S[ng]\backslash NP)^a$ allows rule a, but not rule b.
3. $(S[ng]\backslash NP)^b$ allows rule b, but not rule a.

Instead of encoding a reference to a rule, we encode the production rule itself in the category.

[2] $S\backslash NP$ is occasionally abbreviated as *VP*.

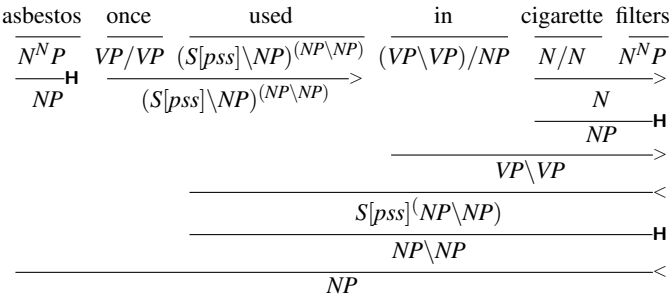

Figure 3: Analysis of a reduced relative clause with lexicalised type-changing.

$$\begin{bmatrix} \text{CAT} & (S[ng]\backslash NP)^{NP\backslash NP}/NP \\ \text{RES} & \begin{bmatrix} \text{CAT} & (S[ng]\backslash NP)^{NP\backslash NP} \\ \text{RES} & \begin{bmatrix} \text{CAT} & S \\ \text{FEAT} & ng \end{bmatrix} \\ \text{ARG} & NP_1 \\ \text{DIR} & \backslash \\ \text{HAT} & NP\backslash NP_1 \end{bmatrix} \\ \text{ARG} & NP \\ \text{DIR} & / \\ \text{HAT} & [\text{-}] \end{bmatrix}$$

Figure 4: AVM of a hat category.

This allows us to remove the rule from the grammar. Since the bottom of the production will always be the category itself, we can just specify how the category can be rewritten:

1. $S[ng]\backslash NP$ can be combined, but not rewritten.
2. $(S[ng]\backslash NP)^{NP\backslash NP}$ can be rewritten as $NP\backslash NP$.
3. $(S[ng]\backslash NP)^{VP\backslash VP}$ can be rewritten as $VP\backslash VP$.

We refer to the superscript category as a *hat* category, as a reference to the notation, but also to denote the fact that it allows the category to perform a different function, or put a different 'hat' on. Categories that have a hat specified are referred to as *hatted* categories.

5.1 Changes to Category Objects

Figure 4 shows an AVM representation of the $(S[ng]\backslash NP)^{NP\backslash NP}/NP$ category. A field, labelled *hat*, has been added to store the destination category of the result, $NP\backslash NP$. The NP argument in the hat category is co-indexed with the NP argument in the hatted category. The NP argument is also co indexed with the result of the destination category, reflecting the fact that the $NP\backslash NP$ category is a modifier, whose head will be the head of its argument.

Hat categories are handled the same as any other field during unification. If the two hat fields cannot be unified, unification fails; and if one hat field has an empty value, it inherits the value of the hat field of the other category when unification succeeds. CCG already requires a unification process for agreement features (Hockenmaier and Steedman, 2007); the hat categories we have introduced behave identically.

As Figure 4 shows, hat categories can be added to inner results, allowing arguments to be applied before the type-changing rule. We add a restriction that prevents categories with an outermost hat field from applying arguments — essentially equivalent to stipulating that the slash in a category like $S[ng]\backslash NP$ must have a null mode.

We also stipulate that only adjuncts may apply hatted arguments, which can also be lexically represented by assuming that all non-adjunct categories have a null value in their hat field, causing unification with a hatted category to fail.

Together, these restrictions ensure that the unary rule is used. The hatted category cannot function as a non-hatted category, because it cannot use its own arguments, and cannot be used as an argument of another category. This prevents hat categories from forming categories that are functionally *disjunctive*: the notation cannot be used to simulate something like an optional argument.

5.2 The Type-Change Rule

To replace the 204 PSG rules in CCGbank, we only need to introduce one extra schematic rule into the grammar:

$$X^Y \Rightarrow Y \tag{5}$$

This rule simply unpacks the category, performing the lexically specified type-change.

5.3 Generative Power

Because hat fields are only transmitted when categories are successfully unified, there is no way to produce a novel $X \Rightarrow Y$ unary production during a derivation. This means that any derivation that can be produced using the schematic type-change rule we have added to the grammar can be produced by adding a set of unary phrase-structure rules instead — ensuring that we do not require any extra generative power than is required to parse CCGbank.

The hat categories do increase the strong generative power of a CCG grammar that does not include the CCGbank type-changing rules. We suggest that this is desirable, in line with Joshi's (1999) argument that formalisms should be designed to have the maximum expressivity while maintaining the minimum weak generative power necessary to produce the constructions that have been observed in natural language.

6 Lexicalising Type-raising

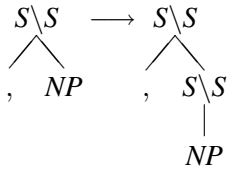
So far, we have focused on replacing the phrase-structure rules added to CCGbank, which are not part of the CCG linguistic theory. However, the theory does include some type-changing rules, referred to as *type-raising*. Forward and backward type-raising are used to transform a category X into the logically equivalent categories $T/(T\backslash X)$ and $T\backslash(T/X)$ respectively.

Type-raising is generally described as a lexical operation, rather than a grammatical rule, because only certain language specific combinations of T and X produce valid type-raise categories. However, no specific mechanism for controlling type-raising has been proposed.

Hat categories are an obvious candidate for this, so we perform an additional set of experiments which lexicalise the type-raising rules in CCGbank, in addition to the PSG rules.

7 Adapting CCGbank

This section describes how we converted CCGbank's PSG rules into analyses that used hat categories. Most of the PSG rules are unary, which meant that our changes were limited to adding hat categories to the child of the unary production and its subtree. The binary PSG rules that we converted effectively just used punctuation as a cue for a unary type-change, as seen in the extraposition rule in Figure 2. These were handled by adding an extra node for the punctuation application, leaving a unary production:



(6)

An alternative analysis would be to assign the punctuation mark a category to perform the type-change — in this case, $(S\backslash S)/NP$. However, this analysis will be unreliable for many genres, where punctuation is used inconsistently, so we preferred that hat category analysis, which we found produced slightly better results.

We used the same method to convert cases where CCGbank used conjunctions to cue a type-change, where the Penn Treebank conversion process produced a derivation where two sides of a coordination had different categories. There were 90 such conjunction coercion rules, which we have not counted amongst the 204 PSG rules, since they are ultimately caused by conversion noise.

The main complication when adapting CCGbank was the fact that CCG node labels are interdependent through a derivation. If one node label is changed, its immediate children have to change node label too, and the changes must be propagated further from there.

Since the dependency between the parent and its two children is different for each combinator, our node change rules determine the rule used for the original production, and then invoke the appropriate replacement rule. In general, the rules find the result (A_r) and argument (A_a) of the original parent A and replace them with the appropriate part of the new parent B. If one of the children is an adjunct category, a different rule is used. The node change rules for forward combinators are:

App	A/Y	Y	$\Rightarrow$	B/Y	Y
Comp	A_r/Y	Y/A_a	$\Rightarrow$	B_r/Y	Y/B_a
Adj. app	A/A	A	$\Rightarrow$	B/B	B
Adj. comp	A_r/A_r	A_r/A_a	$\Rightarrow$	B_r/B_r	B_r/B_a

The translation rules for backward and crossed combinators are directly analogous, with the slashes permuted appropriately.

8 Adapting the CCG Parser

We took the standard 1.02 release of the C&C parser Clark and Curran (2007) and implemented the changes required for lexically specified type-changing.

Table 1: Labelled Precision, Recall and F-measure, coverage results on Section 00 and Section 23.

The most significant change was building hat passing and unification into the existing unification engine. For many parsers, this would have been straightforward since they already support unification with complex feature structures. However, one of the advantages of CCGbank is that the unification required is quite simple, which is one of the reasons why the C&C parser is very fast. We would estimate that adding hat passing doubled the complexity of the unification engine.

The second step was to add support for hat passing to all of the existing combinators, because they do not use the unification engine to construct the result category. Since each of the combinators is hard-coded for speed, this was time-consuming and error prone. However, we created a detailed set of regression tests for the new versions which greatly reduced our development time.

Finally, we needed to turn off the existing unary rules in the parser, and add the simple additional type-change rule.

9 Setting Dictionary Thresholds

The main parameterisation we performed on the development section was to tune the K parameter of the parser, which controls the frequency at which a word's *tag dictionary* is used during supertagging. For words more frequent than K, the supertagger is restricted to choosing between categories that have been assigned to the word in the training data. Otherwise, the POS dictionary is used instead. The K parameter has multiple values, because the supertagger and parser are integrated such that the supertagger initially supplies only a narrow beam of categories to the parser, which is widened if parsing fails.

Since we have made the category set larger, the default values of $K = 20, 20, 20, 20, 150$ produces poor performance, up to 1.5% lower than the figures we report in Table 1. We set the K parameter to $50, 300, 80, 80, 3000$. We investigated the effect of this setting on the original model, and found that it had little effect, so we continued using the default values for the original model.

We also experimented with altering the β values for the hat parser, which did not improve the performance of the state-of-the-art parsing models.

10 Parsing Results

The left side of Table 1 shows our performance on the development data, Section 00. All of the dependency results we report refer to the original dependencies distributed with CCGbank. To ensure our results were comparable, we produced a mapping table of dependency labels from sections 02-21, used for parser training. The table maps the dependency labels in our corpus to the most frequent label assigned to matching dependencies in CCGbank. The correct label is assigned 99.94% of the time. The hat categories move to the the lexicon information that used to be represented in the grammar, resulting in a larger, more informative

category set, making the category accuracies (the *cat* column in the table) not comparable.

We experimented with two of the parsing models described by Clark and Curran (2007). The *derivs* model uses features calculated over the derivations, while the *hybrid* model uses features calculated on the dependency structures. However, unlike the *deps* model Clark and Curran (2007) describe, the *hybrid* model uses two sets of derivation-based constraints. One set are the normal form constraints, as described by Eisner (1996). It also uses constraints that prevent the parser from using productions that were not seen in the training data. The hybrid model is slightly more accurate, but also slightly slower, because the dependency-based decoding is less efficient.

All of the systems were within 0.5% in accuracy on the development set, with one exception. The HAT+TR version performed very poorly with the hybrid model, while its performance with the derivs model was comparable to the other systems. The same drop in performance occurs on the evaluation set. We do not currently have a convincing explanation for this, but we presume it is the result of some unforeseen interaction between the removal of the type-raising rules from the grammar and the dependency-based features.

The accuracy results on the test data, Section 23, saw similar trends, except that the gap between the hat systems and the original CCGbank increased slightly. The CCGbank hybrid model was only 0.1% more accurate than the HAT hybrid model on Section 00, but is 0.5% more accurate on Section 23.

Table 2 compares the parse speeds for the lexicalised hat corpora against a parser trained on the original CCGbank, using the two models. Exactly the same settings were used to obtain parse times as were used in the accuracy experiments. The experiments were all performed on a single core 2.6GHz Pentium 4 Xeon. Speeds are reported as words parsed per second.

On both Section 00 and Section 23, with both the derivs and hybrid models, the HAT system was substantially faster than the original parser. The HAT+TR system was faster than the HAT system using automatic POS tags, and slightly faster on Section 00.

The hat categories allow quite favourable tradeoffs between speed and accuracy to be made. The original models allow us to parse with automatic POS tags at 480 words per second with 85.27% accuracy with the hybrid model, or at 544 words per second with 84.86% accuracy using the derivs model. Using the HAT derivs model, we could instead parse at 827 words per second with 84.76% accuracy, or at 906 words per second and 84.67% accuracy using the HAT+TR system.

In summary, the HAT and CCGbank derivs models are equivalent in accuracy, but the HAT version is 52% faster. The CCGbank hybrid model remains the most accurate, but there will also be many tasks where the 88% improvement in speed will make it worth using the HAT+TR derivs parser instead of the CCGbank hybrid model, at a cost of 0.6% accuracy.

11 Corpus Statistics

Table 3 shows the number of types and the number of occurrences of CCG combinatory rules and PSG rules occurred in CCGbank and the hat corpus.

The hat corpus removes almost all unlicensed productions, leaving only a long tail of rare productions that are the result of noisy derivations. These productions are generally symptomatic of problematic analyses, and are difficult to address automatically because they do not conform to any consistent pattern. We have omitted the hat+TR corpus in these figures, because it only differs from the the hat corpus with respect to type-raising productions.

Lexicalising the corpus increases the number of categories required substantially. There are 407 categories that occur 10 or more times in the training section of CCGbank. The equivalent figure for the HAT corpus is 507, and for the HAT+TR corpus it is 540.

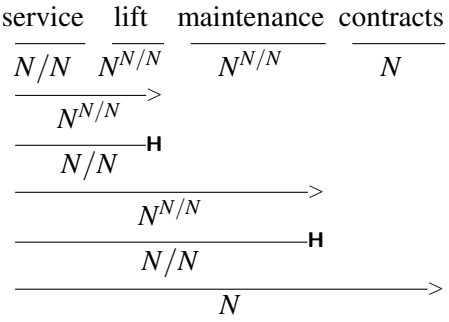
12 Cleaner Analyses with Hat Categories

The lexicalised type-changing scheme we have proposed offers many opportunities for favourable analyses, because it allows form and function to be represented simultaneously. However, we have limited our changes to replacing the existing CCGbank non-combinatory rules. This allows us to compare the two strategies for controlling modifier category proliferation more closely, but still offers some improved analyses.

The most frequent unary production in CCGbank, the $N \Rightarrow NP$ rule, ensures that nominals can always take the N category, so adjectives seldom need to be assigned NP/NP. Because ad-

jectives and nouns are open class, and bare noun phrases are fairly common, this reduction in category sparseness is quite important.

Lexicalising the type changing rule forces the head noun to acquire a different category, but does ensure that its modifiers can attach at the *N* level — which is also more linguistically desirable:



This analysis also prevents the extreme category proliferation problem caused by left-branching noun phrases:

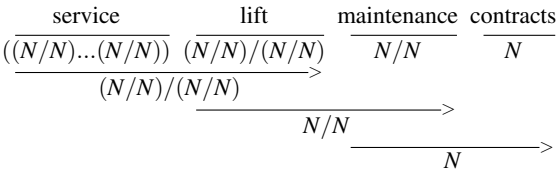


Figure 3 shows a more typical example of an improved analysis. The non-finite clause is functioning as an adnominal, but its modifier is able to select its canonical category.

One of the advantages of the CCGbank phrase-structure rules is that they allow the corpus to include derivations for which no valid CCG parse can be formed. The C&C parser has difficulty taking advantage of these extra sentences, however, because only so many of the arbitrary binary PSG rules can be added to the grammar without making it too ambiguous. Once these rules are lexicalised, the categories that produce them can be added to the lexicon as unexceptional, albeit rare, cases.

13 Conclusion

Lexicalised grammars represent most of the information in a derivation with a sequence of lexical categories. Traditional CCG analyses require redundancy between categories whenever there is nested modification, which suggests that such analyses will encounter sparse data problems.

While the addition of phrase-structure rules prevents this proliferation of modifier categories, it does so at a high price. The bulk of the type-changing rules in CCGbank are not implemented in the C&C parser, because to do so would increase the ambiguity in the grammar enormously.

CCG parsers must carefully manage ambiguity, because there are many ways to bracket the same CCG derivation. Even with a restricted set of PSG rules, the C&C parser experiences very large chart sizes. In addition to making the grammar more ambiguous, the PSG rules make it less theoretically sound, and more difficult to produce semantic analyses from the parser's output.

We have show how CCG analyses can be fully lexicalised in a way that closely mirrors the introduction of phrase-structure rules. The result is a corpus that produces faster, accurate parsers, is well suited for domain adaptation, and allows for more transparent semantic analysis. We can also use the same mechanism to lexically specify type-raising, the first concrete proposal to handle type-raising as a lexical transformation we are aware of.

From an immediate, empirical perspective, we have substantially improved the parsing speed of what is already the fastest deep parser available. Improvements in parsing efficiency are important in making parsing a practical technology, since the volume of text we have available for processing is growing even faster than the processing resources we have available.

Abstract

Jointly parsing two languages has been shown to improve accuracies on either or both sides. However, its search space is much bigger than the monolingual case, forcing existing approaches to employ complicated modeling and crude approximations. Here we propose a much simpler alternative, *bilingually-constrained monolingual parsing*, where a source-language parser learns to exploit reorderings as additional observation, but *not* bothering to build the target-side tree as well. We show specifically how to enhance a shift-reduce dependency parser with alignment features to resolve shift-reduce conflicts. Experiments on the bilingual portion of Chinese Treebank show that, with just 3 bilingual features, we can improve parsing accuracies by 0.6% (absolute) for both English and Chinese over a state-of-the-art baseline, with negligible (∼6%) efficiency overhead, thus much faster than biparsing.

1 Introduction

Ambiguity resolution is a central task in Natural Language Processing. Interestingly, not all languages are ambiguous in the same way. For example, prepositional phrase (PP) attachment is (notoriously) ambiguous in English (and related European languages), but is strictly unambiguous in Chinese and largely unambiguous Japanese; see

(1a) I [saw Bill] [with a telescope].
wo [*yong wangyuanjin*] [*kandao le Bi'er*].
"I used a telescope to see Bill."

(1b) I saw [Bill [with a telescope]].
wo kandao le [[*na wangyuanjin*] *de Bi'er*].
"I saw Bill who had a telescope at hand."

Figure 1: PP-attachment is unambiguous in Chinese, which can help English parsing.

Figure 1 for an example.[1] It is thus intuitive to use two languages for better disambiguation, which has been applied not only to this PP-attachment problem (Fossum and Knight, 2008; Schwartz et al., 2003), but also to the more fundamental problem of syntactic parsing which subsumes the former as a subproblem. For example, Smith and Smith (2004) and Burkett and Klein (2008) show that joint parsing (or reranking) on a bitext improves accuracies on either or both sides by leveraging bilingual constraints, which is very promising for syntax-based machine translation which requires (good-quality) parse trees for rule extraction (Galley et al., 2004; Mi and Huang, 2008).

However, the search space of joint parsing is inevitably much bigger than the monolingual case,

[1] Chinese uses word-order to disambiguate the attachment (see below). By contrast, Japanese resorts to case-markers and the unambiguity is limited: it works for the "V or N" attachment ambiguities like in Figure 1 (see (Schwartz et al., 2003)) but not for the "N_1 or N_2" case (Mitch Marcus, p.c.).

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1222–1231,
Singapore, 6-7 August 2009.

forcing existing approaches to employ complicated modeling and crude approximations. Joint parsing with a simplest synchronous context-free grammar (Wu, 1997) is $O(n^6)$ as opposed to the monolingual $O(n^3)$ time. To make things worse, languages are *non-isomorphic*, i.e., there is no 1-to-1 mapping between tree nodes, thus in practice one has to use more expressive formalisms such as synchronous tree-substitution grammars (Eisner, 2003; Galley et al., 2004). In fact, rather than joint parsing per se, Burkett and Klein (2008) resort to separate monolingual parsing and *bilingual reranking* over k^2 tree pairs, which covers a tiny fraction of the whole space (Huang, 2008).

We instead propose a much simpler alternative, *bilingually-constrained monolingual parsing*, where a source-language parser is extended to exploit the reorderings between languages as additional observation, but *not* bothering to build a tree for the target side simultaneously. To illustrate the idea, suppose we are parsing the sentence

(1) I saw Bill [$_{\text{PP}}$ with a telescope].

which has 2 parses based on the attachment of PP:

(1a) I [saw Bill] [$_{\text{PP}}$ with a telescope].

(1b) I saw [Bill [$_{\text{PP}}$ with a telescope]].

Both are possible, but with a Chinese translation the choice becomes clear (see Figure 1), because a Chinese PP always immediately precedes the phrase it is modifying, thus making PP-attachment strictly unambiguous.[2] We can thus use Chinese to help parse English, i.e., whenever we have a PP-attachment ambiguity, we will consult the Chinese translation (from a bitext), and based on the alignment information, decide where to attach the English PP. On the other hand, English can help Chinese parsing as well, for example in deciding the scope of relative clauses which is unambiguous in English but ambiguous in Chinese.

This method is much simpler than joint parsing because it remains *monolingual* in the backbone, with alignment information merely as soft evidence, rather than hard constraints since automatic word alignment is far from perfect. It is thus straightforward to implement within a monolingual parsing algorithm. In this work we choose shift-reduce dependency parsing for its simplicity and efficiency. Specifically, we make the following contributions:

- we develop a baseline shift-reduce dependency parser using the less popular, but classical, "arc-standard" style (Section 2), and achieve similar state-of-the-art performance with the the dominant but complicated "arc-eager" style of Nivre and Scholz (2004);
- we propose bilingual features based on word-alignment information to prefer "target-side contiguity" in resolving shift-reduce conflicts (Section 3);
- we verify empirically that shift-reduce conflicts are the major source of errors, and correct shift-reduce decisions strongly correlate with the above bilingual contiguity conditions *even* with automatic alignments (Section 5.3);
- finally, with just three bilingual features, we improve dependency parsing accuracy by 0.6% for both English and Chinese over the state-of-the-art baseline with negligible ($\sim$6%) efficiency overhead (Section 5.4).

2 Simpler Shift-Reduce Dependency Parsing with Three Actions

The basic idea of classical shift-reduce parsing from compiler theory (Aho and Ullman, 1972) is to perform a left-to-right scan of the input sentence, and at each step, choose one of the two actions: either *shift* the current word onto the stack, or *reduce* the top two (or more) items on the stack, replacing them with their combination. This idea has been applied to constituency parsing, for example in Sagae and Lavie (2006), and we describe below a simple variant for dependency parsing similar to Yamada and Matsumoto (2003) and the "arc-standard" version of Nivre (2004).

2.1 The Three Actions

Basically, we just need to split the reduce action into two symmetric (sub-)actions, reduce$_{\text{L}}$ and reduce$_{\text{R}}$, depending on which one of the two

[2] to be precise, in Fig. 1(b), the English PP is translated into a Chinese relative clause, but nevertheless all phrasal modifiers attach to the immediate right in Mandarin Chinese.

	stack	queue	arcs
previous	S	$w_i \vert Q$	A
shift	$S \vert w_i$	Q	A
previous	$S \vert s_{t-1} \vert s_t$	Q	A
reduce_L	$S \vert s_t$	Q	$A \cup \{(s_t, s_{t-1})\}$
reduce_R	$S \vert s_{t-1}$	Q	$A \cup \{(s_{t-1}, s_t)\}$

Table 1: Formal description of the three actions. Note that shift requires non-empty queue while reduce requires at least two elements on the stack.

items becomes the head after reduction. More formally, we describe a parser configuration by a tuple $\langle S, Q, A \rangle$ where S is the stack, Q is the queue of remaining words of the input, and A is the set of dependency arcs accumulated so far.[3] At each step, we can choose one of the three actions:

1. shift: move the head of (a non-empty) queue Q onto stack S;
2. reduce_L: combine the top two items on the stack, s_t and s_{t-1} ($t \geq 2$), and replace them with s_t (as the head), and add a left arc (s_t, s_{t-1}) to A;
3. reduce_R: combine the top two items on the stack, s_t and s_{t-1} ($t \geq 2$), and replace them with s_{t-1} (as the head), and add a right arc (s_{t-1}, s_t) to A.

These actions are summarized in Table 1. The initial configuration is always $\langle \emptyset, w_1 \ldots w_n, \emptyset \rangle$ with empty stack and no arcs, and the final configuration is $\langle w_j, \emptyset, A \rangle$ where w_j is recognized as the root of the whole sentence, and A encodes a spanning tree rooted at w_j. For a sentence of n words, there are exactly $2n - 1$ actions: n shifts and $n - 1$ reductions, since every word must be pushed onto stack once, and every word except the root will eventually be popped in a reduction. The time complexity, as other shift-reduce instances, is clearly $O(n)$.

2.2 Example of Shift-Reduce Conflict

Figure 2 shows the trace of this paradigm on the example sentence. For the first two configurations

[3] a "configuration" is sometimes called a "state" (Zhang and Clark, 2008), but that term is confusing with the states in shift-reduce LR/LL parsing, which are quite different.

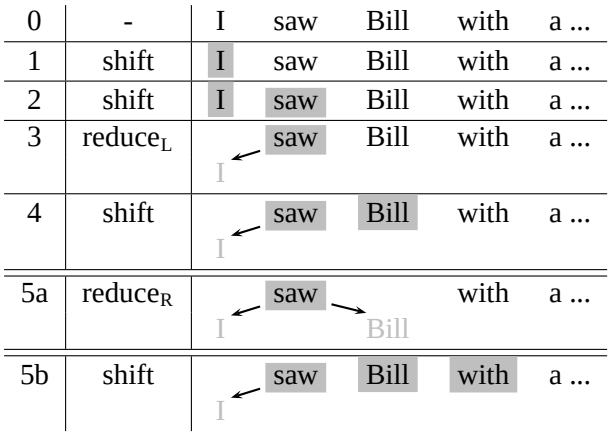

Figure 2: A trace of 3-action shift-reduce on the example sentence. Shaded words are on stack, while gray words have been popped from stack. After step (4), the process can take either (5a) or (5b), which correspond to the two attachments (1a) and (1b) in Figure 1, respectively.

(0) and (1), only shift is possible since there are not enough items on the stack for reduction. At step (3), we perform a reduce_L, making word "I" a modifier of "saw"; after that the stack contains a single word and we have to shift the next word "Bill" (step 4). Now we face a *shift-reduce conflict*: we can either combine "saw" and "Bill" in a reduce_R action (5a), or shift "Bill" (5b). We will use features extracted from the configuration to resolve the conflict. For example, one such feature could be a bigram $s_t \circ s_{t-1}$, capturing how likely these two words are combined; see Table 2 for the complete list of feature templates we use in this baseline parser.

We argue that this kind of shift-reduce conflicts are the major source of parsing errors, since the other type of conflict, reduce-reduce conflict (i.e., whether left or right) is relatively easier to resolve given the part-of-speech information. For example, between a noun and an adjective, the former is much more likely to be the head (and so is a verb vs. a preposition or an adverb). Shift-reduce resolution, however, is more non-local, and often involves a triple, for example, (saw, Bill, with) for a typical PP-attachment. On the other hand, if we indeed make a wrong decision, a reduce-reduce mistake just flips the head and the modifier, and often has a more local effect on the shape of the tree, whereas a shift-reduce mistake always leads

Type	Features		
Unigram	s_t	$T(s_t)$	$s_t \circ T(s_t)$
	s_{t-1}	$T(s_{t-1})$	$s_{t-1} \circ T(s_{t-1})$
	w_i	$T(w_i)$	$w_i \circ T(w_i)$
Bigram	$s_t \circ s_{t-1}$	$T(s_t) \circ T(s_{t-1})$	$T(s_t) \circ T(w_i)$
	$T(s_t) \circ s_{t-1} \circ T(s_{t-1})$	$s_t \circ s_{t-1} \circ T(s_{t-1})$	$s_t \circ T(s_t) \circ T(s_{t-1})$
	$s_t \circ T(s_t) \circ s_{t-1}$	$s_t \circ T(s_t) \circ s_{t-1} \circ T(s_{t-1})$	
Trigram	$T(s_t) \circ T(w_i) \circ T(w_{i+1})$	$T(s_{t-1}) \circ T(s_t) \circ T(w_i)$	$T(s_{t-2}) \circ T(s_{t-1}) \circ T(s_t)$
	$s_t \circ T(w_i) \circ T(w_{i+1})$	$T(s_{t-1}) \circ s_t \circ T(w_i)$	
Modifier	$T(s_{t-1}) \circ T(lc(s_{t-1})) \circ T(s_t)$	$T(s_{t-1}) \circ T(rc(s_{t-1})) \circ T(s_t)$	$T(s_{t-1}) \circ T(s_t) \circ T(lc(s_t))$
	$T(s_{t-1}) \circ T(s_t) \circ T(rc(s_t))$	$T(s_{t-1}) \circ T(lc(s_{t-1})) \circ s_t$	$T(s_{t-1}) \circ T(rc(s_{t-1})) \circ s_t$
	$T(s_{t-1}) \circ s_t \circ T(lc(s_t))$		

Table 2: Feature templates of the baseline parser. s_t, s_{t-1} denote the top and next to top words on the stack; w_i and w_{i+1} denote the current and next words on the queue. $T(\cdot)$ denotes the POS tag of a given word, and $lc(\cdot)$ and $rc(\cdot)$ represent the leftmost and rightmost child. Symbol $\circ$ denotes feature conjunction. Each of these templates is further conjoined with the 3 actions shift, reduce$_{\text{L}}$, and reduce$_{\text{R}}$.

to vastly incompatible tree shapes with crossing brackets (for example, [saw Bill] vs. [Bill with a telescope]). We will see in Section 5.3 that this is indeed the case in practice, thus suggesting us to focus on shift-reduce resolution, which we will return to with the help of bilingual constraints in Section 3.

2.3 Comparison with Arc-Eager

The three action system was originally described by Yamada and Matsumoto (2003) (although their methods require multiple passes over the input), and then appeared as "arc-standard" in Nivre (2004), but was argued against in comparison to the four-action "arc-eager" variant. Most subsequent works on shift-reduce or "transition-based" dependency parsing followed "arc-eager" (Nivre and Scholz, 2004; Zhang and Clark, 2008), which now becomes the dominant style. But we argue that "arc-standard" is preferable because:

1. in the three action "arc-standard" system, the stack always contains a list of *unrelated* subtrees recognized so far, with no arcs between any of them, e.g. (I← saw) and (Bill) in step 4 of Figure 2), whereas the four action "arc-eager" style can have left or right arrows between items on the stack;

2. the semantics of the three actions are atomic and disjoint, whereas the semantics of 4 actions are *not* completely disjoint. For example, their Left action assumes an implicit Reduce of the left item, and their Right action assumes an implicit Shift. Furthermore, these two actions have non-trivial preconditions which also causes the next problem (see below). We argue that this is rather complicated to implement.

3. the "arc-standard" scan always succeeds, since at the end we can always reduce with empty queue, whereas the "arc-eager" style sometimes goes into deadends where no action can perform (prevented by preconditions, otherwise the result will not be a well-formed tree). This becomes parsing failures in practice (Nivre and Scholz, 2004), leaving more than one fragments on stack.

As we will see in Section 5.1, this simpler arc-standard system performs equally well with a state-of-the-art arc-eager system (Zhang and Clark, 2008) on standard English Treebank parsing (which is never shown before). We argue that all things being equal, this simpler paradigm should be preferred in practice. [4]

2.4 Beam Search Extension

We also enhance deterministic shift-reduce parsing with beam search, similar to Zhang and Clark (2008), where k configurations develop in parallel. Pseudocode 1 illustrates the algorithm, where we keep an agenda $\mathbf{V}$ of the current active configurations, and at each step try to extend them by applying one of the three actions. We then dump the best k new configurations from the buffer back

[4] On the other hand, there are also arguments for "arc-eager", e.g., "incrementality"; see (Nivre, 2004; Nivre, 2008).

Pseudocode 1 beam-search shift-reduce parsing.

Input: POS-tagged word sequence $w_1 \dots w_n$
$start \leftarrow \langle \emptyset, w_1 \dots w_n, \emptyset \rangle$ ▷ initial config: empty stack, no arcs
$\mathbf{V} \leftarrow \{start\}$ ▷ initial agenda
for $step \leftarrow 1 \dots 2n-1$ **do**
  $\mathbf{BUF} \leftarrow \emptyset$ ▷ buffer for new configs
  for each $config$ in agenda $\mathbf{V}$ **do**
    for $act \in \{\text{shift}, \text{reduce}_\text{L}, \text{reduce}_\text{R}\}$ **do**
      if act is applicable to $config$ **then**
        $next \leftarrow$ apply act to $config$
        insert $next$ into buffer $\mathbf{BUF}$
  $\mathbf{V} \leftarrow$ top k configurations of $\mathbf{BUF}$
Output: the tree of the best config in $\mathbf{V}$

into the agenda for the next step. The complexity of this algorithm is $O(nk)$, which subsumes the determinstic mode as a special case ($k = 1$).

2.5 Online Training

To train the parser we need an "oracle" or gold-standard action sequence for gold-standard dependency trees. This oracle turns out to be *non-unique* for the three-action system (also non-unique for the four-action system), because left dependents of a head can be reduced either before or after all right dependents are reduced. For example, in Figure 2, "I" is a left dependent of "saw", and can in principle wait until "Bill" and "with" are reduced, and then finally combine with "saw". We choose to use the heuristic of "shortest stack" that always prefers reduce_L over shift, which has the effect that all left dependents are first recognized inside-out, followed by all right dependents, also inside-out, which coincides with the head-driven constituency parsing model of Collins (1999).

We use the popular online learning algorithm of structured perceptron with parameter averaging (Collins, 2002). Following Collins and Roark (2004) we also use the "early-update" strategy, where an update happens whenever the gold-standard action-sequence falls off the beam, with the rest of the sequence neglected. As a special case, for the deterministic mode, updates always co-occur with the first mistake made. The intuition behind this strategy is that future mistakes are often caused by previous ones, so with the parser on the wrong track, future actions become irrelevant for learning. See Section 5.3 for more discussions.

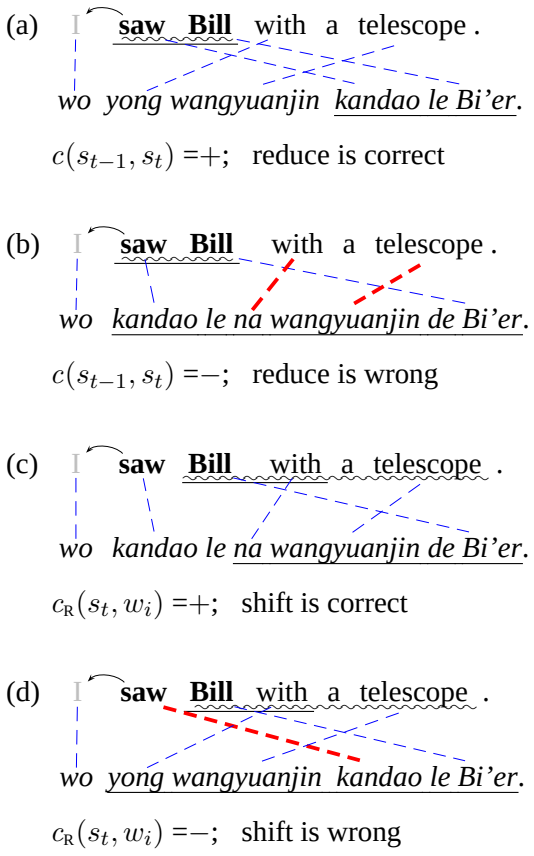

Figure 3: Bilingual contiguity features $c(s_{t-1}, s_t)$ and $c_\text{R}(s_t, w_i)$ at step (4) in Fig. 2 (facing a shift-reduce decision). Bold words are currently on stack while gray ones have been popped. Here the stack tops are s_t = **Bill**, s_{t-1} = **saw**, and the queue head is w_i = with; underlined texts mark the source and target spans being considered, and wavy underlines mark the *allowed spans* (Tab. 3). Red bold alignment links violate contiguity constraints.

3 Soft Bilingual Constraints as Features

As suggested in Section 2.2, shift-reduce conflicts are the central problem we need to address here. Our intuition is, whenever we face a decision whether to combine the stack tops s_{t-1} and s_t or to shift the current word w_i, we will consult the other language, where the word-alignment information would hopefully provide a preference, as in the running example of PP-attachment (see Figure 1). We now develop this idea into *bilingual contiguity features*.

3.1 A Pro-Reduce Feature $c(s_{t-1}, s_t)$

Informally, if the correct decision is a reduction, then it is likely that the corresponding words of s_{t-1} and s_t on the target-side should also form a contiguous span. For example, in Figure 3(a), the source span of a reduction is [saw .. Bill], which maps onto [*kandao . . . Bi'er*] on the Chinese side. This target span is contiguous, because no word within this span is aligned to a source word outside of the source span. In this case we say feature $c(s_{t-1}, s_t)$ =+, which encourages "reduce".

However, in Figure 3(b), the source span is still [saw .. Bill], but this time maps onto a much longer span on the Chinese side. This target span is discontiguous, since the Chinese words *na* and *wangyuanjin* are alinged to English "with" and "telescope", both of which fall outside of the source span. In this case we say feature $c(s_{t-1}, s_t)$ =−, which discourages "reduce" .

3.2 A Pro-Shift Feature $c_{\text{R}}(s_t, w_i)$

Similarly, we can develop another feature $c_{\text{R}}(s_t, w_i)$ for the shift action. In Figure 3(c), when considering shifting "with", the source span becomes [Bill .. with] which maps to [*na .. Bi'er*] on the Chinese side. This target span looks like discontiguous in the above definition with *wangyuanjin* aligned to "telescope", but we tolerate this case for the following reasons. There is a crucial difference between shift and reduce: in a shift, we do not know yet the subtree spans (unlike in a reduce we are always combining two well-formed subtrees). The only thing we are sure of in a shift action is that s_t and w_i will be combined *before* s_{t-1} and s_t are combined (Aho and Ullman, 1972), so we can tolerate any target word aligned to source word still in the queue, but do not allow any target word aligned to an already recognized source word. This explains the notational difference between $c_{\text{R}}(s_t, w_i)$ and $c(s_{t-1}, s_t)$, where subscript "R" means "right contiguity".

As a final example, in Figure 3(d), Chinese word *kandao* aligns to "saw", which is already recognized, and this violates the right contiguity. So $c_{\text{R}}(s_t, w_i)$ =−, suggesting that shift is probably wrong. To be more precise, Table 3 shows the formal definitions of the two features. We basically map a source span sp to its target span $M(sp)$, and check whether its reverse image back onto the source language $M^{-1}(M(sp))$ falls inside the allowed span ap. For $c_{\text{R}}(s_t, w_i)$, the allowed span extends to the right end of the sentence.[5]

feature f	source span sp	target span tp	allowed span ap
$c(s_{t-1}, s_t)$	$[s_{t-1}..s_t]$	$M(sp)$	$[s_{t-1}..s_t]$
$c_{\text{R}}(s_t, w_i)$	$[s_t..w_i]$	$M(sp)$	$[s_t..w_n]$
$f = +$	iff. $M^{-1}(M(sp)) \subseteq ap$		

Table 3: Formal definition of bilingual features. $M(\cdot)$ is maps a source span to the target language, and $M^{-1}(\cdot)$ is the reverse operation mapping back to the source language.

3.3 Variations and Implementation

To conclude so far, we have got two alignment-based features, $c(s_{t-1}, s_t)$ correlating with reduce, and $c_{\text{R}}(s_t, w_i)$ correlating with shift. In fact, the conjunction of these two features,

$$c(s_{t-1}, s_t) \circ c_{\text{R}}(s_t, w_i)$$

is another feature with even stronger discrimination power. If

$$c(s_{t-1}, s_t) \circ c_{\text{R}}(s_t, w_i) = + \circ -$$

it is strongly recommending reduce, while

$$c(s_{t-1}, s_t) \circ c_{\text{R}}(s_t, w_i) = - \circ +$$

is a very strong signal for shift. So in total we got three bilingual feature (templates), which in practice amounts to 24 instances (after cross-product with $\{-, +\}$ and the three actions). We show in Section 5.3 that these features do correlate with the correct shift/reduce actions in practice.

The naive implemention of bilingual feature computation would be of $O(kn^2)$ complexity in the worse case because when combining the largest spans one has to scan over the whole sentence. We envision the use of a clever datastructure would reduce the complexity, but leave this to future work, as the experiments (Table 8) show that

[5] Our definition implies that we only consider *faithful* spans to be contiguous (Galley et al., 2004). Also note that source spans include all dependents of s_t and s_{t-1}.

the parser is only marginally (∼6%) slower with the new bilingual features. This is because the extra work, with just 3 bilingual features, is not the bottleneck in practice, since the extraction of the vast amount of other features in Table 2 dominates the computation.

4 Related Work in Grammar Induction

Besides those cited in Section 1, there are some other related work on using bilingual constraints for grammar induction (rather than parsing). For example, Hwa et al. (2005) use simple heuristics to project English trees to Spanish and Chinese, but get discouraging accuracy results learned from those projected trees. Following this idea, Ganchev et al. (2009) and Smith and Eisner (2009) use constrained EM and parser adaptation techniques, respectively, to perform more principled projection, and both achieve encouraging results.

Our work, by constrast, never uses bilingual tree pairs not tree projections, and only uses word alignment alone to enhance a monolingual grammar, which learns to prefer target-side contiguity.

5 Experiments

5.1 Baseline Parser

We implement our baseline monolingual parser (in C++) based on the shift-reduce algorithm in Section 2, with feature templates from Table 2. We evaluate its performance on the standard Penn English Treebank (PTB) dependency parsing task, i.e., train on sections 02-21 and test on section 23 with automatically assigned POS tags (at 97.2% accuracy) using a tagger similar to Collins (2002), and using the headrules of Yamada and Matsumoto (2003) for conversion into dependency trees. We use section 22 as dev set to determine the optimal number of iterations in perceptron training. Table 4 compares our baseline against the state-of-the-art graph-based (McDonald et al., 2005) and transition-based (Zhang and Clark, 2008) approaches, and confirms that our system performs at the same level with those state-of-the-art, and runs extremely fast in the deterministic mode (k=1), and still quite fast in the beam-search mode (k=16).

parser	accuracy	secs/sent
McDonald et al. (2005)	90.7	0.150
Zhang and Clark (2008)	91.4	0.195
our baseline at k=1	90.2	0.009
our baseline at k=16	91.3	0.125

Table 4: Baseline parser performance on standard Penn English Treebank dependency parsing task. The speed numbers are not exactly comparable since they are reported on different machines.

	Training	Dev	Test
CTB Articles	1-270	301-325	271-300
Bilingual Paris	2745	273	290

Table 5: Training, dev, and test sets from bilingual Chinese Treebank à la Burkett and Klein (2008).

5.2 Bilingual Data

The bilingual data we use is the translated portion of the Penn Chinese Treebank (CTB) (Xue et al., 2002), corresponding to articles 1-325 of PTB, which have English translations with gold-standard parse trees (Bies et al., 2007). Table 5 shows the split of this data into training, development, and test subsets according to Burkett and Klein (2008). Note that not all sentence pairs could be included, since many of them are not one-to-one aligned at the sentence level. Our word-alignments are generated from the HMM aligner of Liang et al. (2006) trained on approximately 1.7M sentence pairs (provided to us by David Burkett, p.c.). This aligner outputs "soft alignments", i.e., posterior probabilities for each source-target word pair. We use a pruning threshold of 0.535 to remove low-confidence alignment links,[6] and use the remaining links as hard alignments; we leave the use of alignment probabilities to future work.

For simplicity reasons, in the following experiments we always supply gold-standard POS tags as part of the input to the parser.

5.3 Testing our Hypotheses

Before evaluating our bilingual approach, we need to verify empirically the two assumptions we made about the parser in Sections 2 and 3:

[6] and also removing notoriously bad links in $\{\text{the, a, an}\} \times \{de, le\}$ following Fossum and Knight (2008).

	sh ▷ re	re ▷ sh	sh-re	re-re
#	92	98	190	7
%	46.7%	49.7%	**96.4%**	**3.6%**

Table 6: [Hypothesis 1] Error distribution in the baseline model ($k = 1$) on English dev set. "sh ▷ re" means "should shift, but reduced". Shift-reduce conflicts overwhelmingly dominate.

1. (monolingual) shift-reduce conflict is the major source of errors while reduce-reduce conflict is a minor issue;

2. (bilingual) the gold-standard decisions of shift or reduce should correlate with contiguities of $c(s_{t-1}, s_t)$, and of $c_{\text{R}}(s_t, w_i)$.

Hypothesis 1 is verified in Table 6, where we count all the *first mistakes* the baseline parser makes (in the deterministic mode) on the English dev set (273 sentences). In shift-reduce parsing, further mistakes are often caused by previous ones, so only the first mistake in each sentence (if there is one) is easily identifiable;[7] this is also the argument for "early update" in applying perceptron learning to these incremental parsing algorithms (Collins and Roark, 2004) (see also Section 2). Among the 197 first mistakes (other 76 sentences have perfect output), the vast majority, 190 of them (96.4%), are shift-reduce errors (equally distributed between shift-becomes-reduce and reduce-becomes-shift), and only 7 (3.6%) are due to reduce-reduce conflicts.[8] These statistics confirm our intuition that shift-reduce decisions are much harder to make during parsing, and contribute to the overwhelming majority of errors, which is studied in the next hypothesis.

Hypothesis 2 is verified in Table 7. We take the gold-standard shift-reduce sequence on the English dev set, and classify them into the four categories based on bilingual contiguity features: (a) $c(s_{t-1}, s_t)$, i.e. whether the top 2 spans on stack is contiguous, and (b) $c_{\text{R}}(s_t, w_i)$, i.e. whether the stack top is contiguous with the current word w_i. According to discussions in Section 3, when (a) is contiguous and (b) is not, it is a clear signal for reduce (to combine the top two elements on the stack) rather than shift, and is strongly supported by the data (first line: 1209 reduces vs. 172 shifts); and while when (b) is contiguous and (a) is not, it should suggest shift (combining s_t and w_i before s_{t-1} and s_t are combined) rather than reduce, and is mildly supported by the data (second line: 1432 shifts vs. 805 reduces). When (a) and (b) are both contiguous or both discontiguous, it should be considered a neutral signal, and is also consistent with the data (next two lines). So to conclude, this bilingual hypothesis is empirically justified.

$c(s_{t-1}, s_t)$	$c_{\text{R}}(s_t, w_i)$	shift		reduce
$+$	$-$	172	$\ll$	1,209
$-$	$+$	1,432	$>$	805
$+$	$+$	4,430	$\sim$	3,696
$-$	$-$	525	$\sim$	576
total		6,559	$=$	6,286

Table 7: [Hyp. 2] Correlation of *gold-standard* shift/reduce decisions with bilingual contiguity conditions (on English dev set). Note there is always one more shift than reduce in each sentence.

On the other hand, we would like to note that these correlations are done with *automatic* word alignments (in our case, from the Berkeley aligner) which can be quite noisy. We suspect (and will finish in the future work) that using *manual* alignments would result in a better correlation, though for the main parsing results (see below) we can only afford automatic alignments in order for our approach to be widely applicable to *any* bitext.

5.4 Results

We incorporate the three bilingual features (again, with automatic alignments) into the baseline parser, retrain it, and test its performance on the English dev set, with varying beam size. Table 8 shows that bilingual constraints help more with larger beams, from almost no improvement with the deterministic mode (k=1) to +0.5% better with the largest beam (k=16). This could be explained by the fact that beam-search is more robust than the deterministic mode, where in the latter, if our

[7] to be really precise one can define "*independent mistakes*" as those not affected by previous ones, i.e., errors made after the parser *recovers* from previous mistakes; but this is much more involved and we leave it to future work.

[8] Note that shift-reduce errors include those due to the non-uniqueness of oracle, i.e., between some reduce_{L} and shift. Currently we are unable to identify "genuine" errors that would result in an incorrect parse. See also Section 2.5.

	baseline		+bilingual	
k	accuracy	time (s)	accuracy	time (s)
1	84.58	0.011	84.67	0.012
2	85.30	0.025	85.62	0.028
4	85.42	0.040	85.81	0.044
8	85.50	0.081	85.95	0.085
16	85.57	0.158	86.07	0.168

Table 8: Effects of beam size k on efficiency and accuracy (on English dev set). Time is average per sentence (in secs). Bilingual constraints show more improvement with larger beams, with a fractional efficiency overhead over the baseline.

	English	Chinese
monolingual baseline	86.9	85.7
+bilingual features	**87.5**	**86.3**
improvement	+0.6	+0.6
signficance level	$p < 0.05$	$p < 0.08$
Berkeley parser	86.1	87.9

Table 9: Final results of dependency accuracy (%) on the test set (290 sentences, beam size k=16).

bilingual features misled the parser into a mistake, there is no chance of getting back, while in the former multiple configurations are being pursued in parallel. In terms of speed, both parsers run proportionally slower with larger beams, as the time complexity is linear to the beam-size. Computing the bilingual features further slows it down, but only fractionally so (just 1.06 times as slow as the baseline at k=16), which is appealing in practice. By contrast, Burkett and Klein (2008) reported their approach of "monolingual k-best parsing followed by bilingual k^2-best reranking" to be "3.8 times slower" than monolingual parsing.

Our final results on the test set (290 sentences) are summarized in Table 9. On both English and Chinese, the addition of bilingual features improves dependency arc accuracies by +0.6%, which is mildly significant using the Z-test of Collins et al. (2005). We also compare our results against the Berkeley parser (Petrov and Klein, 2007) as a reference system, with the exact same setting (i.e., trained on the bilingual data, and testing using gold-standard POS tags), and the resulting trees are converted into dependency via the same headrules. We use 5 iterations of split-merge grammar induction as the 6th iteration overfits the small training set. The result is worse than our baseline on English, but better than our bilingual parser on Chinese. The discrepancy between English and Chinese is probably due to the fact that our baseline feature templates (Table 2) are engineered on English not Chinese.

6 Conclusion and Future Work

We have presented a novel parsing paradigm, *bilingually-constrained monolingual parsing*, which is much simpler than joint (bi-)parsing, yet still yields mild improvements in parsing accuracy in our preliminary experiments. Specifically, we showed a simple method of incorporating alignment features as soft evidence on top of a state-of-the-art shift-reduce dependency parser, which helped better resolve shift-reduce conflicts with fractional efficiency overhead.

The fact that we managed to do this with only three alignment features is on one hand encouraging, but on the other hand leaving the bilingual feature space largely unexplored. So we will engineer more such features, especially with lexicalization and soft alignments (Liang et al., 2006), and study the impact of alignment quality on parsing improvement. From a linguistics point of view, we would like to see how *linguistics distance* affects this approach, e.g., we suspect English-French would not help each other as much as English-Chinese do; and it would be very interesting to see what types of syntactic ambiguities can be resolved across different language pairs. Furthermore, we believe this bilingual-monolingual approach can easily transfer to shift-reduce constituency parsing (Sagae and Lavie, 2006).

Abstract

There have been considerable attempts to incorporate semantic knowledge into coreference resolution systems: different knowledge sources such as WordNet and Wikipedia have been used to boost the performance. In this paper, we propose new ways to extract WordNet feature. This feature, along with other features such as named entity feature, can be used to build an accurate *semantic class* (SC) classifier. In addition, we analyze the SC classification errors and propose to use relaxed SC agreement features. The proposed accurate SC classifier and the relaxation of SC agreement features on ACE2 coreference evaluation can boost our baseline system by 10.4% and 9.7% using MUC score and anaphor accuracy respectively.

1 Introduction

Coreference resolution is used to determine which noun phrases (including pronouns, proper names, and common nouns) refer to the same entities in documents. Much work on coreference resolution is based on (Soon et al., 2001), which built a decision tree classifier to label pairs of mentions as coreferent or not. Recent work aims to improve the performance from two aspects: new models and new features. The former cast the pair wise mention classifications into various forms such as the best path in a Bell tree (Luo et al., 2004), the best graph cut (Nicolae and Nicolae, 2006), integer linear programming (Denis and Baldridge, 2007) and graph partition based conditional model (McCallum and Wellner, 2004). The latter develop and investigate new linguistic features for the problem. For instance, WordNet (Poesio et al., 2004), Wikipedia (Ponzetto and Strube, 2006), semantic neighbor words (Ng, 2007a), and pattern based features (Yang and Su, 2007) have been extensively studied.

Deeper linguistic knowledge is required to enable the coreference resolution to reach a higher level of performance (Kehler et al., 2004). An important type of semantic knowledge that has been employed in coreference resolution system is the semantic class (SC) of an NP, which can be used to filter out the coreference between semantically incompatible NPs. However, the difficulty is to accurately compute the semantic class features. In this paper, we show that the WordNet may not be efficiently employed in the traditional way such as (Soon et al., 2001; Ng, 2007a; Ponzetto and Strube, 2006) to compute the semantic class features. We introduce new ways to use the WordNet and the experiments show its effectiveness in determining the semantic classes for noun phrases. In addition, we analyze the classification errors of the SC classifier and propose to use relaxed SC agreement features. With these proposed features and other standard syntactic features (which are commonly employed in existing coreference systems), our coreference resolution system can obtain an increase of 10.4% for MUC score and 9.7% for anaphor accuracy from the baseline in ACE2 evaluation.

2 Related Work

WordNet (Fellbaum, 1998) as an important knowledge source has been widely employed in previous coreference resolution work. For example, Harabagiu et al. (2001) have used WordNet relations such as synonym and is-a to mine the patterns of WordNet paths for pairs of antecedents and anaphors. Due to the nature of the rule based coreference system (in contrast to machine learning based), the weights of relations may not be accurately estimated. Vieira and Poesio (2000) and Markert and Nissim (2005) have used WordNet synonym and hyponym etc. to determine if an anaphor semantically relates to one previous NP. Ponzetto and Strube (2006) have used WordNet semantic similarity and relatedness scores between antecedents and candidate anaphors. Their

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1232–1240,
Singapore, 6-7 August 2009.

work is different to this work in the following: 1) Their work involves various relations such as hyponyms and meronyms while ours only makes use of hypernyms; and 2) Their work focuses on investigating if two NPs have particular WordNet relations or not, while ours focuses on using WordNet hypernyms for their SC classification and then testing their SC compatibility. In doing so, we can directly model the accuracy of semantic class classification and test its impact on coreference resolution.

While the SC of a proper name is computed fairly accurately using a named entity (NE) recognizer, many coreference resolution systems simply assign to a common noun the first (i.e., most frequent) WordNet synset as its SC (Soon et al., 2001; Markert and Nissim, 2005). This heuristics, apparently, did not lead to good performance. The best reported ACE2 coreference resolution system (Ng, 2007a; Ng, 2007b) has proposed an accurate SC classifier which used heterogeneous semantic knowledge sources. WordNet is just one of the several knowledge sources which have been utilized. However, the WordNet based features is not informative compared to other features such as the semantic neighbor feature. Similarly, Ponzetto and Strube (2006) have discovered that the WordNet feature is no more informative than the community-generated Wikipedia feature. In this paper, we focus on the investigation of various usages of WordNet for the SC classification task. The work which is directly comparable to ours would be (Ng, 2007a; Ng, 2007b).

Other similar work includes the *mention detection* (MD) task (Florian et al., 2006) and joint probabilistic model of coreference (Daumé III and Marcu, 2005). The MD task identifies the boundary of a mention, its mention type (e.g., pronoun, name), and its semantic type (e.g., person, organization). Unlike them, we do not perform the boundary detection, as we make use of the noun phrases directly from the noun phrase chunker and NE recognizer. The joint probabilistic model models the MD and coreference simultaneously, while our work focuses on them separately.

3 Semantic Class Classification

In this section, we describe how we compile the training corpus and extract features using WordNet. We report our results on the ACE coreference corpus due to that it has been commonly used and it was annotated SCs of six types.[1] As in (Ng, 2007a), we first train a classifier to predict the SC of an NP. This SC information is used later in the coreference resolution stage. For example, *the audience* is classified as SC of *person*, and it thus should not be coreferent with *the security industry*, which is usually classified as *organization*. This task is by no means trivial. First, while the classification of *Tom Hanks* being SC of *person* can be accurately achieved by an NE recognizer, the association of *audience* and *person* requires semantic language source such as WordNet. Second, the same noun phrase can be annotated with different SCs under different context. For example, *the authorities* is usually annotated as *person*, but it is sometimes as *organization*. Even worse, the same noun phrases are sometimes annotated with one of the five explicitly annotated classes while sometimes are not annotated at all (thus falling into the other SC). For example, *people* is annotated as *person* SC explicitly 20 times and is not annotated at all 21 times in the ACE2 testset. This inconsistent annotation adversely affects the performance of an SC classifier. And this in turn would cause errors during coreference stage. In section 4.3, we show how to relax the strict SC agreement feature to address this.

3.1 Training instance creation

We use ACE Phase 2 Coreference corpus to train the SC classifier. Each noun phrase which is identified by the noun phrase chunker or NE recognizer is used to create a training instance. Each instance is represented by a set of lexical, syntactic and semantic features, as described below. If the NP under consideration is annotated as one of the five ACE SCs in the corpus, then the classification of the associated training instance is the ACE SC of the NP. Otherwise, the instance is labeled as other.

ACE 2 corpus has a training set and a test set which comprise of 422 and 97 texts respectively. We divide the training set into a new training and a development set: the former consists of 90% randomly generated and stratified original training instances and the latter consists of the rest 10% instances. The test set remains the same as in ACE2 corpus. The size of each dataset and its SC distributions are shown in Table 1. Note that the training and development datasets have exactly the same distributions of SCs due to the stratification procedure. That is, each class has the same proportion in training and development datasets. We tune the feature parameters against development set and report performance on both development set and test set.

[1] Person, organization, gpe, location and facility are explicitly annotated. The rest noun phrases are other type.

Table 1: Distributions of SCs in ACE2 corpus.

	Size	PER	ORG	GPE	FAC	LOC	OTH
Train	55629	20.29	7.30	8.42	0.61	0.55	62.80
Dev	6181	20.29	7.30	8.42	0.61	0.55	62.80
Test	15360	20.48	7.57	6.90	0.85	0.41	63.79

3.2 Lexical features

Each instance is represented as a bag of features and is fed into a classifier in training stage. We present four binary lexical feature sets as follows.

Word unigrams and bigrams: An N-gram is a sub-sequence of N words from a given noun phrase. Unigram forms the bag of words feature, and bigram forms the pairs of words feature, and so forth. We have considered word unigram and bigram features in our experiments.

First and last words: This feature extracts the first and last words of an NP. For example, the first word *the* and the last word *store* are extracted from the NP *the main store*. This feature does not only coarsely models the influence of the first word, for example, *a* or *the*, but also models the head word, since the head word usually is the last word in the NP.

Head word: We use Collins style rules (Collins, 1999) to extract the head words for given NPs. These features should be most informative if the training corpus is large enough.[2] For example, the head word *company* of the NP *the company* immediately determines its SC being *organization*. However, due to the sparseness of training data, its potential importance is adversely affected.

3.3 Semantic features

NE feature is extracted from Stanford named entity recognizer (NER) (Finkel et al., 2005). Three types of named entities: person, location and organization can be recognized for a given NP. This feature is primarily useful for SC classification of proper nouns.

WordNet is a large English lexicon in which semantically related words are connected via cognitive synonyms (synsets). The WordNet is a useful tool for word semantics analysis and has been widely used in natural language processing applications. In WordNet, synsets are organized into hierarchies with hypernym/hyponym relationships: Y is a hypernym of X if every X is a (kind of) Y (X is called a hyponym of Y in this case).

The WordNet is employed in (Ng, 2007a) as following to create the **WN_CLASS** feature. For each keyword w as shown in the right column of Table 2, if the head noun of a given NP is a hyponym of w in WordNet,[3] then the word w becomes a feature for such NP. It is explained that these keywords are correlated with the ACE SCs and they are obtained via experimentation with WordNet and the ACE SCs of the NPs in the ACE training data. However, it is likely that these handcrafted keywords have poor coverage for general cases. As a result, it may not make full use of WordNet semantic knowledge. This will be shown in our individual feature contribution experiment in Section 3.5.

Table 2: List of keywords used in WordNet semantic feature in (Ng, 2007a).

ACE SC	Keywords
PER	person
ORG	social group
FAC	establishment, construction, building, facility, workplace
GPE	country, province, government, town, city, administration, society, island, community
LOC	dry land, region, landmass, body of water geographical area, geological formation

There are other ways of using WordNet for semantic feature extraction. For example, Ponzetto and Strube (2006) have employed WordNet similarity measure for coreference resolution. The difference is that they created the feature directly at the coreference resolution stage, ie, using the WordNet similarity between the antecedent and anaphor to determine if they are coreferent, while we focus on using this feature to classify an NP into a particular SC. For comparison, we implemented a WordNet similarity based feature (**WN_SIM**) as follows: for a given NP head word and a key word as listed in Table 2, the WordNet similarity package (Seco et al., 2004) models the length of path traveling from the head word to the key word over the WordNet network. It then computes the semantic similarity based on the path. For example, the similarity between *company* and *social group* is 0.77, while the similarity between *company* and *person* is 0.59. The key word which receives the highest similarity to the head word is marked as a feature.

The WN_CLASS feature may suffer from the coverage problem and the WN_SIM feature is heavily dependent on the definition of similarity metric which may turn out to be inappropriate for coreference resolution task. To make better use of WordNet knowledge, we attempt to directly introduce hypernyms for the NP head words (we denote

[2] It, however, is mostly useful for nominal noun phrase and not for the pronoun and proper noun phrases.

[3] Only the first synset of the NP is used.

it as **WN_HYP** feature). The most similar work to ours is (Daumé III and Marcu, 2005), in which two most common synsets from WordNet for *all* words in an NP and their hypernyms are extracted as features. We avoid augmenting the hypernyms for non-head words in the NP to prevent introducing noisy information, which may potentially corrupt the hypernym feature space.

Considering a WordNet hypernym structure as shown in Fig. 1 for the word *company*, its first synset (an institution created to conduct business) has a unique id of 08058098 and can also be represented by a set of description words (company in this case). Its third synset (the state of being with someone) has an id of 13929588 and description words of company, companionship, fellowship, society. Each synset can be extended by its hypernym synsets. For example, the direct hypernym of the first synset is the synset of 08053576 which can be described as institution, establishment. The augmentation of hypernyms for NP head words can introduce useful information, but can also bring noise if the head word or the synset of head word are not correctly identified. For an optimal use of WordNet hypernyms, four questions shall be addressed: 1) how many depths are required to tradeoff the generality (thus more informative) and the specificity (thus less noisy)? 2) which synset of the given word is needed to be augmented? 3) which representation (synset id or synset word) is better? and 4) is it helpful to encode the hypernym depth into the hypernym feature?[4] These four questions provide the guideline to search the optimal use of WordNet. We will design experiments in Section 3.5 to determine the optimal configuration of WN_HYP feature.

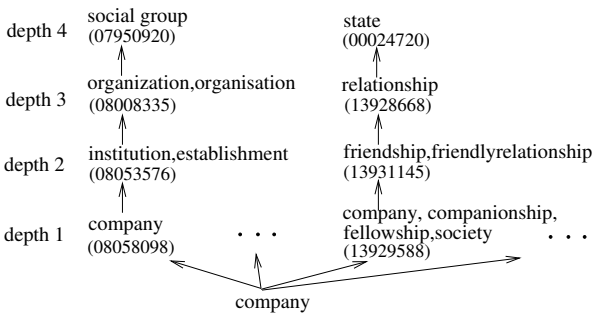

Figure 1: WordNet hypernym hierarchy for the word *company*.

[4]For example, we encode the synset 08053576 as 08053576-1, with the last digit 1 indicating the depth of hypernym with regard to the entry word *company*.

3.4 Learning algorithm

Maximum entropy (ME) models (Berger et al., 1996; Manning and Klein, 2003), also known as log-linear and exponential learning models, has been adopted in the SC classification task. Maximum entropy models can integrate features from many heterogeneous information sources for classification. Each feature corresponds to a constraint on the model. Given a training set of (C, D), where C is a set of class labels and D is a set of feature represented data points, the maximum entropy model attempts to maximize the log likelihood

$$\log P(C|D,\lambda) = \sum_{(c,d)\in(C,D)} \log \frac{\exp \sum_i \lambda_i f_i(c,d)}{\sum_{c'} \exp \sum_j \lambda_j f_i(c,d)} \quad (1)$$

where $f_i(c,d)$ are feature indicator functions and λ_i are the parameters to be estimated. We use ME models for both SC classification and mention pair classification.

3.5 SC classification evaluation

We design three experiments to test the accuracy of our classifiers. The first experiment evaluates the individual contribution of different feature sets to SC classification accuracy. In particular, a ME model is trained on the 55,629 training instances using the following feature sets separately: 1) unigram, 2) bigram, 3) first-last word, 4) head word (HW), 5) named entities (NE), 6) HW+WN_CLASS, 7) HW+WN_SIM, and 8) variants of HW+WN_HYP. Note that HW+WN_CLASS is the semantic feature used in (Ng, 2007a), HW+WN_SIM is the semantic feature using WordNet similarity measure (Seco et al., 2004), and variants of HW+WN_HYP are the work proposed in this paper. We combine head word and the semantic features due to the fact that WordNet features are dependent on head words and they could be treated as units. In the second experiment, features are fed into the ME model incrementally until all features have been used.[5] Finally, we perform the feature ablation experiments. That is, we remove one feature at a time from the entire feature set and test the accuracy loss. The SC classification performance is measured by accuracy, i.e., the proportion of the correctly classified instances among all test instances.

Individual feature contribution Table 3 shows the SC classification accuracy of all NPs (all) and non-pronoun NPs (non-PN) on the development and test datasets using individual feature

[5]The optimal of HW+WN_HYP configuration is used.

sets. Among all the lexical features, unigram feature performs the best (81.3%) for all NPs over the development dataset. The bigram feature performs poorly due to the sparsity problem: NPs usually consist of one to three words. The first-last word feature effectively models the prefix words (such as *a* and *the*) and the head words and thus obtains a reasonably high accuracy of 80.1%. As mentioned before, the head word feature may suffer from the sparsity and it results in the accuracy of 78.2%. We also list the accuracies for non-pronoun NP SC classification, which are slightly different compared to all NP SC classification except for bigram, in which the accuracy has increased 3.9%.

Table 3: SC classification accuracy of ME using individual feature sets for development and test ACE2 datasets.

Feature type	dev		test	
	all	non-PN	all	non-PN
unigram	81.3	81.6	72.4	71.9
bigram	32.5	36.4	26.3	28.4
first-last word	80.1	80.2	71.6	71.0
HW	78.2	78.0	68.3	67.1
NE	74.0	82.8	73.1	81.9
HW+WN_CLASS	79.5	79.4	70.3	69.5
HW+WN_SIM	81.2	81.4	73.8	73.6
HW+WN_HYP (1)	82.6	83.1	74.8	74.7
HW+WN_HYP (3)	82.8	83.4	75.2	75.2
HW+WN_HYP (6)	**83.1**	83.7	75.6	75.7
HW+WN_HYP (9)	83.0	83.6	75.7	75.7
HW+WN_HYP (∞)	83.1	83.7	75.8	75.9
HW+WN_HYP (6) word form	82.8	83.3	75.6	75.7
HW+WN_HYP (6) depth encoded	82.9	83.5	75.4	75.4
HW+WN_HYP (6) first synset	83.0	83.6	76.4	76.6

Although Stanford NER performs well on named entity recognition task, it results in accuracy of 74.0% for all NP SC classification, due to its inability to deal with pronouns such as *he* and common nouns such as *the government*. The removal of pronouns significantly boosts its accuracy to 82.8%. The introduction of semantic feature HW+WN_CLASS boosts the performance to 79.5% compared to the head word alone of 78.2%. This conforms to (Ng, 2007a) that only small gain can be achieved using WN_CLASS feature. The HW+WN_SIM feature outperforms HW+WN_CLASS and the accuracy reaches 81.2%. For the variants of HW+WN_HYP, we first search the optimal depth. This is performed by using all synsets for NP head word, encoding the feature using synset id (rather than synset word), and no hypernym depth is encoded in the features. We try various depths of 1, 3, 6, 9 and ∞, with ∞ signifies that no depth constraint is imposed. The optimal depth of 6 is obtained with the accuracy of 83.1% over the development dataset. We then fix the depth of 6 to try using synset word as features, using synset id with depth encoded as features, and using first synset only. The results show that the optimum is to encode the features using hypernym synset id without hypernym depth information and all synsets are considered for hypernym extraction. This is slightly different from the previous finding (Soon et al., 2001; Lin, 1998b) that a coreference resolution system employing only the first WordNet synset performs slightly better than that employing more than one synset.[6] The best result reaches the accuracy of 83.1%. Although the best semantic feature only outperforms the best lexical feature by 1.8% on the development dataset, its gain in the test dataset is more significant (3.2%, from 72.4% to 75.6%).

Incremental feature contribution Once we use the training and development datasets to find the optimal configuration of HW+WN_HYP semantic feature, we use all lexical features and the optimal HW+WN_HYP feature incrementally to train an ME model over the combination of training and development datasets. Table 4 shows the SC classification accuracy of all NPs (all) and non-pronoun NPs (non-PN) on the training+development (we refer it as training hereafter) and test datasets.

Table 4: SC classification accuracy of ME using incremental feature sets for training and test ACE2 datasets.

Feature type	train		test	
	all	non-PN	all	non-PN
HW	87.8	89.0	68.6	67.6
+WN_HYP	87.8	89.0	75.7	75.8
+unigram	91.5	93.3	77.7	78.1
+bigram	93.1	95.2	78.7	79.2
+first-last word	93.2	95.3	78.8	79.3
+NE	93.4	95.6	**83.1**	**84.4**
Ng 2007a	-	85.0	-	83.3

Note that the significant higher accuracies in training compared to test are due to the overfitting problem. The interesting evaluation thus remains on the test data. As can be seen, the inclusion of more features results in higher performance. This is more obvious in the test dataset than in the training dataset. The inclusion of the

[6] In fact, the accuracy of the test data supports their claims. The accuracy using the first synset compared to using all synsets results in the accuracy increase from 75.6% to 76.4% for all NPs over the test dataset.

optimized WN_HYP feature (ie, using all synsets' hypernyms up to 6 depth and with synset id encoding) results in 7.1% increase for all NP SC classification over test data. This shows the effectiveness of the WN_HYP features to overcome the sparsity of head word feature. The unigram, bigram and first-last word features offer reasonable accuracy gain, and the final inclusion of NE boosts the overall performance to 83.1% for all NP and 84.4% for non pronoun NPs over test data. This result can be directly compared to the SC classification accuracy as reported in (Ng, 2007a), in which the highest accuracy is 83.3% for non pronoun NPs.[7] The large difference between the highest training accuracies is due to that our classifier is trained directly on the ACE2 training dataset, while their SC classifier was trained on BBN Entity Type Corpus (Weischedel and Brunstein, 2005), which is five times larger than the ACE2 corpus used by us. In addition to WordNet, they have adopted multiple knowledge sources which include BBN's IdentiFinder (this is equivalent to the Stanford NER in our work), BLLIP corpus and Reuters Corpus,[8] and dependency based thesaurus (Lin, 1998a). It is remarkable that our SC classifier can achieve even higher accuracy only using WordNet hypernym and NE features. It is worth noting that the small accuracy gain is indeed hard to achieve considering that the test data size is large (15360).

Feature ablation experiment We now perform the feature ablation experiments to further determine the importance of individual features. We remove one feature at a time from the entire feature set. Table 5 shows the SC classification accuracy of all NPs (all) and non-pronoun NPs (non-PN) on the training and test datasets respectively.

Table 5: SC classification accuracy of ME by removing one feature at a time for training and test ACE2 datasets.

Feature type	train		test	
	all	non-PN	all	non-PN
overall	93.4	95.6	83.1	84.4
-HW	93.4	95.5	82.9	84.2
-WN_HYP	93.4	95.5	82.6	83.8
-HW+WN_HYP	93.4	95.5	82.3	83.5
-unigram	93.4	95.5	82.9	84.2
-bigram	92.5	94.5	82.7	84.0
-first-last word	93.4	95.5	82.9	84.1
-NE	93.2	95.3	78.8	79.3

Again, the significant higher accuracies in training compared to test are due to overfitting. The removal of NE feature results in the largest accuracy loss of 4.3% (from 83.1% to 78.8%) for all nouns on test data. It follows WN_HYP (0.5% loss) and the bigram (0.4%). If we treat HW+WN_HYP as one feature, the removal of it results in accuracy loss of 0.8% for all nouns on test data. The unigram, first-last word and head word each results in the loss of 0.2%. The reason that the removal of NE results in a much significant loss is due to the fact that the NE feature is quite different from other features. Its strength is to distinguish SCs for proper names, while other features are more similar (their targets are common nouns). The proposed use of HW+WN_HYP can bring 0.8% gain on top of other features, higher than other informative lexical features including unigram and first-last word.

3.6 Error analysis

A closer look at the errors produced by our SC classifier reveals that the second probable label is very likely to be the actual labels if the first probable one is wrong. In fact, if we allow the classifier to predict two most probable labels and the classification is judged to be true if the actual label is one of the two predictions, then the classification accuracy increases from 83.1% to 96.4%. This is because that the same noun phrases are sometimes annotated with one of the five explicitly annotated classes while sometimes are not annotated at all (thus falling into the other SC). Again for the example of *people*. It is annotated as *person* SC 20 times and is not annotated at all 21 times. Given the same feature set for this instance, the best the classifier can do is to classify it to *other* semantic class. To address this annotation inconsistency issue, we relax the SC agreement feature from the strict match in designing coreference resolution features. For example, if the first probable SC of an NP matches the second probable SC of another NP, we still give some partial match credit.

4 Application to Coreference Resolution

We can now incorporate the NP SC classifier into our ME based coreference resolution system. This section examines how our WordNet hypernym features help improve the coreference resolution performance.

4.1 Experimental setup

We use the ACE-2 (version 1.0) coreference corpus. Each raw text in this corpus was preprocessed automatically by a pipeline of NLP components, including sentence boundary detection,

[7] All NP accuracy was not reported as they excluded the pronouns in creating their training and test data.

[8] They use these corpus to extract patterns to induce SC of common nouns.

POS-tagging and text chunking. The statistics of corpus and mention extraction are shown in Table 6, where g-mention is the automatically extracted mentions which contain the annotated (gold) mentions. The recalls of gold mentions are 95.88% and 95.93% for training and test data respectively.

Table 6: Statistics for corpus and extracted mentions.

	text#	mention#	g-mention#	gold#	recall(%)
train	422	61810	22990	23977	95.88
test	97	15360	5561	5797	95.93

Our coreference system uses Maximum Entropy model to determine whether two NPs are coreferent. As in (Soon et al., 2001; Ponzetto and Strube, 2006), we generate training instances as follows: a positive instance is created for each anaphoric NP, NP_j, and its closest antecedent, NP_i; and a negative instance is created for NP_j paired with each of the intervening NPs, NP_{i+1}, NP_{i+2}, ..., NP_{j-1}. Each instance is represented by syntactic or semantic features described as follows. All training data are used to train a maximum entropy model. In the test stage,we select the closest preceding NP that is classified as coreferent with NP_j as the antecedent of NP_j. If no such NP exists, no antecedent is selected for NP_j.

Unlike other natural language processing tasks such as information extraction which have de facto evaluation metrics, it is an open question which evaluation is the most suitable one. The evaluation becomes more complicated when automatically extracted mentions (in contrast to the gold mentions) are used. To facilitate the comparison with previous work, we report performance using two different scoring metrics: the commonly-used MUC scorer (Vilain et al., 1995) and the *accuracy* of the anaphoric references (Ponzetto and Strube, 2006). An anaphoric reference is correctly resolved if it and its closest antecedent are in the same coreference chain in the resulting partition.

4.2 Baseline features

We briefly review the baseline features used in this paper as follows. More detailed information and implementations can be found at (Soon et al., 2001; Versley et al., 2008). For example, the ALIAS feature takes values of true or false. The value of true means that the antecedent and the anaphor refer to the same entity (date, person, organization or location). The ALIAS feature detection works differently depending on the named entity type. For date, the day, month, and year values are extracted and compared. For person, the last words of the noun phrases are compared. For organization names, the alias detection checks for acronym match such as *IBM* and *International Business Machines Corp*.

Lexical features STRING MATCH: true if NP_i and NP_j have the same spelling after removing article and demonstrative pronouns, false otherwise. ALIAS: true if NP_j is the alias of NP_i.

Grammatical features I_PRONOUN: true if NP_i is a pronoun; J_PRONOUN: true if NP_j is pronoun; J_REFL_PRONOUN: true if NP_j is reflexive pronoun; J_PERS_PRONOUN: true if NP_j is personal pronoun; J_POSS_PRONOUN: true if NP_j is possessive pronoun; J_PN: true if NP_j is proper noun; J_DEF: true if NP_j starts with *the*; J_DEM: true if NP_j starts with *this*, *that*, *these* or *those*; J_DEM_NOMINAL: true if NP_j is a demonstrative nominal noun; J_DEM_PRONOUN: true if NP_j is a demonstrative pronoun; PROPER_NAME: true if both NP_i and NP_j are proper names; NUMBER: true if NP_i and NP_j agree in number; GENDER: true if NP_i and NP_j agree in gender; APPOSITIVE: true if NP_i and NP_j are appositions.

Distance feature DISTANCE: how many sentences NP_i and NP_j are apart.

Semantic feature SEMCLASS: This feature is implemented from (Soon et al., 2001). Its possible values are true, false, or unknown. First the following semantic classes are defined: *female*, *male*, *person*, *organization*, *location*, *date*, *time*, *money*, *percent*, and *object*. Each of these defined semantic classes is then mapped to a WordNet synset. Then the semantic class determination module determines the semantic class for every NP as the first synset of the head noun of the NP. If such synset is a hyponym of defined semantic class, then such semantic class is assigned to the NP. Otherwise, *unknown* class is assigned. Finally, the agreement of semantic classes of NP_i and NP_j is unknown if either assigned class is *unknown*; true if their assigned class are the same, false otherwise. Notice that the WordNet use in (Ng, 2007a) and this feature apply in the same principle except that 1) the former is used in SC classification while the latter is used directly for coreference resolution, and 2) they have different semantic class categories.

4.3 Proposed WordNet agreement features

For each instance which consists of NP_i and NP_j, we apply our SC classifier to label them, say l_i and l_j respectively. We then use these two induced la-

bels to propose the SC agreement feature for NP_i and NP_j. In particular, SC_STRICT is true if l_i and l_j are the same and they are not of other type, false otherwise; SC_COARSE is true if both l_i and l_j are not of other type; In addition, we propose two other SC agreement features to cope with the SC classification errors. SC_RELAX1 is true if the first probable of NP_i, l_{i1}, is not other type and is the same as the second probable of N_j, l_{j2}, or vice visa. SC_RELAX2 is true if the second probable of NP_i, l_{i2}, is not other type and is the same as the second probable label of NP_j, l_{j2}. The purpose in using SC_RELAX1 and SC_RELAX2 features is to relax the strict SC agreement feature in the hope that partial SC match is useful for coreference resolution.

4.4 Coreference results

Table 7 shows the MUC score for ACE2 corpus and its three partitions: bnews, npaper, and nwire using baseline and the proposed semantic features. It also shows the accuracy of resolving anaphors for all nouns in ACE2 corpus. SC_STRICT is the configuration that uses the baseline features with the SEMCLASS (Soon et al., 2001) replaced by SC_STRICT, and SC_COARSE, SC_RELAX1, and SC_RELAX2 are incrementally included into the SC_STRICT feature set.

As can be seen, the SC_STRICT significantly boosts the performance: it improves the MUC F score and anaphor accuracy of baseline from 57.7% to 65.7% and 37.7% to 46.3% respectively. It is remarkable that the new use of WordNet can obtain such significant gain in both MUC score and anaphor accuracy. The large improvement of the precision from 58.1% to 73.3% for all NPs shows that the SC_STRICT feature can effectively filter out the semantic incompatible pairs of antecedents and anaphors. In accordance with our hypothesis, the relaxation of strict SC agreement by including SC_COARSE, SC_RELAX1 and SC_RELAX2 help improve the performance further, which is reflected by both MUC score and anaphor accuracy. For example, compared to the baseline, the use of all proposed four SC agreement features results in the maximal accuracy gain of 9.7% (from 37.7% to 47.4%) and the use of SC_STRICT, SC_COARSE, and SC_RELAX1 results in the maximal MUC score gain of 10.4% (from 57.7% to 68.1%).

Our best MUC score is 68.1% which outperforms the MUC score of 64.6% as reported in (Ng, 2007a) by 3.5%, while our best accuracy of anaphor is 47.4%, which is 4.1% less than the accuracy of 51.5% in (Ng, 2007a). Note that, unlike (Ng, 2007a) which performed extensive experiments using different machine learning algorithms, alternative use of features (either constraint or normal features), and heterogeneous knowledge sources, this paper simply uses one learning classifier (ME model) and only employs WordNet and Stanford NER semantic sources.

The different MUC and accuracy scores reflect the non-trivial cases of evaluating coreference systems. While we leave out the discussion of which evaluation is more appropriate, we focus on showing that the proposed SC classifier can bring significant boost from the baseline using both MUC and accuracy metrics.

5 Conclusion

We have showed that the traditional use of WordNet in coreference resolution may not effectively exploit the WordNet semantic knowledge. We proposed new ways to extract WordNet feature. This feature, along with other features such as named entity feature, can be used to build an accurate *semantic class* (SC) classifier. In addition, we analyzed the classification errors of the SC classifier and relaxed SC agreement features to cope with part of the classification errors. The proposed accurate SC classifier and the relaxation of SC agreement features can boost our baseline coreference resolution system by 10.4% and 9.7% using MUC score and anaphor accuracy respectively.

Acknowledgments

We wish to thank Yannick Versley for his support with BART coreference resolution system and the three anonymous reviewers for their invaluable comments. This research was supported by British Telecom grant CT1080028046 and BISC Program of UC Berkeley.

Abstract

We present a method for detecting and correcting multiple real-word spelling errors using the Google Web 1T 3-gram data set and a normalized and modified version of the Longest Common Subsequence (LCS) string matching algorithm. Our method is focused mainly on how to improve the detection recall (the fraction of errors correctly detected) and the correction recall (the fraction of errors correctly amended), while keeping the respective precisions (the fraction of detections or amendments that are correct) as high as possible. Evaluation results on a standard data set show that our method outperforms two other methods on the same task.

1 Introduction

Real-word spelling errors are words in a text that occur when a user mistakenly types a correctly spelled word when another was intended. Errors of this type may be caused by the writer's ignorance of the correct spelling of the intended word or by typing mistakes. Such errors generally go unnoticed by most spellcheckers as they deal with words in isolation, accepting them as correct if they are found in the dictionary, and flagging them as errors if they are not. This approach would be sufficient to detect the non-word error *myss* in "It doesn't know what the *myss* is all about." but not the real-word error *muss* in "It doesn't know what the *muss* is all about." To detect the latter, the spell-checker needs to make use of the surrounding context such as, in this case, to recognise that *fuss* is more likely to occur than *muss* in the context of *all about*. Ironically, errors of this type may even be caused by spelling checkers in the correction of non-word spelling errors when the *auto-correct* feature in some word-processing software sometimes silently change a non-word to the wrong real word (Hirst and Budanitsky, 2005), and sometimes when correcting a flagged error, the user accidentally make a wrong selection from the choices offered (Wilcox-O'Hearn et al., 2008).

An extensive review of real-word spelling correction is given in (Pedler, 2007; Hirst and Budanitsky, 2005) and the problem of spelling correction more generally is reviewed in (Kukich, 1992).

The Google Web 1T data set (Brants and Franz, 2006), contributed by Google Inc., contains English word *n*-grams (from unigrams to 5-grams) and their observed frequency counts calculated over 1 trillion words from web page text collected by Google in January 2006. The text was tokenised following the Penn Treebank tokenisation, except that hyphenated words, dates, email addresses and URLs are kept as single tokens. The sentence boundaries are marked with two special tokens <S> and </S>. Words that occurred fewer than 200 times were replaced with the special token <UNK>. Table 1 shows the data sizes of the Web 1T corpus. The n-grams themselves must appear at least 40 times to be included in the Web 1T corpus[1]. It is expected that this data will be useful for statistical language modeling, e.g.,

Table 1: Google Web 1T Data Sizes

Number of	Number	Size on disk (in KB)
Tokens	1,024,908,267,229	N/A
Sentences	95,119,665,584	N/A
Unigrams	13,588,391	185,569
Bigrams	314,843,401	5,213,440
Trigrams	977,069,902	19,978,540
4-grams	1,313,818,354	32,040,884
5-grams	1,176,470,663	33,678,504

[1]Details of the Google Web 1T data set can be found at www.ldc.upenn.edu/Catalog/docs/LDC2006T13/readme.txt

Singapore, 6-7 August 2009.

for machine translation or speech recognition, as well as for other uses.

In this paper, we present a method for detecting and correcting multiple real-word spelling errors using the Google Web 1T 3-gram data set, and a normalized and modified version of the Longest Common Subsequence (LCS) string matching algorithm (details are in section 3.1). By *multiple* errors, we mean that if we have n words in the input sentence, then we try to detect and correct at most n-1 errors. We do not try to detect and correct an error, if any, in the first word as it is not computationally feasible to search in the Google Web 1T 3-grams while keeping the first word in the 3-gram as a variable. Our intention is to focus on how to improve the detection recall (the fraction of errors correctly detected) or correction recall (the fraction of errors correctly amended) while maintaining the respective precisions (the fraction of detections or amendments that are correct) as high as possible. The reason behind this intention is that if the recall for any method is around 0.5, this means that the method fails to detect or correct around 50 percent of the errors. As a result, we can not completely rely on these type of methods, for that we need some type of human interventions or suggestions to detect or correct the rest of the undetected or uncorrected errors. Thus, if we have a method that can detect or correct almost 80 percent of the errors, even generating some extra candidates that are incorrect is more helpful to the human.

This paper is organized as follow: Section 2 presents a brief overview of the related work. Our proposed method is described in Section 3. Evaluation and experimental results are discussed in Section 4. We conclude in Section 5.

2 Related Work

Work on real-word spelling correction can roughly be classified into two basic categories: methods based on semantic information or human-made lexical resources, and methods based on machine learning or probability information. Our proposed method falls into the latter category.

2.1 Methods Based on Semantic Information

The 'semantic information' approach first proposed by Hirst and St-Onge (1998) and later developed by Hirst and Budanitsky (2005) detected semantic anomalies, but was not restricted to checking words from predefined confusion sets. This approach was based on the observation that the words that a writer intends are generally semantically related to their surrounding words, whereas some types of real-word spelling errors are not, such as (using Hirst and Budanitsky's example), "It is my sincere hole (hope) that you will recover swiftly." Such "malapropisms" cause "a perturbation of the cohesion (and coherence) of a text." Hirst and Budanitsky (2005) use semantic distance measures in WordNet (Miller et al., 1993) to detect words that are potentially anomalous in context - that is, semantically distant from nearby words; if a variation in spelling results in a word that was semantically closer to the context, it is hypothesized that the original word is an error (a "malapropism") and the closer word is its correction.

2.2 Methods Based on Machine Learning

Machine learning methods are regarded as lexical disambiguation tasks and confusion sets are used to model the ambiguity between words. Normally, the machine learning and statistical approaches rely on pre-defined confusion sets, which are sets (usually pairs) of commonly confounded words, such as {*their*, *there*, *they're*} and {*principle*, *principal*}. The methods learn the characteristics of typical context for each member of the set and detect situations in which one member occurs in context that is more typical of another. Such methods, therefore, are inherently limited to a set of common, predefined errors, but such errors can include both content and function words. Given an occurrence of one of its confusion set members, the spellchecker's job is to predict which member of that confusion set is the most appropriate in the context. Golding and Roth (1999), an example of a machine-learning method, combined the Winnow algorithm with weighted-majority voting, using nearby and adjacent words as features. Another example of a machine-learning method is that of Carlson et al. (2001).

2.3 Methods Based on Probability Information

Mays et al. (1991) proposed a statistical method using word-trigram probabilities for detecting and correcting real-word errors without requiring predefined confusion sets. In this method, if the trigram-derived probability of an observed sentence is lower than that of a sentence obtained by replacing one of the words with a spelling varia-

tion, then we hypothesize that the original is an error and the variation is what the user intended.

Wilcox-O'Hearn et al. (2008) analyze the advantages and limitations of Mays et al. (1991)'s method, and present a new evaluation of the algorithm, designed so that the results can be compared with those of other methods, and then construct and evaluate some variations of the algorithm that use fixed-length windows. They consider a variation of the method that optimizes over relatively short, fixed-length windows instead of over a whole sentence (except in the special case when the sentence is smaller than the window), while respecting sentence boundaries as natural breakpoints. To check the spelling of a span of d words requires a window of length d+4 to accommodate all the trigrams that overlap with the words in the span. The smallest possible window is therefore 5 words long, which uses 3 trigrams to optimize only its middle word. They assume that the sentence is bracketed by two BoS and two EoS markers (to accommodate trigrams involving the first two and last two words of the sentence). The window starts with its left-hand edge at the first BoS marker, and the Mays et al. (1991)'s method is run on the words covered by the trigrams that it contains; the window then moves d words to the right and the process repeats until all the words in the sentence have been checked. As Mays et al. (1991)'s algorithm is run separately in each window, potentially changing a word in each, Wilcox-O'Hearn et al. (2008)'s method as a side-effect also permits multiple corrections in a single sentence.

Wilcox-O'Hearn et al. (2008) show that the trigram-based real-word spelling-correction method of Mays et al. (1991) is superior in performance to the WordNet-based method of Hirst and Budanitsky (2005), even on content words ("malapropisms"), especially when supplied with a realistically large trigram model. Wilcox-O'Hearn et al. (2008) state that their attempts to improve the method with smaller windows and with multiple corrections per sentence were not successful, because of excessive false positives.

Verberne (2002) proposed a trigram-based method for real-word errors without explicitly using probabilities or even localizing the possible error to a specific word. This method simply assumes that any word trigram in the text that is attested in the British National Corpus (Burnard, 2000) is correct, and any unattested trigram is a likely error. When an unattested trigram is observed, the method then tries the spelling variations of all words in the trigram to find attested trigrams to present to the user as possible corrections. The evaluation of this method was carried out on only 7100 words of the Wall Street Journal corpus, with 31 errors introduced (i.e., one error in every approximately 200 words) obtaining a recall of 0.33 for correction, a precision of 0.05 and a F-measure of 0.086.

3 Proposed Method

The proposed method first tries to determine some probable candidates and then finds the best one among the candidates or sorts them based on some weights. We consider a string similarity function and a normalized frequency value function in our method. The following sections present a detailed description of each of these functions followed by the procedure to determine some probable candidates along with the procedure to sort the candidates.

3.1 Similarity between Two Strings

We use the longest common subsequence (LCS) (Allison and Dix, 1986) measure with some normalization and small modifications for our string similarity measure. We use the same three different modified versions of LCS that we (Islam and Inkpen, 2008) used, along with another modified version of LCS, and then take a weighted sum of these[2]. Kondrak (2005) showed that edit distance and the length of the longest common subsequence are special cases of n-gram distance and similarity, respectively. Melamed (1999) normalized LCS by dividing the length of the longest common subsequence by the length of the longer string and called it longest common subsequence ratio (LCSR). But LCSR does not take into account the length of the shorter string which sometimes has a significant impact on the similarity score.

Islam and Inkpen (2008) normalized the *longest common subsequence* so that it takes into account the length of both the shorter and the longer string and called it *normalized longest common subse-*

[2]We (Islam and Inkpen, 2008) use modified versions because in our experiments we obtained better results (precision and recall) for schema matching on a sample of data than when using the original LCS, or other string similarity measures.

quence (NLCS) which is:

$$v_1 = NLCS(s_i, s_j) = \frac{len(LCS(s_i, s_j))^2}{len(s_i) \times len(s_j)} \quad (1)$$

While in classical LCS, the common subsequence needs not be consecutive, in spelling correction, a consecutive common subsequence is important for a high degree of matching. We (Islam and Inkpen, 2008) used *maximal consecutive longest common subsequence* starting at character 1, $MCLCS_1$ and *maximal consecutive longest common subsequence* starting at any character n, $MCLCS_n$. $MCLCS_1$ takes two strings as input and returns the shorter string or maximal consecutive portions of the shorter string that consecutively match with the longer string, where matching must be from first character (character 1) for both strings. $MCLCS_n$ takes two strings as input and returns the shorter string or maximal consecutive portions of the shorter string that consecutively match with the longer string, where matching may start from any character (character n) for both of the strings. We normalized $MCLCS_1$ and $MCLCS_n$ and called it *normalized* $MCLCS_1$ ($NMCLCS_1$) and *normalized* $MCLCS_n$ ($NMCLCS_n$), respectively.

$$v_2 = NMCLCS_1(s_i, s_j) = \frac{len(MCLCS_1(s_i, s_j))^2}{len(s_i) \times len(s_j)} \quad (2)$$

$$v_3 = NMCLCS_n(s_i, s_j) = \frac{len(MCLCS_n(s_i, s_j))^2}{len(s_i) \times len(s_j)} \quad (3)$$

Islam and Inkpen (2008) did not consider consecutive common subsequences ending at the last character, though $MCLCS_n$ sometimes covers this, but not always. We argue that the consecutive common subsequence ending at the last character is as significant as the consecutive common subsequence starting at the first character. So, we introduce the *maximal consecutive longest common subsequence* ending at the last character, $MCLCS_z$ (Algorithm 1). Algorithm 1, takes two strings as input and returns the shorter string or the maximal consecutive portions of the shorter string that consecutively matches with the longer string, where matching must end at the last character for both strings. We normalize $MCLCS_z$ and call it *normalized* $MCLCS_z$ ($NMCLCS_z$).

$$v_4 = NMCLCS_z(s_i, s_j) = \frac{len(MCLCS_z(s_i, s_j))^2}{len(s_i) \times len(s_j)} \quad (4)$$

We take the weighted sum of these individual values v_1, v_2, v_3, and v_4 to determine string similarity score, where α_1, α_2, α_3, α_4 are weights and $\alpha_1 + \alpha_2 + \alpha_3 + \alpha_4 = 1$. Therefore, the similarity of the two strings, $S \in [0, 1]$ is:

$$S(s_i, s_j) = \alpha_1 v_1 + \alpha_2 v_2 + \alpha_3 v_3 + \alpha_4 v_4 \quad (5)$$

We heuristically set equal weights for our experiments[3]. Theoretically, $v_3 \geq v_2$ and $v_3 \geq v_4$. To give an example, consider $s_i = albastru$ and $s_j = alabasteru$, then

$LCS(s_i, s_j) = albastru$
$MCLCS_1(s_i, s_j) = al$
$MCLCS_n(s_i, s_j) = bast$
$MCLCS_z(s_i, s_j) = ru$
$NLCS(s_i, s_j) = 8^2/(8 \times 10) = 0.8$
$NMCLCS_1(s_i, s_j) = 2^2/(8 \times 10) = 0.05$
$NMCLCS_n(s_i, s_j) = 4^2/(8 \times 10) = 0.2$
$NMCLCS_z(s_i, s_j) = 2^2/(8 \times 10) = 0.05$

The string similarity, $S = \alpha_1 v_1 + \alpha_2 v_2 + \alpha_3 v_3 + \alpha_4 v_4 = 0.25 \times 0.8 + 0.25 \times 0.05 + 0.25 \times 0.2 + 0.25 \times 0.05 = 0.275$

3.2 Normalized Frequency Value

We determine the normalized frequency value of each candidate word for a single position with respect to all other candidates for the same position. If we find n replacements of a word w_i which are $\{w_{i1}, w_{i2}, \cdots, w_{ij}, \cdots, w_{in}\}$, and their frequencies $\{f_{i1}, f_{i2}, \cdots, f_{ij}, \cdots, f_{in}\}$, where f_{ij} is the frequency of a 3-gram (where any candidate word w_{ij} is a member of the 3-gram), then we determine the normalized frequency value of any candidate word w_{ij}, represented as $F(w_{ij}) \in (0, 1]$, as the frequency of the 3-gram having w_{ij} over the maximum frequency among all the candidate words for that position:

$$F(w_{ij}) = \frac{f_{ij}}{\max(f_{i1}, f_{i2}, \cdots, f_{ij}, \cdots, f_{in})} \quad (6)$$

3.3 Determining Candidate Words

Our task is to correct real-word spelling error from an input text using Google Web 1T 3-gram data set. Let us consider an input text W which

[3]We use equal weights in several places in this paper in order to keep the system unsupervised. If development data would be available, we could adjust the weights.

Algorithm 1: $MCLCS_z$ (Maximal Consecutive LCS ending at the last character)

input : s_i, s_j /* s_i and s_j are input strings where $|s_i| \leq |s_j|$ */
output: str /* str is the Maximal Consecutive LCS ending at the last character */

```
str ← NULL
c ← 1
while |s_i| ≥ c do
    x ← SubStr(s_i, −c, 1)    /* returns cth character of s_i from the end */
    y ← SubStr(s_j, −c, 1)    /* returns cth character of s_j from the end */
    if x = y then
        str ← SubStr(s_i, −c, c)
    else
        return str
    end
    increment c
end
```

after tokenization[4] has m words, i.e., $W = \{w_1, w_2, \ldots, w_m\}$. Our method aims to correct m-1 spelling errors, for all m-1 word positions, except for the first word position, as we do not try to correct the first word. We use a slight different way to correct the first word (i.e., w_2) and the last word (i.e., w_m) among those m-1 words, than for the rest of the words. First, we discuss how we find the candidates for a word (say w_i, where $2<i<m$) which is not either w_2 or w_m. Then, we discuss the procedure to find the candidates for either w_2 or w_m. Our method could have worked for the first word too. We did not do it here due to efficiency reasons. Google 3-grams are sorted based on the first word, then the second word, and so on. Based on this sorting, all Google 3-grams are stored in 97 different files. All the 97 Google 3-gram files could have been needed to access a single word, instead of accessing just one 3-gram file as we do for any other words. This is because when the first word needs to be corrected, it might be in any file among those 97 Google 3-gram files. No error appears in the first position among 1402 inserted malapropisms. The errors start appearing from the second position till the last position.

[4]We need to tokenize the input sentence to make the 3-grams formed using the tokens returned after the tokenization consistent with the Google 3-grams. The input sentence is tokenized in a manner similar to the tokenization of the Wall Street Journal portion of the Penn Treebank. Notable exceptions include the following:

- Hyphenated word are usually separated, and hyphenated numbers usually form one token.
- Sequences of numbers separated by slashes (e.g., in dates) form one token.
- Sequences that look like urls or email addresses form one token.

3.3.1 Determining Candidate Words for w_i $(2 < i < m)$

We use the following steps:

1. We define the term *cut off frequency* for word w_i or word w_{i+1} as the frequency of the 3-gram $w_{i-1}\ w_i\ w_{i+1}$ in the Google Web 1T 3-grams, if the said 3-gram exists. Otherwise, we set the *cut off frequency* of w_i as 0. The intuition behind using the *cut off frequency* is the fact that, if the word is misspelled, then the correct one should have a higher frequency than the misspelled one. Thus, using the *cut off frequency*, we isolate a large number of candidates that we do not need to process.

2. We find all the 3-grams (where only w_i is changed while w_{i-1} and w_{i+1} are unchanged) having frequency greater than the *cut off frequency* of w_i (determined in step 1). Let us consider that we find n replacements of w_i which are $R_1 = \{w_{i1}, w_{i2}, \cdots, w_{in}\}$ and their frequencies $F_1 = \{f_{i1}, f_{i2}, \cdots, f_{in}\}$ where f_{ij} is the frequency of the 3-gram $w_{i-1}\ w_{ij}\ w_{i+1}$.

3. We determine the *cut off frequency* for word w_{i-1} or word w_i as the frequency of the 3-gram $w_{i-2}\ w_{i-1}\ w_i$ in the Google Web 1T 3-grams, if the said 3-gram exists. Otherwise, we set the *cut off frequency* of w_i as 0.

4. We find all the 3-grams (where only w_i is changed while w_{i-2} and w_{i-1} are unchanged) having frequency greater than the *cut off frequency* of w_i (determined in step 3). Let us consider that we find n replacements of w_i which are $R_2 = \{w_{i1}, w_{i2}, \cdots, w_{in}\}$ and their frequencies

$F_2 = \{f_{i1}, f_{i2}, \cdots, f_{in}\}$ where f_{ij} is the frequency of the 3-gram $w_{i-2}\ w_{i-1}\ w_{ij}$.

5. For each $w_{ij} \in R_1$, we calculate the string similarity between w_{ij} and w_i using equation (5) and then assign a weight using the following equation (7) only to the words that return the string similarity value greater than 0.5.

$$weight = \beta S(w_i, w_{ij}) + (1-\beta)F(w_{ij}) \quad (7)$$

Equation (7) is used to ensure a balanced weight between the string similarity function and the normalized frequency value function where β refers to how much importance we give to the string similarity function with respect to the normalized frequency value function[5].

6. For each $w_{ij} \in R_2$, we calculate the string similarity between w_{ij} and w_i using equation (5), and then assign a weight using the equation (7) only to the words that return the string similarity value greater than 0.5.

7. We sort the words found in step 5 and in step 6 that were given weights, if any, in descending order by the assigned weights and keep only one word as candidate word[6].

3.3.2 Determining Candidate Words for w_2

We use the following steps:

1. We determine the *cut off frequency* for word w_2 as the frequency of the 3-gram $w_1\ w_2\ w_3$ in the Google Web 1T 3-grams, if the said 3-gram exists. Otherwise, we set the *cut off frequency* of w_2 as 0.

2. We find all the 3-grams (where only w_2 is changed while w_1 and w_3 are unchanged) having frequency greater than the *cut off frequency* of w_2 (determined in step 1). Let us consider that we find n replacements of w_2 which are $R_1 = \{w_{21}, w_{22}, \cdots, w_{2n}\}$, and their frequencies $F_1 = \{f_{21}, f_{22}, \cdots, f_{2n}\}$, where f_{2j} is the frequency of the 3-gram $w_1\ w_{2j}\ w_3$.

3. For each $w_{2j} \in R_1$, we calculate the string similarity between w_{2j} and w_2 using equation (5), and then assign a weight using the following equation only to the words that return the string similarity value greater than 0.5.

$$weight = \beta S(w_2, w_{2j}) + (1-\beta)F(w_{2j})$$

4. We sort the words found in step 3 that were given weights, if any, in descending order by the assigned weights and keep only one word as candidate word.

3.3.3 Determining Candidate Words for w_m

We use the following steps:

1. We determine the *cut off frequency* for word w_m as the frequency of the 3-gram $w_{m-2}\ w_{m-1}\ w_m$ in the Google Web 1T 3-grams, if the said 3-gram exists. Otherwise, we set the *cut off frequency* of w_m as 0.

2. We find all the 3-grams (where only w_m is changed while w_{m-2} and w_{m-1} are unchanged) having frequency greater than the *cut off frequency* of w_m (determined in step 1). Let us consider that we find n replacements of w_m which are $R_2 = \{w_{m1}, w_{m2}, \cdots, w_{mn}\}$ and their frequencies $F_2 = \{f_{m1}, f_{m2}, \cdots, f_{mn}\}$, where f_{mj} is the frequency of the 3-gram $w_{m-2}\ w_{m-1}\ w_{mj}$.

3. For each $w_{mj} \in R_2$, we calculate the string similarity between w_{mj} and w_m using equation (5) and then assign a weight using the following equation only to the words that return the string similarity value greater than 0.5.

$$weight = \beta S(w_m, w_{mj}) + (1-\beta)F(w_{mj})$$

4. We sort the words found in step 3 that were given weights, if any, in descending order by the assigned weights and keep only one word as the candidate word.

[5] We give more importance to string similarity function with respect to frequency value function throughout the section of 'determining candidate words' to have more candidate words so that the chance of including the target word into the set of candidate words gets higher. For this reason, we heuristically set β=0.85 in equation (7) instead of setting β=0.5.

[6] Sometimes the top candidate word might be either a plural form or a past participle form of the original word. Or even it might be a high frequency function word (e.g., *the*). We omit these type of words from the candidacy.

4 Evaluation and Experimental Results

We used as test data the same data that Wilcox-O'Hearn et al. (2008) used in their evaluation of Mays et al. (1991) method, which in turn was a replication of the data used by Hirst and St-Onge (1998) and Hirst and Budanitsky (2005) to evaluate their methods.

The data consisted of 500 articles (approximately 300,000 words) from the 1987−89 *Wall Street Journal* corpus, with all headings, identifiers, and so on removed; that is, just a long stream of text. It is assumed that this data contains no errors; that is, the *Wall Street Journal* contains no malapropisms or other typos. In fact, a few typos (both non-word and real-word) were noticed during the evaluation, but they were small in number compared to the size of the text.

Malapropisms were randomly induced into this text at a frequency of approximately one word in 200. Specifically, any word whose base form was listed as a noun in WordNet (but regardless of whether it was used as a noun in the text; there was no syntactic analysis) was potentially replaced by any spelling variation found in the lexicon of the *ispell* spelling checker[7]. A *spelling variation* was defined as any word with an *edit distance* of 1 from the original word; that is, any single-character insertion, deletion, or substitution, or the transposition of two characters, that results in another real word. Thus, none of the induced malapropisms were derived from closed-class words, and none were formed by the insertion or deletion of an apostrophe or by splitting a word. The data contained 1402 inserted malapropisms.

Because it had earlier been used for evaluating Mays et al. (1991)'s trigram method, which operates at the sentence level, the data set had been divided into three parts, without regard for article boundaries or text coherence: sentences into which no malapropism had been induced; the original versions of the sentences that received malapropisms; and the malapropized sentences. In addition, all instances of numbers of various kinds had been replaced by tags such as <INTEGER>, <DOLLAR VALUE>, and <PERCENTAGE VALUE>. Actual (random) numbers or values were restored for these tags. Some spacing anomalies around punctuation marks were corrected. A detailed description of this data can be found in (Hirst, 2008; Wilcox-O'Hearn et al., 2008).

[7]Ispell is a fast screen-oriented spelling checker that shows you your errors in the context of the original file, and suggests possible corrections when it can figure them out. The original was written in PDP-10 assembly in 1971, by R. E. Gorin. The C version was written by Pace Willisson of MIT. Geoff Kuenning added the international support and created the current release.

SUCCESSFUL CORRECTION:
The Iran revelations were particularly disturbing to the Europeans because they came on the heels of the Reykjavik summit between President Reagan and Soviet *reader* → leader [leader] Mikhail Gorbachev.
Even the now sainted Abraham Lincoln was often reviled while in *officer* → office [office], sometimes painted by cartoonists and editorial writers as that baboon in the White House.
FALSE POSITIVE:
· · · by such public displays of interest in *Latinos* → Latin [Latinos], many undocumented · · ·
The southeast Asian nation was one reported *contributor* → contribution [contributor] to the Nicaraguans.
FALSE NEGATIVE:
Kevin Mack, Geldermann president and chief executive officer, didn't return calls for comment on the Clayton *purchaser* [purchase].
U.S. *manufactures* [manufacturers], in short, again are confronting a ball game in which they will be able to play.
TRUE POSITIVE DETECTION, FALSE POSITIVE CORRECTION:
Hawkeye also is known to *rear* → reader [fear] that a bankruptcy-law filing by the parent company, which theoretically shouldn't affect the operations of its member banks, would spark runs on the banks that could drag down the whole entity.
The London Daily News has quoted sources saying as many as 23 British mercenaries were enlisted by KMS to *lid* → slide [aid] the Contras.

Table 2: Examples of successful and unsuccessful corrections. Italics indicate observed word, arrow indicates correction, square brackets indicate intended word.

Some examples of successful and unsuccessful corrections using our proposed method are shown in Table 2.

Table 3 shows our method's results on the described data set compared with the results for the trigram method of Wilcox-O'Hearn et al. (2008)

Detection			correction		
R	P	F_1	R	P	F_1
Lexical cohesion (Hirst and Budanitsky, 2005)					
0.306	0.225	0.260	0.281	0.207	0.238
Trigrams (Wilcox-O'Hearn et al., 2008)					
0.544	0.528	0.536	0.491	0.503	0.497
Multiple 3-grams					
0.890	0.445	0.593	0.763	0.381	0.508

Table 3: A comparison of recall, precision, and F_1 score for three methods of malapropism detection and correction on the same data set.

and the lexical cohesion method of Hirst and Budanitsky (2005). The data shown here for trigram method are not from (Wilcox-O'Hearn et al., 2008), but rather are later results following some corrections reported in (Hirst, 2008). We have not tried optimizing our adjustable parameters: β and αs, because the whole data set was used as testing set by the other methods we compare with. To keep the comparison consistent, we did not use any portion of the data set for training purpose. Having optimized parameters could lead to a better result. The performance is measured using *Recall* (R), *Precision* (P) and F_1:

$$R = \frac{\text{true positives}}{\text{true positives} + \text{false negatives}}$$

$$P = \frac{\text{true positives}}{\text{true positives} + \text{false positives}}$$

$$F_1 = \frac{2PR}{P + R}$$

The fraction of errors correctly detected is the detection *recall* and the fraction of detections that are correct is the detection *precision*. Again, the fraction of errors correctly amended is the correction *recall* and the fraction of amendments that are correct is the correction *precision*. To give an example, consider a sentence from the data set: "The Philippine president, in her commencement address at the academy, complained that the U.S. was *living* → giving [giving] advice instead of the *aid* → said [aid] it pledged.", where italics indicate the observed word, arrow indicates the correction and the square brackets indicate the intended word. The detection *recall* of this sentence is 1.0 and the *precision* is 0.5. The correction *recall* of this sentence is 1.0 and the *precision* is 0.5. For both cases, the F_1 score is 0.667.

We loose some precision because our method tries to detect and correct errors for all the words (except the first word) in the input sentence, and, as a result, it generates more false positives than the other methods. Even so, we get better F_1 scores than the other competing methods. Accepting 8.3 percents extra incorrect detections, we get 34.6 percents extra correct detections of errors, and similarly, accepting 12.2 percents extra incorrect amendments, we get 27.2 percents extra correct amendments of errors compared with the trigrams method (Wilcox-O'Hearn et al., 2008)[8].

5 Conclusion

The Google 3-grams proved to be very useful in detecting real-word errors, and finding the corrections. We did not use the 4-grams and 5-grams because of data sparsity. When we tried with 5-grams the results were lower than the ones presented in Section 4. Having sacrificed a bit the precision score, our proposed method achieves a very good detection recall (0.89) and correction recall (0.76). Our attempts to improve the detection recall or correction recall, while maintaining the respective precisions as high as possible are helpful to the human correctors who post-edit the output of the real-word spell checker. If there is no postediting, at least more errors get corrected automatically. Our method could also detect and correct misspelled words, not only malapropisms, without any modification. In future work, we plan to extend our method to allow for deleted or inserted words, and to find the corrected strings in the Google Web 1T n-grams. In this way we will be able to correct grammar errors too. We also plan more experiments using the 5-grams, but backing off to 4-grams and 3-grams when needed.

Acknowledgments

This work is funded by the Natural Sciences and Engineering Research Council of Canada. We want to thank Professor Graeme Hirst from the Department of Computer Science, University of Toronto, for providing the evaluation data set.

[8]We can run our algorithm on subsets of data to check for variance in the results. We cannot test statistical significance compared to the related work (t-test), because we do not have the system from related work to run it on subsets of the data.

Abstract

In this paper, we present a semi-supervised method for automatic speech act recognition in email and forums. The major challenge of this task is due to lack of labeled data in these two genres. Our method leverages labeled data in the Switchboard-DAMSL and the Meeting Recorder Dialog Act database and applies simple domain adaptation techniques over a large amount of unlabeled email and forum data to address this problem. Our method uses automatically extracted features such as phrases and dependency trees, called subtree features, for semi-supervised learning. Empirical results demonstrate that our model is effective in email and forum speech act recognition.

1 Introduction

Email and online forums are important social media. For example, thousands of emails and posts are created daily in online communities, e.g., Usenet newsgroups or the TripAdvisor travel forum[1], in which users interact with each other using emails/posts in complicated ways in discussion threads. To uncover the rich interactions in these email exchanges and forum discussions, we propose to apply speech act recognition to email and forum threads.

Despite extensive studies of speech act recognition in many areas, developing speech act recognition for online forms of conversation is very challenging. A major challenge is that emails and forums usually have no labeled data for training statistical speech act recognizers. Fortunately, labeled speech act data are available in other domains (i.e., telephone and meeting conversations in this paper) and large unlabeled data sets can be collected from the Web. Thus, we focus on the problem of how to accurately recognize speech acts in emails and forums by making maximum use of data from existing resources.

Recently, there are increasing interests in speech act recognition of online text-based conversations. Analysis of speech acts for online chat and instant messages and have been studied in computer-mediated communication (CMC) and distance learning (Twitchell et al., 2004; Nastri et al., 2006; Rosé et al., 2008). In natural language processing, Cohen et al. (2004) and Feng et al. (2006) used speech acts to capture the intentional focus of emails and discussion boards. However, they assume that enough labeled data are available for developing speech act recognition models.

A main contribution of this paper is that we address the problem of learning speech act recognition in a semi-supervised way. To our knowledge, this is the first use of semi-supervised speech act recognition in emails and online forums. To do this, we make use of labeled data from spoken conversations (Jurafsky et al., 1997; Dhillon et al., 2004). A second contribution is that our model learns subtree features that constitute discriminative patterns: for example, variable length n-grams and partial dependency structures. Therefore, our model can capture both local features such as n-grams and non-local dependencies. In this paper, we extend subtree pattern mining to the semi-supervised learning problem.

This paper is structured as follows. Section 2 reviews prior work on speech act recognition and Section 3 presents the problem statement and our data sets. Section 4 describes a supervised method of learning subtree features that shows the effectiveness of subtree features on labeled data sets. Section 5 proposes semi-supervised learning techniques for speech act recognition and Section 6 demonstrates our method applied to email and on-

line forum thread data. Section 7 concludes this paper with future work.

2 Related Work

Speech act theory is fundamental to many studies in discourse analysis and pragmatics (Austin, 1962; Searle, 1969). A speech act is an illocutionary act of conversation and reflects shallow discourse structures of language. Recent research on spoken dialog processing has investigated computational speech act models of human-human and human-computer conversations (Stolcke et al., 2000) and applications of these models to CMC and distance learning (Twitchell et al., 2004; Nastri et al., 2006; Rosé et al., 2008).

Our work in this paper is closely related to prior work on email and forum speech act recognition. Cohen et al. (2004) proposed the notion of 'email speech act' for classifying the intent of an email sender. They defined verb and noun categories for email speech acts and used supervised learning to recognize them. Feng et al. (2006) presented a method of detecting conversation focus based on the speech acts of messages in discussion boards. Extending Feng et al. (2006)'s work, Ravi and Kim (2007) applied speech act classification to detect unanswered questions. However, none of these studies have focused on the semi-supervised speech act recognition problem and examined their methods across different genres.

The speech processing community frequently employs two large-scale corpora for speech act annotation: Switchboard-DAMSL (SWBD) and Meeting Recorder Dialog Act (MRDA). SWBD is an annotation scheme and collection of labeled dialog act[2] data for telephone conversations (Jurafsky et al., 1997). The main purpose of SWBD is to acquire stochastic discourse grammars for training better language models for automatic speech recognition. More recently, an MRDA corpus has been adapted from SWBD but its tag set for labeling meetings has been modified to better reflect the types of interaction in multi-party face-to-face meetings (Dhillon et al., 2004). These two corpora have been extensively studied, e.g., (Stolcke et al., 2000; Ang et al., 2005; Galley et al., 2004). We also use these for our experiments.

[2]A dialog act is the meaning of an utterance at the level of illocutionary force (Austin, 1962), and broadly covers the speech act and adjacency pair (Stolcke et al., 2000). In this paper, we use only the term 'speech act' for clarity.

This paper focuses on the problem of semi-supervised speech act recognition. The goal of semi-supervised learning techniques is to use auxiliary data to improve a model's capability to recognize speech acts. The approach in Tur et al. (2005) presented semi-supervised learning to employ auxiliary unlabeled data in call classification, and is closely related to our work. However, our approach uses the most discriminative subtree features, which is particularly attractive for reducing the model's size. Our problem setting is closely related to the domain adaptation problem (Ando and Zhang, 2005), i.e., we seek to obtain a model that analyzes target domains (emails and forums) by adapting a method that analyzes source domains (SWBD and MRDA). Recently, this type of domain adaptation has become an important topic in natural language processing.

3 Problem Definition

3.1 Problem Statement

We define speech act recognition to be the task that, given a sentence, maps it to one of the speech act types. Figure 1 shows two examples of our email and forum speech act recognition. E1∼6 are all sentences in an email message. F1∼3, F4∼5, and F6 are three posts in a forum thread. A sentence interacts alone or with others, for example, F6 agrees with the previous post (F4∼5). To gain insight into our work, it is useful to consider that E2, 3 and F1, 4, 6 are summaries of two discourses. In particular, F1 denotes a question and F4 and F6 are corresponding answers. More recently, using speech acts has become an appealing approach in summarizing the discussions (Galley et al., 2004; McKeown et al., 2007).

Next, we define speech act category based on MRDA. Dhillon et al. (2004) included definitions of speech acts for colloquial style interactions (e.g., backchannel, disruption, and floorgrabber), but these are not applicable in emails and forums. After removing these categories, we define 12 tags (Table 1). Dhillon et al. (2004) provides detailed descriptions of each tag. We note that our tag set definition is different from (Cohen et al., 2004; Feng et al., 2006; Ravi and Kim, 2007) for two reasons. First, prior work primarily interested in the domain-specific speech acts, but our work use domain-independent speech act tags. Second, we focus on speech act recognition on the sentence-level.

QW	Wh-question
QY	Yes-no question
R	Reject response
S	Statement
U	Uncertain response

The goal of semi-supervised speech act recognition is to learn a classifier using both labeled and unlabeled data. We formally define our problem as follows. Let $\mathbf{x} = \{x_j\}$ be a *forest*, i.e., a set of trees that represents a natural language structure, for example, a sequence of words and a dependency parse tree. We will describe this in more detail in Section 4. Let y be a *speech act*. Then, we define $\mathcal{D}_L = \{\mathbf{x}_i, y_i\}_{i=1}^{n}$ as the set of labeled training data, and $\mathcal{D}_U = \{\mathbf{x}_i\}_{i=n+1}^{l}$ as the set of unlabeled training data where $l = n + m$ and m is the number of unlabeled data instances. Our goal is to find a learning method to minimize the classification errors in $\mathcal{D}_L$ and $\mathcal{D}_U$.

3.2 Data Preparation

In this paper, we separate labeled ($\mathcal{D}_L$) and unlabeled data ($\mathcal{D}_U$). First we use SWBD[3] and MRDA[4] as our labeled data. We automatically map original annotations in SWBD and MRDA to one of the 12 speech acts.[5] Inter-annotator agreement κ in both data sets is ~ 0.8 (Jurafsky et al., 1997; Dhillon et al., 2004). For evaluation purposes, we divide labeled data into three sets: training, development, and evaluation sets (Table 2). Of the 1,155 available conversations in the SWBD corpus, we use 855 for training, 100 for development, and 200 for evaluation. Among the 75 available meetings in the MRDA corpus, we exclude two meetings of different natures (btr001 and btr002). Of the remaining meetings, we use 59 for training, 6 for development, and 8 for evaluation. Then we merge multi-segments utterances that belong to the same speaker and then divide all data sets into sentences.

As stated earlier, our unlabeled data consists of email (EMAIL) and online forum (FORUM) data. For the EMAIL set, we selected 22,391 emails from Enron data[6] (discussion_threads, all_documents, and calendar folders). For the FORUM set, we crawled 11,602 threads and 55,743 posts from the TripAdvisor travel forum site (Beijing, Shanghai, and Hongkong forums). As our evaluation sets, we used 40 email threads of the BC3 corpus[7] for EMAIL and 100 threads selected from the same travel forum site for FORUM. Every sentences was automatically segmented by the MSRA sentence boundary detector (Table 2). Annotation was performed by two human annotators, and inter-annotator agreements were $\kappa = 0.79$ for EMAIL and $\kappa = 0.73$ for FORUM.

Overall performance of automatic evaluation measures usually depends on the distribution of tags. In both labeled and unlabeled sets, the most

frequent tag is the statement (S) tag (Figure 2). Distributions of tags are similar in training and development sets of SWBD and MRDA.

4 Speech Act Recognition

Previous work in speech act recognition used a large set of lexical features, e.g., bag-of-words, bigrams and trigrams (Stolcke et al., 2000; Cohen et al., 2004; Ang et al., 2005; Ravi and Kim, 2007). However, these methods create a large number of lexical features that might not be necessary for speech act identification. For example, a Wh-question "What site should we use to book a Beijing-Chonqing flight?" can be predicted by two discriminative features, "(<s>, WRB) → QW" and "(?, </s>) → QW" where <s> and </s> are sentence start and end symbols, and WRB is a part-of-speech tag that denotes a Wh-adverb. In addition, useful features could be of various lengths, i.e. not fixed length n-grams, and non-adjacent. One key idea of this paper is a novel use of subtree features to model these for speech act recognition.

4.1 Exploiting Subtree Features

To exploit subtree features in our model, we use a *subtree pattern mining* method proposed by Kudo and Matsumoto (2004). We briefly introduce this algorithm here. In Section 3.1, we defined $\mathbf{x} = \{x_j\}$ as the forest that is a set of trees. More precisely, x_j is a labeled ordered tree where each node has its own label and is ordered left-to-right. Several types of labeled ordered trees

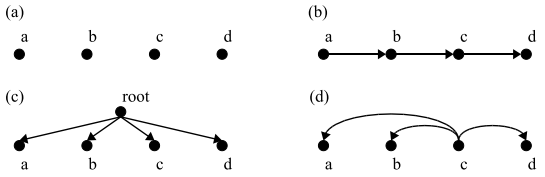

Figure 3: Representations of tree: (a) bag-of-words, (b) n-gram, (c) word pair, and (d) dependency tree. A node denotes a word and a directed edge indicates a parent-and-child relationship.

are possible (Figure 3). Note that S-expression can be used instead for computation, for example `(a(b(c(d))))` for the n-gram (Figure 3(b)). Moreover, we employ a combination of multiple trees as the input of the subtree pattern mining algorithm.

We extract subtree features from the forest set $\{\mathbf{x}_i\}$. A subtree t is a tree if $t \subseteq \mathbf{x}$. For example, `(a)`, `(a(b))`, and `(b(c(d)))` are subtrees of Figure 3(b). We define the subtree feature as a weak learner:

$$f(y, t, \mathbf{x}) \triangleq \begin{cases} +y & t \subseteq \mathbf{x}, \\ -y & \text{otherwise}, \end{cases} \quad (1)$$

where we assume a binary case $y \in \mathcal{Y} = \{+1, -1\}$ for simplicity. Even though the approach in Kudo and Matsumoto (2004) and ours are simiar, there are two clear distinctions. First, our method employs multiple tree structures, and uses different constraints to generate subtree candidates. In this paper, we only restrict generating

the dependency subtrees which should have 3 or more nodes. Second, our method is of interest for semi-supervised learning problems. To learn subtree features, Kudo and Matsumoto (2004) assumed supervised data $\{(\mathbf{x}_i, y_i)\}$. Here, we describe the supervised learning method and will describe our semi-supervised method in Section 5.

4.2 Supervised Boosting Learning

Given training examples, we construct a ensemble learner $F(\mathbf{x}) = \sum_k \lambda_k f(y_k, t_k, \mathbf{x})$, where λ_k is a coefficient for linear combination. A final classifier $h(\mathbf{x})$ can be derived from the ensemble learner, i.e., $h(\mathbf{x}) \triangleq sgn(F(\mathbf{x}))$. As an optimization framework (Mason et al., 2000), the objective of boosting learning is to find F such that the cost of functional

$$\mathcal{C}(F) = \sum_{i \in \mathcal{D}} \alpha_i C[y_i F(\mathbf{x}_i)] \tag{2}$$

is minimized for some non-negative and monotonically decreasing cost function $C : \mathbb{R} \to \mathbb{R}$ and the weight $\alpha_i \in \mathbb{R}^+$. In this paper, we use the AdaBoost algorithm (Schapire and Singer, 1999); thus the cost function is defined as $C(z) = e^{-z}$.

Constructing an ensemble learner requires that the user choose a base learner, $f(y, t, \mathbf{x})$, to maximize the inner product $-\langle \nabla \mathcal{C}(F), f \rangle$ (Mason et al., 2000). Finding $f(y, t, \mathbf{x})$ to maximize $-\langle \nabla \mathcal{C}(F), f \rangle$ is equivalent to searching for $f(y, t, \mathbf{x})$ to minimize $2 \sum_{i: f(y,t,\mathbf{x}_i) \neq y_i} w_i - 1$, where w_i for $i \in \mathcal{D}_L$, is the empirical data distribution $w_i^{(k)}$ at step k. It is defined as:

$$w_i^{(k)} = \alpha_i \cdot e^{-y_i F(\mathbf{x}_i)}. \tag{3}$$

From Eq. 3, a proper base learner (i.e., subtree) can be found by maximizing weighted gain, where

$$\text{gain}(t, y) = \sum_{i \in \mathcal{D}_L} y_i w_i f(y, t, \mathbf{x}_i). \tag{4}$$

Thus, subtree mining is formulated as the problem of finding $(\hat{t}, \hat{y}) = \underset{(t,y) \in \mathcal{X} \times \mathcal{Y}}{\arg\max}\ \text{gain}(t, y)$. We need to search with respect to a non-monotonic score function (Eq. 4), thus we use the monotonic bound, $\text{gain}(t, y) \leq \mu(t)$, where

$$\mu(t) = \max \left(2 \sum_{\{i | y_i = +1, t \subseteq \mathbf{x}_i\}} w_i - \sum_{i=1}^{n} y_i f(y, t, \mathbf{x}_i), \right.$$
$$\left. 2 \sum_{\{i | y_i = -1, t \subseteq \mathbf{x}_i\}} w_i + \sum_{i=1}^{n} y_i f(y, t, \mathbf{x}_i) \right). \tag{5}$$

Table 3: Result of supervised learning experiment; columns are micro-averaged F_1 score with macro-averaged F_1 score in parentheses. MAXENT: maximum entropy model; BOW: bag-of-words model; NGRAM: n-gram model; +POSTAG, +DEPTREE, +SPEAKER indicate that the components were added individually onto NGRAM. '*' indicates results significantly better than the NGRAM model ($p < 0.001$).

Model	SWBD	MRDA
MAXENT	92.76 (63.54)	82.48 (57.19)
BOW	91.32 (54.47)	82.17 (55.42)
NGRAM	92.60 (58.43)	83.30 (57.53)
+POSTAG	92.69 (60.07)	83.60 (58.46)
+DEPTREE	92.67 (61.75)	*83.57 (57.45)
+SPEAKER	*92.86 (63.13)	83.40 (58.20)
ALL	*92.87 (63.77)	83.49 (59.04)

The subtree set is efficiently enumerated using a branch-and-bound procedure based on $\mu(t)$ (Kudo and Matsumoto, 2004).

After finding an optimal base leaner, $f(\hat{y}, \hat{t}, \mathbf{x})$, we need to set the coefficient λ_k to form a new ensemble, $F(\mathbf{x}_i) \leftarrow F(\mathbf{x}_i) + \lambda_k f(\hat{t}, \hat{y}, \mathbf{x}_i)$. In AdaBoost, we choose

$$\lambda_k = \frac{1}{2} \log \left(\frac{1 + \text{gain}(\hat{t}, \hat{y})}{1 - \text{gain}(\hat{t}, \hat{y})} \right). \tag{6}$$

After K iterations, the boosting algorithm returns the ensemble learner $F(\mathbf{x})$ which consists of a set of appropriate base learners $f(y, t, \mathbf{x})$.

4.3 Evaluation on Labeled Data

We verified the effectiveness of using subtree features on the SWBD and MRDA data sets. For boosting learning, one typically assumes $\alpha_i = 1$. In addition, the number of iterations, which relates to the number of patterns, was determined by a development set. We also used a one-vs.-all strategy for the multi-class problem. Precision and recall were computed and combined into micro- and macro-averaged F_1 scores. The significance of our results was evaluated using the McNemar paired test (Gillick and Cox, 1989), which is based on individual labeling decisions to compare the correctness of two models. All experiments were implemented in C++ and executed in Windows XP on a PC with a Dual 2.1 GHz Intel Core2 processor and 2.0 Gbyte of main memory.

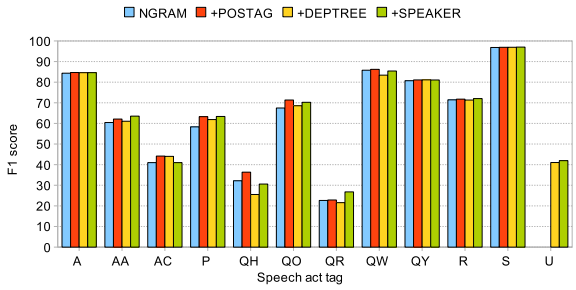

Figure 4: Comparison of different trees (SWBD)

We show that use of subtree features is effective to solve the supervised speech act recognition problem. We also compared our model with the state-of-the-art maximum entropy classifier (MAXENT). We used bag-of-words, bigram and trigram features for MAXENT, which modeled 702k (SWBD) and 460k (MRDA) parameters (i.e., patterns), and produced micro-averaged F_1 scores of 92.76 (macro-averaged F_1 = 63.54) for SWBD and 82.48 (macro-averaged F_1 = 57.19) for MRDA. In contrast, our method generated approximately 4k to 5k patterns on average with similar or greater F_1 scores (Table 3); hence, compared to MAXENT, our model requires fewer calculations and is just as accurate.

The n-gram model (NGRAM) performed significantly better than the bag-of-words model (McNemar test; $p < 0.001$) (Table 3). Unlike MAXENT, NGRAM automatically selects a relevant set of variable length n-gram features (i.e., phrase features). To this set, we separately added two syntax type features, part-of-speech tag n-gram (POSTAG) and dependency parse tree (DEPTREE) automatically parsed by Minipar[8], and one discourse type feature, speaker n-gram (SPEAKER). Although some micro-averaged F_1 are not statistically significant between the original NGRAM and the models that include POSTAG, DEPTREE or SPEAKER, macro-averaged F_1 values indicate that minor classes can take advantage of other structures. For example, in the result of SWBD (Figure 4), DEPTREE and SPEAKER models help to predict uncertain responses (U), whereas NGRAM and POSTAG cannot do this.

5 Semi-supervised Learning

Our goal is to eventually make maximum use of existing resources in SWBD and MRDA for email/forum speech act recognition. We call the model trained on the mixed data of these two corpora BASELINE. We use ALL features in constructing the BASELINE for the semi-supervised experiments. While this model gave promising results using SWBD and MRDA, language used in emails and forums differs from that used in spoken conversation. For example, 'thanx' is an expression commonly used as a polite mechanism in online communications. To adapt our model to understand this type of difference between spoken and online text-based conversations, we should induce new patterns from unlabeled email and forum data. We describe here two methods of semi-supervised learning.

5.1 Method 1: Bootstrapping

First, we bootstrap the BASELINE model using automatically predicted unlabeled examples. However, using all of the unlabeled data results in noisy models; therefore filtering or selecting data is very important in practice. To this end, we only select similar examples by criterion, $d(\mathbf{x}_i, \mathbf{x}_j) < r$ or k nearest neighbors where $\mathbf{x}_i \in \mathcal{D}_L$ and $\mathbf{x}_j \in \mathcal{D}_U$. In practice, r or k are fixed. In our method, examples are represented by trees; hence we use a "tree edit distance" for calculating $d(\mathbf{x}_i, \mathbf{x}_j)$ (Shasha and Zhang, 1990). Selected examples are evaluated using BASELINE, and using subtree pattern mining runs on the augmented data (i.e. unlabeled). We call this method BOOTSTRAP.

5.2 Method 2: Semi-supervised Boosting

Our second method is based on a principle of semi-supervised boosting learning (Bennett et al., 2002). Because we have no supervised guidance for $\mathcal{D}_U$, our objective functional to find F is defined as:

$$\mathcal{C}(F) = \sum_{i \in \mathcal{D}_L} \alpha_i C[y_i F(\mathbf{x}_i)] + \sum_{i \in \mathcal{D}_U} \beta_i C[|F(\mathbf{x}_i)|] \quad (7)$$

This cost functional is non-differentiable. To solve it, we introduce pseudo-labels $\tilde{y}$ where $\tilde{y} = sgn(F(\mathbf{x}))$ and $|F(\mathbf{x})| = \tilde{y}F(\mathbf{x})$. Using the same derivation in Section 4.2, we obtain the following

[8] http://www.cs.ualberta.ca/∼lindek/minipar.htm

gain function and update rules:

$$\text{gain}(t, y) = \sum_{i \in \mathcal{D}_L} y_i w_i f(y, t, \mathbf{x}_i) + \sum_{i \in \mathcal{D}_U} \tilde{y}_i w_i f(y, t, \mathbf{x}_i), \quad (8)$$

$$w_i = \begin{cases} \alpha_i \cdot e^{-y_i F(\mathbf{x}_i)} & i \in \mathcal{D}_L, \\ \beta_i \cdot e^{-\tilde{y}_i F(\mathbf{x}_i)} & i \in \mathcal{D}_U. \end{cases} \quad (9)$$

Intuitively, an unlabeled example that has a high-confidence $|F(\mathbf{x})|$ at the current step, will probably receive more weight at the next step. That is, similar instances become more important when learning and mining subtrees. This semi-supervised boosting learning iteratively generates pseudo-labels for unlabeled data and finds the value of F that minimizes training errors (Bennett et al., 2002). Also, the algorithm infers new features from unlabeled data, and these features are iteratively re-evaluated by the current ensemble learner. We call this method SEMIBOOST.

6 Experiment

6.1 Setting

We describe specific settings used in our experiment. Because we have no development set, we set the maximum number of iterations K at 10,000. At most K patterns can be extracted, but this seldom happens because duplicated patterns are merged. Typical settings for semi-supervised boosting are $\alpha_i = 1$ and $\beta_i = 0.5$, that is, we penalize the weights for unlabeled data.

For efficiency, BASELINE model used 10% of the SWBD and MRDA data, selected at random. We observed that this data set does not degrade the results of semi-supervised speech act recognition. For BOOTSTRAP and SEMIBOOST, we selected $k = 100$ nearest neighbors of unlabeled examples for each labeled example using tree edit distance, and then used 24,625 (SWBD) and 54,961 (MRDA) sentences for the semi-supervised setting.

All trees were combined as described in Section 4.3 (ALL model). In EMAIL and FORUM data we added different types of discourse features: message type (e.g., initial or reply posts), authorship (e.g., an identification of 2nd or 3rd posts written by the same author), and relative position of a sentence. In Figure 1, for example, F1∼3 is an initial post, and F4∼5 and F6 are reply posts. Moreover, F1, F4, and F6 are the first sentence in each post.

Table 4: Results of speech act recognition on online conversations; columns are micro-averaged F_1 score with macro-averaged scores in parentheses. '⋆' indicates that the result is significantly better than BASELINE ($p < 0.001$).

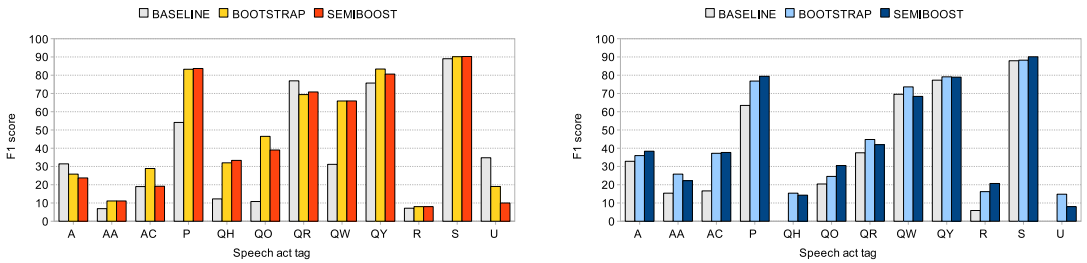
Model	EMAIL	FORUM
BASELINE	78.87 (37.44)	78.93 (35.57)
BOOTSTRAP	⋆83.11 (44.90)	79.09 (44.38)
SEMIBOOST	⋆82.80 (44.64)	⋆81.76 (44.21)
SUPERVISED	90.95 (75.71)	83.67 (40.68)

These features do not occur in SWBD or MRDA because these are utterance-by-utterance conversations.

6.2 Result and Discussion

First, we show that our method of semi-supervised learning can improve modeling of the speech act of emails and forums. As our baseline, BASELINE achieved a micro-averaged F_1 score of $\sim$ 79 for both data sets. This implies that SWBD and MRDA data are useful for our problem. Using unlabeled data, semi-supervised methods BOOTSTRAP and SEMIBOOST perform better than BASELINE (Table 4; Figure 5). To verify our claim, we evaluated the supervised speech act recognition on EMAIL and FORUM evaluation sets with 5-fold cross validation (SUPERVISED in Table 4). In particular, our semi-supervised speech act recognition is competitive with the supervised model in FORUM data.

The difference in performance between supervised results in EMAIL and FORUM seems to indicate that the latter is a more difficult data set. However, our SEMIBOOST method were able to come close to the supervised FORUM results (81.76 vs. 83.67). This is also close to the range of supervised MRDA data set ($F_1 = 83.49$ for ALL, Table 3). Moreover, we analyzed a main reason of why transfer results were competitive in the FORUM but not in the EMAIL. This might be due to the mismatch in the unlabeled data, that is, we used different email collections, the BC3 corpus (email communication of W3C on w3.org sites), for evaluation while used Enron data for adaption. We also conjecture that the discrepancy between EMAIL and FORUM is probably due to the more heterogeneous nature of the FORUM data where anyone can post and reply while EMAIL (Enron or



(a) EMAIL (b) FORUM

Figure 5: Result of the semi-supervised learning method

BC3) might have a more fix set of participants.

The improvement of less frequent tags is prominent, for example 25% for action motivator (AC), 40% for polite mechanism (P), and 15% for rhetorical question (QR) error rate reductions were achieved in FORUM data (Figure 5(b)). Therefore, the semi-supervised learning method is more effective with small amounts of labeled data (i.e., less frequent annotations). We believe that despite their relative rarity, these speech acts are more important than the statement (S) in some applications, e.g., summarization.

Next, we give a qualitative analysis for better interpretation of our problem and results. Due to limited space, we focus on FORUM data, which can potentially be applied to many applications. Of the top ranked patterns extracted by SEMIBOOST (Figure 6(a)), subtree patterns of n-gram, part-of-speech, dependency parse trees are most discriminative. The patterns from unlabeled data have relatively lower ranks, but this is not surprising. This indicates that BASELINE model provides the base knowledge for semi-supervised speech act recognition. Also, unlabeled data for EMAIL and FORUM help to induce new patterns or adjust the model's parameters. As a result, the semi-supervised method is better than the BASELINE when an identical number of patterns is modeled (Figure 6(b)). For this result, we conclude that our method successfully transfers knowledge from a source domain (i.e., SWBD and MRDA) to a target domain (i.e., EMAIL and FORUM); hence it can be a solution to the domain adaption problem.

Finally, we determine the main reasons for error (in SEMIBOOST), to gain insights that may allow development of better models in future work (Figure 6(c)). We sorted speech act tags by their semantics and partitioned the confusion matrix into question type (Q*) and statement, which are two high-level speech acts. Most errors occur in the similar categories, that is, language usage in question discourse is definitely distinct from that in statement discourse. From this analysis, we believe that more advanced techniques (e.g. two-stage classification and learning with hierarchy-augmented loss) can improve our model.

7 Conclusion

Despite the increasing interest in online text-based conversations, no study to date has investigated semi-supervised speech act recognition in email and forum threads. This paper has addressed the problem of learning to recognize speech acts using labeled and unlabeled data. We have also contributed to the development of a novel application of boosting subtree mining. Empirical results have demonstrated that semi-supervised learning of speech act recognition with subtree features improves the performance in email and forum data sets. An attractive future direction is to exploit prior knowledge for semi-supervised speech act recognition. Druck et al. (2008) described generalized expectation criteria in which a discriminative model can employ the labeled features and unlabeled instances. Using prior knowledge, we expect that our model will effectively learn useful patterns from unlabeled data.

As work progresses on analyzing online text-based conversations such as emails, forums, and online chats, the importance of developing models for discourse without annotating much new data will become more important. In the future, we plan to explore other related problems such as adjacency pairs (Levinson, 1983) and discourse parsing (Soricut and Marcu, 2003) for large-scale online forum data.

Abstract

This paper employs morphological structures and relations between sentence segments for opinion analysis on words and sentences. Chinese words are classified into eight morphological types by two proposed classifiers, CRF classifier and SVM classifier. Experiments show that the injection of morphological information improves the performance of the word polarity detection. To utilize syntactic structures, we annotate structural trios to represent relations between sentence segments. Experiments show that considering structural trios is useful for sentence opinion analysis. The best f-score achieves 0.77 for opinion word extraction, 0.62 for opinion word polarity detection, 0.80 for opinion sentence extraction, and 0.54 for opinion sentence polarity detection.

1 Introduction

Sentiment analysis has attracted much attention in recent years because a large scale of subjective information is disseminated through various platforms on the web. Sentiment information can be applied to a wide variety of fields, including product recommendation, review summarization, public polling, and so on.

Opinion dictionaries are important resources for identifying subjective information. Several approaches were proposed to collect such resources. Wiebe (2000) learned subjective adjectives from corpora. Takamura *et al.* (2005) extracted semantic orientations of words. Ku *et al.* (2007) measured sentiment degrees of Chinese words by averaging the sentiment scores of the composing characters. When the opinion words are available, the polarities of sentences and documents can be determined by them. Riloff and Wiebe (2003) learned the extraction patterns for subjective expressions. Kim and Hovy (2004) found the polarity of subjective expressions. Pang *et al.* (2002) and Dave *et al.* (2003) explored various techniques at document level.

Morphological information has been widely used in classifying words, telling the meanings, and doing other in-depth analysis (Tzeng and Chen, 2002). However, morphological information was seldom applied either in Chinese opinion extraction, or in solving the coverage problem of opinion dictionary. Instead of bag-of-characters approach (Ku *et al.*, 2007), this paper employs morphological structures of words to extract opinion words.

Relations between sentence segments are also defined by linguistics in the Chinese language. These are similar to morphological structures between Chinese characters. Based on parsing trees of sentences, we identify these relations and utilize them for opinion analysis on sentences.

As the experimental corpus, some researchers managed to generate annotated materials and gold standards under many constraints. Ku set a standard for generating final answers from annotations of multiple annotators (Ku *et al.*, 2007), and Somasundaran annotated discourse information from meeting dialogs to train a sentiment model (Somasundaran *et al.*, 2007). For multilingual issues, researchers concerned mainly about the applicability of corpus and algorithms from the native language to foreign languages (Banea *et al.*, 2008; Bautin *et al.*, 2008).

Several opinion analysis systems have been developed so far. OASYS (Cesarano *et al.*, 2007) and CopeOpi (Ku *et al.*, 2007) allow users input their queries and select preferred data sources,

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1260–1269,
Singapore, 6-7 August 2009.

and then track opinions in a time zone. For both systems, extracting opinions is the main focus, while holders and targets are identified implicitly when retrieving relevant documents. Carenini's team proposed a graphical user interface for evaluative texts (2006), in which color blocks were used to present the evaluations for components of products. Fair News Reader, a Japanese news Web system, incorporates sentiment information insensibly in an interesting way (Kawai *et al.*, 2007). It provides readers "balanced" reports by analyzing the sentiment in news articles which readers have read, and suggests them new articles according to the analysis results. It leads the application of opinion analysis to the direction of personalization.

2 Chinese Morphological Structures

In the Chinese language, a word is composed of one or more Chinese characters, and its meaning can be interpreted in terms of its composite characters. The morphological structures of Chinese words are formulated by three major processes in linguistics: *compounding*, *affixation*, and *conversion*. *Compounding* is a complex word-formation process. In most cases, two or more morphemes together are formed as a lexical item by this process. *Affixation* is a morphological process, by which grammatical or lexical information is added to a base form. By the *conversion* process, a word is changed from one part of speech into another without the addition or deletion of any morphemes.

Compounding is the most productive way to construct a Chinese word. Mostly, a Chinese character itself carries meanings, so that a morpheme can function as a character and has its own part of speech. In some cases, a Chinese morpheme may carry no specific meaning and just makes a word more readable. Cheng and Tian (1992) divided Chinese words into five morphological types based on the relations between the morphemes in *compounding* words.

(1) Parallel Type: Two morphemes play coordinate roles in a word. For example, the morphemes "財" (money) and "富" (wealth) are parallel in the word "財富" (money-wealth).

(2) Substantive-Modifier Type: A modified morpheme follows a modifying morpheme. For example, the morpheme "哭" (cry) is modified by "痛" (bitterly) in the word "痛哭" (bitterly-cry).

(3) Subjective-Predicate Type: One morpheme is an expresser and the other one is described. The structure is like a subject-verb sentence condensed in one word. For example, the morpheme "心" (heart) is a subject of the predicate "疼" (hurt) in the word "心疼" (heart-hurt).

(4) Verb-Object Type: The first morpheme is usually a verb which governs the second one, making this word similar to a verb followed by its object. For example, the morpheme "控" (control) serves as the object of the verb "失" (lose) in the word "失控" (lose-control).

(5) Verb-Complement Type: The first morpheme is usually a verb but sometimes can be an adjective, and the second morpheme explains the first one from different aspects. For example, the morpheme "清" (clearly) expresses the aspects of the action "看" (look).

Chinese words constructed by *affixation* process can be one of the two cases – say, *morpheme* and *morpheme*, or *morpheme* and *non-morpheme*. In the case of *morpheme* and *morpheme*, the affixation word belongs to one of the above 5 types if the prefix and the suffix are neither negations nor confirmations. Types 6 and 7 defined below represent the affixation words whose prefix or suffix is a negation or a confirmation. The affixation words whose prefix or suffix characters are not morphemes are classified into type 8.

(6) Negation Type: There is at least one negation character in words of this type. For example, the prefix "無" (no) is the negation morpheme in the word "無法" (no-method).

(7) Confirmation Type: There is at least one confirmation character in words of this type. For example, the prefix "有" (do) is a confirmation in the word "有賴" (do-depend on).

(8) Others: Those words that do not belong to the above seven types are assigned to this type, such as words whose meanings are not a function of their composite characters, words whose composite characters are not morphemes, such as "姪子" (nephew-suffix) and "薄荷" (peppermint).

3 Opinion Scores of Chinese Words

The bag-of-characters approach proposed by Ku *et al*. (2007) considers the observation probabilities of characters in Chinese opinion words. It calculates the observation probabilities of characters from a set of seeds first, then dynamically enlarges the set and adjusts their probabilities. In

this approach, the opinion score of a word is determined by the combination of the observation probabilities of its composite characters defined by Formulas (1) and (2).

$$P(C, pos) = \frac{f(C, pos) / \sum_{i=1}^{n} f(C_i, pos)}{f(C, pos) / \sum_{i=1}^{n} f(C_i, pos) + f(C, neg) / \sum_{i=1}^{m} f(C_i, neg)} \quad (1)$$

$$P(C, neg) = \frac{f(C, neg) / \sum_{i=1}^{m} f(C_i, neg)}{f(C, pos) / \sum_{i=1}^{n} f(C_i, pos) + f(C, neg) / \sum_{i=1}^{m} f(C_i, neg)} \quad (2)$$

$$S(C) = P(C, pos) - N(C, neg) \quad (3)$$

$$S(C_1C_2...C_l) = \frac{1}{l}\sum_{i=1}^{l} S(C_i) \quad (4)$$

where C is an arbitrary Chinese character, $f(C, polarity)$ counts the observed frequency of C in a set of Chinese words whose opinion polarity is positive (*pos*) or negative (*neg*); $P(C, pos)$ and $P(C, neg)$ denote the observation probabilities of C as a positive and a negative character, and n and m denote total number of unique characters in positive and negative words. The difference of $P(C, pos)$ and $P(C, neg)$ in Formula (3) determines the sentiment score of character C, denoted by $S(C)$. Formula (4) computes the opinion score of a word of l characters $C_1C_2…C_l$ by averaging their scores.

Instead of counting the weights as in the bag-of-characters approaches, we consider the word structures and propose a scoring function for each morphological type. According to the Frequency Dictionary of Modern Chinese, 96.5% of Chinese words are unigrams and bigrams (Chen, *et al.*, 1997). In the following functions, $S(C_1C_2)$ computes the opinion scores of words with characters C_1 and C_2. $SIGN(s)$ returns -1 if polarity degree s is smaller than 0, i.e., negative, and returns 1 when positive.

(1) Parallel Type: Since the two composite characters of a word of this type are homogeneous, the opinion score is the average score of two characters' opinion scores.

$$S(C_1C_2) = \frac{S(C_1) + S(C_2)}{2} \quad (5)$$

(2) Substantive-Modifier Type: The first morpheme of a word of this type modifies the second one, so that its opinion weight comes from the absolute opinion score of the first character, while the opinion polarity is determined by the occurrence of negative opinion characters. If at least one negative opinion character appears, the word is negative, else it is positive. For example, the word "痛哭" (bitterly cry) is composed of "痛" (bitterly, negative) and "哭" (cry, negative). Negative characters make this word negative and its opinion strength, i.e., the absolute value of the score, is decided by the first character for the degree of crying.

$$\begin{aligned} &\text{if } (S(C_1) \neq 0 \text{ and } S(C_2) \neq 0) \text{ then} \\ &\quad \text{if } (S(C_1) > 0 \text{ and } S(C_2) > 0) \text{ then } S(C_1C_2) = S(C_1) \\ &\quad \text{else } S(C_1C_2) = -1 \times |S(C_1)| \\ &\text{else } S(C_1C_2) = S(C_1) + S(C_2) \end{aligned} \quad (6)$$

(3) Subjective-Predicate Type: The first morpheme of a word of this type is a subject and the second morpheme is the action it performs, so that the action decides the opinion score of the word. If the action is not an opinion or it is neutral, the subject determines the opinion score of this word. For example, the word "山崩" (mudslide, negative) is composed of "山" (mountain, non-opinion) and "崩" (collapse, negative). Its opinion score depends only on the second character "崩" (collapse) since the first character is a subject and usually bears no opinions.

$$\begin{aligned} &\text{if } (S(C_2) \neq 0) \text{ then } S(C_1C_2) = S(C_2) \\ &\text{else } S(C_1C_2) = S(C_1) \end{aligned} \quad (7)$$

(4) Verb-Object Type: The first morpheme of words of this type acts upon the second morpheme. The effect depends not only on the action but on the target. The weight is determined by the action, but the polarity is the multiplication of the signs of the two morphemes. For example, the word "避暑" (to go away for the summer, positive) is composed of "避" (hide, negative) and "暑" (hot summer, negative). Its strength depends on the strength of "避" (hide) and polarity is positive from the multiplication of two negatives.

$$\begin{aligned} &\text{if } (S(C_1) \neq 0 \text{ and } S(C_2) \neq 0) \\ &\quad \text{then } S(C_1C_2) = |S(C_1)| \times SIGN(S(C_1)) \times SIGN(S(C_2)) \\ &\quad \text{else } S(C_1C_2) = S(C_1) + S(C_2) \end{aligned} \quad (8)$$

(5) Verb-Complement Type: The scoring function for words of this type is defined the same as that of a Subjective-Predicate type in Formula (7). The complement morpheme is the deciding factor of the opinion score. For example, the word "提高" (raise, positive) is composed of "提" (carry or lift, non-opinion) and "高" (high,

positive). The complement morpheme "高" (high) describes the resulting state of the verb morpheme "提" (raise), so both strength and polarity depend on the morpheme "高" (high).

(6) Negation Type: A negative character specified in a predefined set *NC* has a negation effect on the opinion score of the other character. The strength depends on the modified morpheme while the polarity of the word is the negation of the polarity of the modified morpheme.

$$\begin{aligned}&\text{if } (C_1 \in NC) \text{ then } S(C_1C_2) = (-1)\times S(C_2)\\&\text{else } S(C_1C_2) = (-1)\times S(C_1)\end{aligned} \quad (9)$$

(7) Confirmation Type: A positive character specified in a predefined set *PC* ensures that the opinion score of a word only comes from the other character. Therefore, the opinion score of this word is determined by the modified morpheme.

$$\text{if } (C_1 \in PC) \text{ then} S(C_1C_2) = S(C_2) \text{ else} S(C_1C_2) = S(C_1) \quad (10)$$

(8) Others: Since words of this type contain no clear cues for their morphological structures, we postulate that both characters have the same contribution, and adopt Formula (5).

4 Identification of Morphological Types

To compute the opinion score of a word according to formulae in Section 3, we must know its morphological type from the morphological structure, i.e., the parts of speech of the composite morphemes. Currently, part of speech tagging is performed at the word level rather than the morpheme level, and morpheme-tagging corpus is not available. We consider an on-line Chinese dictionary, Dictionary of Chinese Words by Ministry of Education, Taiwan (*MOEDCW*), as a corpus, and compute the statistics of each morpheme in it.

Two classifiers, *CRF* classifier and *SVM* classifier are proposed to recognize morphological types (1)-(5). Morphological types (6) to (8) are determined by rules such as whether two composite characters are morphemes; whether there are confirmation/negation morphemes; and so on.

4.1 MOEDCW Corpus

MOEDCW corpus provides possible parts of speech for each morpheme by treating it as a unigram word, and possible senses under each part of speech. In each entry, there are a sense definition and some example words. Figures 1 and 2 show the specifications of two morphemes "冒" and "汗". The morpheme "冒" has three parts of speech (verb, adverb and noun) and includes 3, 1, and 1 senses. There are 3, 3, and 2 example words listed under the three verb senses.

We can find the correct parts of speech of the composite characters of a word when it is an example word in the dictionary. However, not all words are listed in the corpus. Consider the word "冒汗" (sweat, verb). Figure 1 shows that "冒汗" (sweat) is an example word listed under the verb sense of the character "冒" (perspire), thus the character "冒" (perspire) in the word "冒汗" (sweat) functions as a verb. However, "冒汗" (sweat) is not an example for the character "汗" (sweat). Figure 2 show that there are two possible parts of speech, noun and verb, for the character "汗" (sweat). We then show how to identify its function in the word "冒汗".

verb	**1**	Goes out from the button to the top or from inside to outside. For example, **fume**, **smoking**, and **sweat**. 由下往上或往外透出、發散。如：「**冒**煙」、「**冒**氣」、「**冒汗**」。
	2	Burst into or regardless of. For example, **take risk**, **to offend**, and **offense**. 衝犯、不顧。如：「**冒**險」、「**冒**犯」、「衝**冒**」。…
	3	Fake or on the pretext of. For example, **personate** and **to pretend to be**. 假稱、假託。如：「**冒**名」、「假**冒**」。
adverb	**1**	Crude or rash. For example, **offensively** and **advance rashly**. 鹵莽、莽撞。如：「**冒**犯」、「**冒**進」。
noun	**1**	Family name. 姓。

Figure 1: Specification of "冒" in MOEDCW

noun	**1**	Sweat. For example, **cold sweat**, **night sweat**, **sweatiness**, and **to drip with sweat**. 由動物皮膚的毛細孔所排泄出的液體。如：「冷**汗**」、「盜**汗**」、「**汗**流浹背」、「揮**汗**如雨」。…
	2	Family name 姓。
verb	**1**	To sweat 流**汗**、使出**汗**。

Figure 2: Specification of "汗" in MOEDCW

$$T(C, POS) = NumberOfSenses(C, POS) \quad (11)$$

The number of possible meanings one character can bear when it functions as a certain part of

speech is employed to estimate how often this part of speech is used. The function $T(C, POS)$ shown in Formula (11) defines the score of a character C functioning as a particular part of speech POS. Here, POS may be noun (N), adjective (ADJ), verb (V), adverb (ADV), auxiliary (AUX), conjunction (CONJ), pronoun (PRON), preposition (PREP), and interjection (INT). In Figure 2, T(汗<sweat>, N) = 2 and T(汗<sweat>, V) = 1.

4.2 Features for Classifiers

Features for training *SVM* and *CRF* classifiers include the pronunciation and the tone of the word, parts of speech of the first and the second characters of training words, and the position information of the composite characters. The tone of the word is acquired from MOEDCW. The parts of speech are estimated by Formula (11). $f(C, POS, k,$ start/end) counts the number of k-grams (k=2, 3, 4). In Figures 1 and 2, f(冒, V, 2, start)=6, f(冒, V, 2, end)= 2, f(冒, ADV, 2, start) = 2, and f(冒, ADV, 2, end)=0. This example shows that when the character "冒" functions as a verb or an adverb, it serves as the starting character more often than the ending character.

4.3 CRF and SVM Classifier

CRF and *SVM* are both common used algorithms for building classifiers (Lafferty *et al.*, 2001). We adopted *CRF++*[1] and *libSVM* (Chang and Lin, 2001) to develop our classifiers. The features for training our *CRF* and *SVM* classifiers include the input word W, the tone of W, the first and the second characters C_1 and C_2, $T(C_1, POS)$, $T(C_2, POS)$, $f(C_1, POS, k,$ start), $f(C_1, POS, k,$ end), $f(C_2, POS, k,$ start), and $f(C_2, POS, k,$ end). POS denotes one of nine parts of speech in *MOEDCW*, and k equals to 2, 3 or 4.

Using *SVM* is straightforward. To classify a word into one of the morphological structure types, we construct the word's feature vector and input the vector into SVM. When using *CRF*, a different approach is taken. When predicting the classes of two successive instances, *CRF* takes the predicted class of the first instance into account when predicting the second instance's class. Here is how we exploit this capability. In a nutshell, we perform classification at the character level instead of the word level. Let W be a word composed of the two characters C_1 and C_2. Let $\boldsymbol{v}$ be the feature vector of W. Let t be the morphological structure type of W. We define C_1's feature vector to be composed of the features in $\boldsymbol{v}$ which are related to C_1, e.g., $T(C_1,$ verb). Similarly, C_2's feature vector is composed of the features in $\boldsymbol{v}$ which are related to C_2. C_1's class and C_2's class are defined as t_1 and t_2, respectively. Since t has five possible values, there are 10 character classes.

To determine a word W's morphological structure type, we first apply *CRF* on W's constituent characters C_1 and C_2's feature vectors. For C_1, *CRF* will return a set of probabilities $P(C_1,t\_q)$, where $q \in \{1, 2\}$, indicating the likelihood of C_1 being an instance of class t_q. Similarly, a set of probabilities $P(C_2,t\_q)$ is returned for C_2. W's morphological structure type is defined as the value of t which maximizes the product of $P(C_1,t\_1)$ and $P(C_2,t\_2)$.

Though *CRF* is mostly used for sequential labeling, the idea of using CRF is to tail this classification questions into a labeling question in order to utilizing the position information of characters. As mentioned, if a word W of two characters *C1C2* is of type 1, *CRF* will label *C1* 1_1 (type1_1st char) and *C2* 1_2 (type1_2nd char). The labeling of each character considers both the previous character's features and the next character's features. That is, if the current character is the first character, its previous character is an empty character (which is used for segmenting sequences in *CRF*); if the current character is the second character, its next character is an empty character. Hence the position information will be considered by *CRF*.

5 Experiments and Discussion

Experiments verify whether the morphological types benefit opinion polarity detection on words. The relation between the performance of morphological classifiers and opinion polarity detection is discussed.

5.1 Experimental Setup

To compare the bag-of-characters approach (Ku *et al.*, 2007) with our morphological structure approach, we adopt the same evaluation data set containing 836 words. To evaluate the performance of our two morphological classifiers, we prepare two sets of words, including the testing set of 836 words for word-level opinion prediction (abbreviated as *OP*), and a set of 8,186 words selected from words in *MOEDCW* corpus and news documents except those can be classi-

[1] http://crfpp.sourceforge.net/

fied by patterns (abbreviated as *TRAIN set*), all with their morphological types annotated. Table 1 lists the distributions of morphological types in *OP* and *TRAIN* sets.

The polarity of words is predicted by their opinion scores ranging between -1 to 1. We set a positive threshold. Those words with scores above it are considered as positive while those below this threshold multiplied by (-1) are regarded as negative. The words with non-zero scores falling between the positive and negative thresholds are neutral. Fifty grids from 0 to 0.5 are searched for the best threshold. Since the opinion extraction at word level concerns only word structure, no retraining for the best threshold is need when domain shifts, which is a superiority of our method.

5.2 Morphological Type Classification and Polarity Detection

The performances of *CRF* and *SVM* classifiers on each morphological type are listed in Table 2. We perform four-fold cross validation on the *TRAIN* set. Results show that *CRF* classifier achieves better performance than *SVM* classifier in this task. The accuracy of *CRF* classifier (0.70) is 8% higher than that of *SVM* classifier (0.62). Note those type 8 words which could be extracted by rules are excluded from classification experiment. The remaining type 8 words are usually proper names. It is difficult for both classifiers to identify such words.

Table 3 further shows the performance of polarity prediction using morphological types determined by *CRF* classifier and *SVM* classifier. The performance of polarity detection is evaluated by the f-score defined in Formula (12).

The f-scores of polarity detection using *CRF* classified types and *SVM* classified types are 0.5806 and 0.5938, respectively. Both of them outperform baseline's f-score 0.5455, i.e., the bag-of-characters approach (Ku *et al.*, 2007). Experiments show that adopting morphological types annotated by two classifiers for polarity prediction has little difference. In other words, *CRF* and *SVM classifiers* have an 8% f-score difference in their best performance of classification, while the performance gap in word polarity prediction using morphological types provided by these two classifiers is around 1.3% only (0.5806 vs. 0.5938). The reason may be that we define scoring functions of each morphological type in a straightforward way. If they are not the best scoring functions, the benefit of considering the morphological type information could be restricted. Nevertheless, experimental results show that morphological type information is useful for word polarity detection (with p-value less than 0.05).

$$P = \frac{correct(opinion) \cap correct(polarity)}{proposed(opinion)},$$
$$R = \frac{correct(opinion) \cap correct(polarity)}{gold(opinion)}, \quad (12)$$
$$f-score = \frac{2 \cdot P \cdot R}{P + R}.$$

set/type	1	2	3	4	5	6	7	8
TRAIN	26.15	44.97	1.64	15.14	9.22	0	0	2.88
OP	45.8	24.4	1.3	7.9	8.0	2.3	0.5	9.8

Table 1: The Percentage of distribution for morphological types in *TRAIN* and *OP* sets

MorphoType	1	2	3	4	5	8	Accuracy
CRF	0.63	0.78	0.41	0.66	0.78	0.17	0.70
SVM	0.49	0.73	0.22	0.52	0.55	0	0.62

Table 2: The f-score of *CRF* and *SVM* classifiers

We further examine how well our polarity detection method works in combination with a word sentiment dictionary. We use the NTUSD[2] word sentiment dictionary. If a word appears in NTUSD, then the word's polarity is the one specified in NTUSD. If a word does not appear in NTUSD, then the word's polarity is determined using our morphological type method.

After introducing a sentiment dictionary NTUSD[3], *CRF* and *SVM* classifiers both achieve the f-score 0.77 for opinion word extraction, and achieve f-scores 0.61 and 0.62 for polarity detection, respectively. Note that if only NTUSD is used to extract opinion words by string matching, the f-score is only 0.44.

[2] http://nlg18.csie.ntu.edu.tw:8080/opinion/

[3] http://nlg18.csie.ntu.edu.tw:8080/opinion/

Polarity f-score	Without NTUSD	With NTUSD
Ku	0.5455	0.5789
CRF type	0.5806	0.6100
SVM type	0.5938	0.6246

Table 3: Prediction with Morphological Types

We further analyze the improvement of polarity prediction for each morphological type. We find that the f-scores of polarity prediction of all morphological types are improved in different degrees, and among them the performance of type 2 words are improved the most. We have shown that our method can assign an opinion score to an arbitrary word without any word thesauri by considering its morphological information. Moreover, since the Substantive-Modifier (type 2) is the most common way to form a new word in the Chinese language (Cheng and Tian, 1992), the result presents the strength of our method in solving the coverage problem.

6 Syntactic Structure for Chinese Opinion Analysis

As mentioned, the relations introduced in Section 2 exist not only within words, but also between sentence segments. Relations between sentence segments are represented by structural trios hereafter and will be introduced in next section. We have already shown that morphological types are useful when extracting opinion words and would like to further testify whether structural trios also benefit the opinion analysis on sentences. We annotate these relations manually, propose a method to identify these relations, and compare results of experimental settings using structural trios with those not using structural trios.

6.1 Structural Trio

Each node in a parsing tree dominates a word string in a sentence. Linguistics have shown that there are also five relations between sentence segments: Parallel, Substantive-Modifier, Subjective-Predicate, Verb-Object, and Verb-Complement, same as morphological types (1) to (5). Because parsing trees have hierarchical structures, we define a structural trio to represent a relation between two nodes as follows:

(1) A structure trio contains two children nodes which bear a relation.

(2) A structure trio contains one head node which is the nearest common parent of two children nodes in (1).

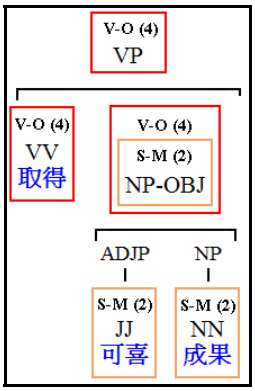

Figure 3: Example of structural trios

Figure 3 shows an example of a structure trio. It is a part of a parsing tree containing words "取得" (obtain), "可喜" (happy), "成果" (results). Two structural trios are shown in this example. The lower one contains two children nodes "可喜" (happy) and "成果" (results), and is labeled as Substantive-Modifier (S-M (2)) in their nearest common parent node, while the upper one contains two children nodes "取得" (obtain) and "可喜成果" (happy results), and is labeled as Verb-Object (V-O (4)).

6.2 Experimental Corpus

To experiment with structural trios, we need the parsing trees of all experimental sentences. For this purpose, we adopted Chinese Treebank 5.1[4] as the experimental materials. Chinese Treebank contains raw Chinese news documents together with their segmented, part of speech tagged, and parsed versions. The parsed documents are adopted in experiments utilizing structural trios, and the part of speech tagged documents are used in experiments not utilizing structural trios.

In Chinese Treebank, a unique ID is labeled on each sentence. For each sentence, we had three annotators label their opinions and then we generate the gold standard following NTCIR[5] MOAT protocol (Seki *et al.*, 2008). We also annotated structure trios in Chinese Treebank. A total of 17,159 sentences are obtained after dropping some faulty sentences such as empty sentences and sentences composed of more than one parsing tree. The statistics of opinion sentences and structural trios in the constructed experimental materials are shown in Table 4 and Table 5.

5	965	1.92
Others	1,054	2.10
Total	50,159	100.00

Table 5: Statistics of structural trios

6.3 Experiment Setup

The aim of our experiments is to know how opinion analysis approach performs when morphological and syntactic structures are incorporated. They are compared with the bag-of-character and bag-of-word approaches. We implemented the bag-of-word approach proposed by Ku *et al.* (2007) to show its performance on Chinese Treebank. In their approach, the opinion scores of words are summed to generate the opinion scores of sentences, and the negation words will negate the closest opinion words. Based on this approach, we further consider structural trios to experiment whether syntactic structures of sentences are beneficial for opinion analysis. Because the scoring functions may not be straight forward as those we have adopted for opinion word extraction, we did not design scoring functions for utilizing all types of structural trios. Instead, we emphasize their original opinion scores by multiplying a variable alpha to see whether these structures are important. In this paper, alpha equals five.

We have shown that word morphological structures benefit the word opinion extraction. When we experiment on sentences, we also incorporate the word morphological structures to see whether they are also useful for opinion analysis on sentences. Five experimental settings are listed as below:

(1) bag[w]-bag[s]: structural information is not considered for both words and sentences. The bag-of-character approach is used to calculate the opinion scores of words, and the bag-of-word approach sentences.

(2) struc[w]-bag[s]: morphological structures are utilized to calculate word opinion scores, but structural trios are not considered. The bag-of-word approach is used to calculate the opinion scores of sentences.

(3) bag[w]-struc[s]: structural trios are considered for calculating sentence opinion scores, while the bag-of-character approach is used to calculate the opinion scores of words.

(4) struc[w]-(m)struc[s]: both word morphological structures and manually labeled structural trios are adopted.

(5) struc[w]-struc[s]: both morphological structure of words and system labeled structural trios are adopted.

As we have shown that NTUSD is beneficial to the opinion analysis at word level, it is used as described in section 5.2 by default.

Our system adopted *CRF* algorithm to label structural trios for setting (5). The content string and the part of speech of the current node, its parent node, its offspring nodes in the next three generations, together with the depth of the current node in the Chinese Treebank, are used as the features for each node in *CRF*. The co-occurrence of the current node and all its siblings are defined in *CRF*'s template file. *CRF* will label whether the current node is the first child or the second child of a certain relation in a structural trio, or it is not part of any structural trios. A four-fold experiment is performed for the learning and testing of this labeling process by *CRF*.

6.4 Results and Discussion

Table 6 shows the statistics of manually labeled structural trios in Chinese Treebank and identification performance of *CRF*. Table 7 shows the performance of five experiment settings described in Section 6.3. The experiment results show that the morphological structures of words do not have a large contribution for opinion sentence analysis (setting 1 vs. setting 2; setting 3 vs. setting 4). However, considering the structural trios improve the performance.

Trio Type	Number	Percentage	f-Score
2	18,483	36.85%	0.4883
3	13,687	27.29%	0.4944
4	15,970	31.84%	0.6360
5	965	1.92%	0.2034
Others	1,054	2.10%	
Total	50159	100%	

Table 6: Statistics and Results of Identifying Structural Trios

Setting	Word [w]	Sentence [s]	f-Score (opinion)	f-Score (polarity)
1	bag	bag	0.7073	0.4988
2	struc	bag	0.7162	0.5117
3	bag	struc	0.8000	0.5361
4	struc	(m)struc	0.7922	0.5297
5	struc	struc	0.7993	0.5187

Table 7: Results of Opinion Extraction on Chinese Treebank

By summarizing the experimental results in Section 5 and this section, we can conclude that considering the word morphological structures benefits the opinion polarity detection, but in the current approach its assistance to words does not propagate to sentences. Considering the syntactic structures, however, do help in opinion analysis both for the opinion sentence extraction and the polarity detection. The performance of opinion extraction boosts to an f-score 0.80 and the performance of polarity detection an f-score 0.54.

However, the utilization of structure trios needs the parsing tree of sentences as the prior knowledge. Hence these two kinds of structural information may be suitable for different applications: structural trios for well written sentences such as those in the news articles, while the morphological structures for casually written sentences such as those appear in SMS messages or articles with limit length on the Web.

Because there are no opinion experiments performed on Chinese Treebank, we mention the performance of Ku's approach (setting (1)) for opinion sentence extraction, f-score 0.6846, in NTCIR-7 MOAT task, on news articles, as a result for comparison. Their approach was ranked the second in this task, and the best team achieved an f-score 0.7453.

7 Conclusion and Future Work

This paper considers morphological and syntactic structures in analyzing Chinese opinion words and sentences. For morphological structures, eight Chinese morphological types are defined. *CRF* classifier and *SVM* classifier for morphological type classification are proposed. Experiments show that *CRF* classifier achieves the best accuracy 0.70 in type classification, which is 8% better than *SVM* classifier. We further show that word morphological structures benefit the opinion word extraction significantly. With the help of the sentiment dictionary NTUSD, the f-score of opinion word extraction achieves 0.77 and the f-score of the word polarity detection achieves 0.62 when the word morphological types are provided by the *SVM* classifier. They are comparably better than bag-of-character approach and the dictionary based approach.

We defined structural trios to represent the relations between sentence segments and also extract these relations using *CRF* algorithm. Results show that considering structural trios benefits the opinion analysis on sentences. An f-score 0.80 for opinion extraction and an f-score 0.54 for polarity detection are achieved, which is a great improvement.

The opinion scoring functions for morphological types and structural trios are critical for polarity detection, and scoring functions for words determine the scoring functions for sentences. Now we define these functions intuitively based on linguistic rules, but learning methods like regression will be investigated in the future. Examining the interaction of cues from word and sentence levels on the opinion sentence extraction and the opinion polarity detection is our next goal.

Finding Short Definitions of Terms on Web Pages

Gerasimos Lampouras[*] and **Ion Androutsopoulos**[*+]

Abstract

We present a system that finds short definitions of terms on Web pages. It employs a Maximum Entropy classifier, but it is trained on automatically generated examples; hence, it is in effect unsupervised. We use ROUGE-W to generate training examples from encyclopedias and Web snippets, a method that outperforms an alternative centroid-based one. After training, our system can be used to find definitions of terms that are not covered by encyclopedias. The system outperforms a comparable publicly available system, as well as a previously published form of our system.

1 Introduction

Definitions of terms are among the most common types of information users search for on the Web. In the TREC 2001 QA track (Voorhees, 2001), where the distribution of question types reflected that of real user logs, 27% of the questions were requests for definitions (e.g., "What is gasohol?", "Who was Duke Ellington?"). Consequently, some Web search engines provide special facilities (e.g., Google's "define:" query prefix) that seek definitions of user-specified terms in on-line encyclopedias or glossaries; to save space, we call both "encyclopedias". There are, however, often terms that are too recent, too old, or less widely used to be included in encyclopedias. Their definitions may be present on other Web pages (e.g., newspaper articles), but they may be provided indirectly (e.g., "He said that *gasohol, a mixture of gasoline and ethanol*, has been great for his business.") and they may be difficult to locate with generic search engines that may return dozens of pages containing, but not defining the terms.

We present a system to find short definitions of user-specified terms on Web pages. It can be used as an add-on to generic search engines, when no definitions can be found in on-line encyclopedias. The system first invokes a search engine using the (possibly multi-word) term whose definition is sought, the *target term*, as the query. It then scans the top pages returned by the search engine to locate 250-character snippets with the target term at their centers; we call these snippets *windows*. The windows are candidate definitions of the target term, and they are then classified as acceptable (positive class) or unacceptable (negative class) using supervised machine learning. The system reports the windows for which it is most confident that they belong in the positive class. Table 1 shows examples of short definitions found by our system. In our experiments, we allow the system to return up to five windows per target term, and the system's response is counted as correct if any of the returned windows contains an acceptable short definition of the target. This is similar to the treatment of definition questions in TREC 2000 and 2001 (Voorhees, 2000; Voorhees, 2001), but the answer is sought on the Web, not in a given document collection of a particular genre.

More recent TREC QA tracks required definition questions to be answered by lists of complementary text snippets, jointly providing required or optional information nuggets (Voorhees, 2003). In contrast, we focus on locating single snippets that include self-contained short definitions. Despite its simpler nature, we believe the task we address is of practical use: a list of single-snippet definitions from Web pages accompanied by the source URLs is a good starting point for users seeking definitions of terms not covered by encyclopedias. We also note that evaluating multi-snippet definitions can be problematic, because it is often difficult to agree which information nuggets should be treated as required, or even optional (Hildebrandt et al., 2004). In contrast, earlier experimental results we have reported (Androutsopoulos and Galanis, 2005) show strong inter-assessor agreement ($K > 0.8$) for single-snippet definitions (Eugenio and Glass, 2004). The task we address also differs from DUC's query focused summarization (Dang, 2005; Dang, 2006). Our queries are single terms, whereas DUC queries are longer topic

descriptions, often entire paragraphs; furthermore, we do not attempt to compose coherent and cohesive summaries from several snippets.

The system we present is based on our earlier work (Miliaraki and Androutsopoulos, 2004), where an SVM classifier (Cristianini and Shawe-Taylor, 2000) was used to separate acceptable windows from unacceptable ones; the SVM also returned confidence scores, which were used to rank the acceptable windows. On datasets from the TREC 2000 and 2001 QA tracks, our earlier system clearly outperformed the methods of Joho and Sanderson (2000; 2001) and Prager et al. (2001; 2002), as reported in previous work (Miliaraki and Androutsopoulos, 2004). To train the SVM, however, thousands of training windows were required, each tagged as a positive or negative example. Obtaining large numbers of training windows is easy, but manually tagging them is very time-consuming. In the TREC 2000 and 2001 datasets, it was possible to tag the training windows automatically by using training target terms and accompanying regular expression patterns provided by the TREC organizers. The regular expressions covered all the known acceptable definitions of the corresponding terms that can be extracted from the datasets. When the training windows, however, are obtained from the Web, it is impossible to construct manually regular expressions for all the possible phrasings of the acceptable definitions in the training windows.

In subsequent work (Androutsopoulos and Galanis, 2005), we developed ATTW (automatic tagging of training windows), a technique that produces arbitrarily large collections of training windows from the Web with practically no manual effort, in effect making our overall system unsupervised. ATTW uses training terms for which several encyclopedia definitions are available, and compares each Web training window (each window extracted from the pages the search engine returned for a training term) to the corresponding encyclopedia definitions. Web training windows that are very similar (or dissimilar) to the corresponding encyclopedia definitions are tagged as positive (or negative) examples; if the similarity is neither too high nor too low, the window is not included in the classifier's training data. Previously reported experiments (Androutsopoulos and Galanis, 2005) showed that ATTW leads to significantly better results, compared to training the classifier on all the available TREC windows, for which regular expressions are available, and then using it to classify Web windows.

Note that in ATTW the encyclopedia definitions are used only during training. Once the classifier has been trained, it can be used to discover definitions on arbitrary Web pages. In fact, during testing we discard windows originating from on-line encyclopedias, simulating the case where we seek definitions of terms not covered by encyclopedias; we also ignore windows from on-line encyclopedias during training. Also, note that the classifier is trained on Web windows, not directly on encyclopedia definitions, which allows it to avoid relying excessively on phrasings that are common in encyclopedia definitions, but uncommon in more indirect definitions of arbitrary Web pages. Fur-

thermore, training the classifier directly on encyclopedia definitions would not provide negative examples.

In our previous work with ATTW (Androutsopoulos and Galanis, 2005) we used a measure constructed by ourselves to assess the similarity between Web windows and encyclopedia definitions. Here, we use the more established ROUGE-W measure (Lin, 2004) instead. ROUGE-W and other versions of ROUGE have been used in summarization to measure how close a machine-authored summary is to multiple human summaries of the same input. We use ROUGE-W in a similar setting, to measure how close a training window is to multiple encyclopedia definitions of the same term. A further difference from our previous work is that we also use ROUGE-W when computing the features of the windows to be classified. Previously, the SVM relied, among others, on Boolean features indicating if the target term was preceded or followed in the window to be classified by a particular phrase indicating a definition (e.g., "target, a kind of", "such as target"). The indicative phrases are selected automatically during training, but now the corresponding features are not Boolean; their values are the ROUGE-W similarity scores between an indicative phrase and the context of the target term in the window. This allows the system to soft-match the phrases to the windows (e.g., encountering "target, another kind of", instead of "target, a kind of").[1]

In our new system we also use a Maximum Entropy (MAXENT) classifier (Ratnaparkhi, 1997) instead of an SVM, because much faster implementations of the former are available.[2] We present experimental results showing that our new system significantly outperforms our previously published one. The use of the MAXENT classifier by itself improved slightly our results, but the improvements come mostly from using ROUGE-W.

Apart from presenting an improved version of our system, the main contribution of this paper is a detailed experimental comparison of our new system against Cui et al.'s (2004; 2005; 2006; 2007). The latter is particularly interesting, because it is well published, it includes both an alternative, centroid-based technique to automatically tag training examples and a soft-matching classifier, and it is publicly available.[3] We show that ATTW outperforms Cui et al.'s centroid-based technique, and that our overall system is also clearly better than Cui et al.'s in the task we address.

Section 2 discusses ATTW with ROUGE-W, Cui et al.'s centroid-based method to tag training examples, and experiments showing that ATTW is better. Section 3 describes our new overall system, the system of Cui et al., and the baselines. Section 4 reports experimental results showing that our system is better than Cui et al.'s, and better than our previously published system. Section 5 discusses related work; and section 6 concludes.

2 Tagging training windows

During both training and testing, for each target term we keep the r most highly ranked Web pages the search engine returns. We then extract the first f windows of the target term from each page, since early occurrences of the target terms on pages are more likely to be definitions. We, thus, obtain $r \cdot f$ windows per term.[4] When testing, we return the k windows of the target term that the classifier is most certain they belong in the positive class. In our experiments, $r = 10$, $f = 5$, $k = 5$. During training, we train the classifier on the $q \cdot r \cdot f$ windows we obtain for q training target terms; in our experiments, q ranged from 50 to 1500. Training requires tagging first the training windows as positive or negative, possibly discarding windows that cannot be tagged automatically.

2.1 ATTW with ROUGE-W similarity

To tag a training window w of a training term t with ATTW and ROUGE-W, we obtain a set C_t of definitions of t from encyclopedias.[5] Stop-words, punctuation, and non-alphanumeric characters are removed from C_t and w, and a stemmer is applied; the testing windows undergo the same preprocessing.[6] For each definition $d \in C_t$, we find the longest common word subsequence of w and d. If w is the word sequence $\langle A, B, F, C, D, E \rangle$

[1] We also experimented with other similarity measures (e.g., edit distance) and ROUGE variants, but we obtained the best results with ROUGE-W.

[2] We use Stanford's classifier; see http://nlp.stanford.edu/.

[3] See http://www.cuihang.com/software.html. The software and a demo of our system, and the datasets we used are also freely available; see http://nlp.cs.aueb.gr/.

[4] We used Altavista in our experiments. We remove HTML tags and retain only the plain text of the pages.

[5] The training terms were randomly selected from the index of http://www.encyclopedia.com/. We used Google's "define:" to obtain definitions from other encyclopedias.

[6] We use the 100 most frequent words of the BNC corpus (http://www.natcorp.ox.ac.uk/) as the stop-list, and Porter's stemmer (http://tartarus.org/∼martin/PorterStemmer/).

and $d = \langle A, B, E, C, G, D \rangle$, the longest common subsequence is $\langle A, B, C, D \rangle$. The longest common subsequence is divided into consecutive matches, producing in our example $\langle A, B|C|D \rangle$. We then compute the following score (weighted longest common subsequence), where m is the number of consecutive matches, k_i is the length of the i-th consecutive match, and f is a weighting function. We use $f(k) = k^a$, where $a > 1$ is a parameter we tune experimentally.

$$WLCS(w, d) = \sum_{i=0}^{m} f(k_i)$$

We then compute the following quantities, where $|\cdot|$ is word length, and f^{-1} is the inverse of f.

$$P(w, d) = f^{-1}(\frac{WLCS(w,d)}{f(|w|)})$$
$$R(w, d) = f^{-1}(\frac{WLCS(w,d)}{f(|d|)})$$
$$F(w, d) = \frac{(1+\beta^2) \cdot R(w,d) \cdot P(w,d)}{R(w,d) + \beta^2 \cdot P(w,d)}$$

In effect, $P(w, d)$ examines how close the longest common substring is to w and $R(w, d)$ how close it is to d. Following Lin (2004), we use $\beta = 8$, assigning greater importance to $R(w, d)$. If $R(w, d)$ is high, the longest common substring is very similar to d; then w (which also includes the longest common substring) intuitively contains almost all the information of d, i.e., all the information of a known acceptable definition (high recall). If $P(w, d)$ is high, the longest common substring is very similar to w; then d (which also includes the longest common substring) contains almost all the information of w, i.e., w does not contain any (redundant) information not included in a known acceptable definition, something we care less for.

The ROUGE-W similarity $sim(w, C_t)$ between w and C_t is the maximum $F(w, d)$, for all $d \in C_t$. Training windows with $sim(w, C_t) > T_+$ are tagged as positive; if $sim(w, C_t) < T_-$, they are tagged as negative; and if $T_- \leq sim(w, C_t) \leq T_+$, they are discarded. We tune the thresholds T_+ and T_- experimentally, as discussed below.

2.2 The centroid-based tagging approach

This method is used in the system of Cui et al. (2004; 2005; 2006; 2007). For each training target term, we construct a "centroid" pseudo-text containing the words that co-occur most frequently with the target term. We then compute the similarity between each training window and the centroid of its target term. If it exceeds a threshold, the window is tagged as positive; Cui et al. produce only positive examples.

The centroid of a training target term t is constructed as follows. For each word u in t's training windows, we compute the centrality score defined below, where SF_t is the number of t's training windows, SF_u is the number of u's windows that can be extracted from the retained Web pages the search engine returned for t, $SF_{t \cap u}$ is the number of windows on the same pages that contain both t and u, and $idf(u)$ is the inverse document frequency of w.[7] Centrality scores are pointwise mutual information with an extra $idf(u)$ factor.

$$centrality(u) = -log(\frac{SF_{t \cap u}}{SF_t + SF_u}) \cdot idf(u)$$

The words u whose centrality scores exceed the mean by at least a standard deviation are added to the centroid of t. Before computing the centrality scores, stop-words, punctuation, and non-alphanumeric characters are removed, and a stemmer is applied, as in ATTW. The similarities between training windows and centroids are then computed using cosine similarity, after turning the centroids and windows into binary vectors that show which words they contain.

2.3 Comparing the tagging approaches

To evaluate the two methods that tag training windows, we selected randomly $q = 200$ target terms, different from those used for training and testing. We collected the $q \cdot r \cdot f = 200 \cdot 10 \cdot 5$ windows from the corresponding Web pages, we selected randomly 400 from the collected 10,000 windows, and tagged them manually as positive or negative.

Figure 1 plots the positive precision of the two methods against their positive recall, and figure 2 shows negative precision against negative recall. For different values of T_+, we obtain a different point in figure 1; similarly for T_- and figure 2. Positive precision is $TP/(TP + FP)$, positive recall is $TP/(TP + FN)$, and likewise for negative precision and recall; TP (true positives) are the positive training windows the method has correctly tagged as positive, FP are the negative windows the method has tagged as positives etc.

For very high (strict) T_+ values, the methods tag very few (or none) training windows as positive; hence, both TP and $TP + FP$ approach (or become) zero; we take positive precision to be zero in that case. Positive recall also approaches (or becomes) zero, which is why both positive recall and

[7] We obtained $idf(u)$ from BNC. Cui et al. use sentences instead of windows, reducing the risk of truncating definitions. We used windows in all systems, to compare fairly.

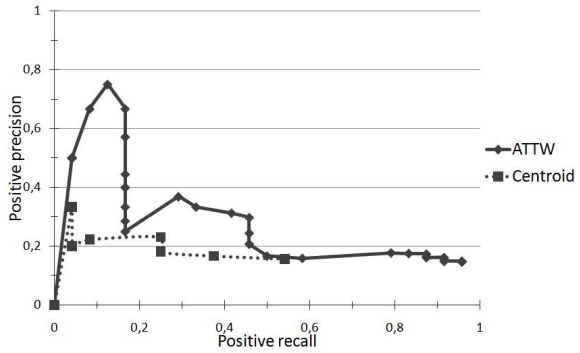

Figure 1: Results of generating positive examples.

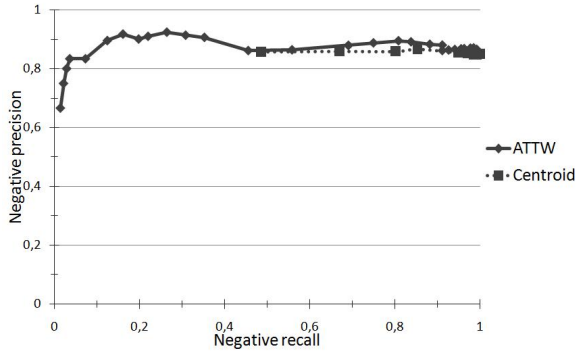

Figure 2: Results of generating negative examples.

precision reach zero in the left of figure 1. Similar comments apply to figure 2, though both methods always tagged correctly at least a few training windows as negative, for the T_- values we tried; hence, negative precision was never zero.

Positive precision shows how certain we can be that training windows tagged as positive are indeed positive; whereas positive recall is the percentage of true positive examples that we manage to tag as such. Figure 1 shows that when using ATTW, we need to settle for a low positive recall, i.e., miss out many positive examples, in order to obtain a reasonably high precision. It also shows that the centroid method is clearly worse when tagging positive examples; its positive precision is almost always less than 0.3. Figure 2 shows that both methods achieve high negative precision and recall; they manage to assign trustworthy negative labels without missing many negative examples. However, ATTW is significantly better when tagging positive examples, as shown in figure 1; hence, it is better than the centroid method.[8]

When using ATTW in practice, we need to select T_+ and T_-. We assign more importance to selecting a T_+ (a point of ATTW's curve in figure 1) that yields high positive precision; the choice of T_- (point in figure 2) is less important, because ATTW's negative precision is always reasonably high. Based on figure 1, we set T_+ to 0.58, which corresponds to positive precision 0.66 and positive recall 0.16. By tuning the two thresholds we can control the number of positively or negatively tagged examples we produce (and their ratio), and the number of examples we discard. Having set T_+, we set T_- to 0.30, a value that maintains the ratio of truly positive to truly negative windows of the 400 manually tagged windows (0.2 to 1), since this is approximately the ratio the classifier will confront during testing; we also experimented with a 1 to 1 ratio, but the results were worse. This T_- value corresponds negative precision 0.70 and negative recall 0.02. Thus, both positive and negative precision is approximately 0.7, which means that approximately 30% of the tags we assign to the examples are incorrect. Our experiments, however, indicate that the classifier is able to generalize well over this noise.

3 Finding new definitions

We now present our overall system, the system of Cui et al., and the baselines.

3.1 Our system

Given a target term, our system extracts $r \cdot f = 10 \cdot 5$ windows from the pages returned by the search engine, and uses the MAXENT classifier to separate them into acceptable and unacceptable definitions.[9] It then returns the $k = 5$ windows the classifier is most confident they are acceptable. The classifier is trained on windows tagged as positive or negative using ATTW. It views each window as a vector of the following features:[10]

SN: The ordinal number of the window on the page it originates from (e.g., second window of the target term from the beginning of the page). Early mentions of a term are more likely to define it.

RK: The ranking of the Web page the window originates from, as returned by the search engine.

[8] We tried different values of ROUGE-W's a parameter in the interval $(1, 2]$. We use $a = 1.4$, which was the value with the best results on the 400 windows. We did not try $a > 2$, as the results were declining as a approached 2.

[9] We do not discuss MAXENT classifiers, since they are a well documented in the literature.

[10] SN and WC originate from Joho and Sanderson (2000).

WC: We create a simple centroid of the window's target term, much as in section 2.2. The centroid's words are chosen based on their frequency in the $r \cdot f$ windows of the target term; the 20 most frequent words are chosen. WC is the percentage of the 20 words that appear in the vector's window.

Manual patterns: 13 Boolean features, each signaling if the window matches a different manually constructed lexical pattern (e.g., "target, a/an/the", as in "Tony Blair, the British prime minister"). The patterns are those used by Joho and Sanderson (2000), and four more introduced in our previous work (Androutsopoulos and Galanis, 2005) and (Miliaraki and Androutsopoulos, 2004). They are intended to perform well across text genres.

Automatic patterns: m numeric features, each showing the degree to which the window matches a different automatically acquired lexical pattern. The patterns are word n-grams ($n \in \{1, 2, 3\}$) that must occur directly before or after the target term (e.g., "*target* which is"). The patterns are acquired as follows. First, all the n-grams directly before or after any target term in the training windows are collected. The n-grams that have been encountered at least 10 times are candidate patterns. From those, the m patterns with the highest precision scores are retained, where precision is the number of positive training windows the pattern matches over the total number of training windows it matches; we use $m = 300$ in our experiments, based on the results of our previous work. The automatically acquired patterns allow the system to detect definition contexts that are not captured by the manual patterns, including genre-specific contexts. The value of each feature is the ROUGE-W score between a pattern and the left or right context of the target term in the window.

3.2 Cui et al.'s system

Given a target term t, Cui et al. (2004; 2005; 2006; 2007) initially locate sentences containing t in relevant documents. We use the $r \cdot f = 10 \cdot 5$ windows from the pages returned by the search engine, instead of sentences. Cui et al. then construct the centroid of t, and compute the cosine similarity of each one of the $r \cdot f$ windows to the centroid, as in section 2.2. The 10 windows that are closer to the centroid are considered candidate answers. All candidate answers are then processed by a part-of-speech (POS) tagger and a chunker. The words of the centroid are replaced in all the candidate answers by their POS tags; the target term, noun phrases, forms of the verb "to be", and articles are replaced by special tags (e.g., TARGET, NP), while adjectives and adverbs are removed. The candidate answers are then cropped to L tokens to the left and right of the target term, producing two subsequences (left and right) per candidate answer; we set $L = 3$, which is Cui et al.'s default.

Cui et al. experimented with two approaches to rank the candidate answers, called Bigram Model and Profile Hidden Markov Model (PHMM). Both are learning components that produce soft patterns, though PHMM is much more complicated. In their earlier work, Cui et al. (2005) found the Bigram Model to perform better than PHMM; in more recent experiments with more data (Cui, 2006; Cui et al., 2007) they found PHMM to perform better, but the difference was not statistically significant. Given these results and the complexity of PHMM, we experimented only with the Bigram Model.

In the Bigram Model, the left and right subsequences of each candidate answer are considered separately. Below $S_1, \ldots, S_L$ refer to the slots (word positions) of a (left or right) subsequence, and $t_1, \ldots, t_L$ to the particular words in the slots. For each subsequence $\langle S_1 = t_1, \ldots, S_L = t_L \rangle$ of a candidate answer, we first estimate:

$$P(t_i|S_i) = \frac{|S_i(t_i)| + \delta}{\sum_{t'} |S_i(t_i)| + \delta \cdot N}$$

$$P(t_i|t_{i-1}) = \frac{|S_i(t_i) \wedge S_{i-1}(t_{i-1})|}{|S_i(t_i)|}$$

$P(t_i|S_i)$ is the probability that t_i will appear in slot S_i of a left or right subsequence (depending on the subsequence considered) of an acceptable candidate answer. $P(t_i|t_{i-1})$ is the probability that t_i will follow t_{i-1} in a (left or right) subsequence of an acceptable candidate answer. Cui et al. use only positive training examples, generated by the centroid-based approach of section 2.2. $|S_i(t_i)|$ is the number of times t_i appeared in S_i in the (left or right) subsequences of the training examples. t' ranges over all the words that occurred in S_i in the training examples. $|S_i(t_i) \wedge S_{i-1}(t_{i-1})|$ is the number of times t_i and t_{i-1} co-occurred in the corresponding slots in the training examples. N is the number of different words that occurred in the (left or right) training subsequences, and δ is a constant set to 2, as in Cui et al.'s experiments. Following Cui et al., if t_i is a POS or other special tag then the probabilities above are estimated by counting

only the tags of the training examples. Similarly, if t_i is an actual word, only the actual words (not tags) of the training examples are considered.

The probability of each subsequence could then be estimated as:

$$P(t_1, \ldots, t_L) = P(t_1|S_1) \cdot \prod_{i=2}^{L} (\lambda \cdot P(t_i|t_{i-1}) + (1 - \lambda) \cdot P(t_i|S_i))$$

Instead, Cui et al. use the following scoring measure, which also accounts for the fact that some subsequences may have length $l < L$. They tune λ by Expectation Maximization.

$$P_{norm}(t_1, \ldots, t_L) = \frac{1}{l} \cdot [\log P(t_1|S_1) + \sum_{i=2}^{L} \log(\lambda \cdot P(t_i|t_{i-1}) + (1 - \lambda) \cdot P(t_i|S_i))]$$

The overall score of a candidate answer is then:

$$P = (1 - \alpha) \cdot P_{norm}(left) + \alpha \cdot P_{norm}(right)$$

Again, Cui et al. tune a by Expectation Maximization. Instead, we tuned λ and α by a grid search in $[0, 1] \times [0, 1]$, with step 0.1 for both parameters. For the tuning, we trained Cui et al.'s system on 2,000 randomly selected target terms, excluding terms used for other purposes. We used 160 manually tagged windows to evaluate the system's performance with the different values of λ and α; the 160 windows were selected randomly from the 10,000 windows of section 2.3, after excluding the 400 manually tagged windows of that section. The resulting values for λ and α were 0.7 and 0.6, respectively. Apart from the modifications we mentioned, we use Cui et al.'s original implementation.

3.3 Baseline methods

The first baseline selects the first window of each one of the five highest ranked Web pages, as returned by the search engine, and returns the five windows. The second baseline returns five windows chosen randomly from the $r \cdot f = 10 \cdot 5$ available ones. The third baseline (centroid baseline) creates a centroid of the $r \cdot f$ windows, as in section 2.2, and returns the five windows with the highest cosine similarity to the centroid.[11]

[11] We also reimplemented the definitions component of Chu-Carroll et al. (2004; 2005), but its performance was worse than our centroid baseline.

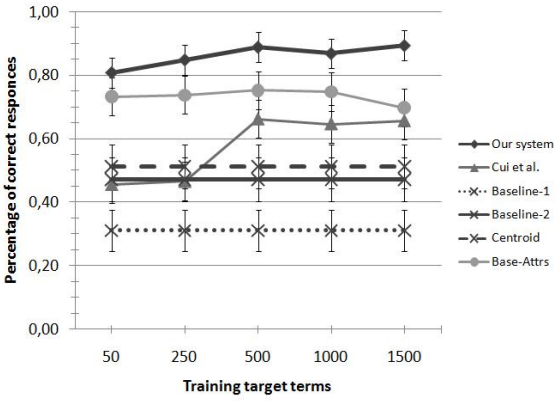

Figure 3: Correct responses, 5 answers/question.

4 Evaluation of systems

We used q training target terms in the experiments of this section, with q ranging from 50 to 1500, and 200 testing terms, with no overlap between training and testing terms, and excluding terms that had been used for other purpose.[12] We had to use testing terms for which encyclopedia definitions were also available, to judge the acceptability of the systems' responses, since many terms are highly technical. We discarded, however, windows extracted from encyclopedia pages when testing, simulating the case where the target terms are not covered by encyclopedias.

As already mentioned, for each target term we extract $r \cdot f = 10 \cdot 5$ windows (or fewer, if fewer are available) from the pages the search engine returns. We then provide these windows to each of the systems, allowing them to return up to $k = 5$ windows, ordered by decreasing confidence. If any of the k windows contains an acceptable short definition of the target term, as judged by a human evaluator, the system's response is counted as correct. We also calculate the Mean Reciprocal Rank (MRR) of each system's responses, as in the TREC QA track: if the first acceptable definition of a response is in the j-th position ($1 \leq j \leq k$), the response's score is $1/j$; MRR is the mean of the responses' scores, i.e., it rewards systems that return acceptable definitions higher in their responses.

Figures 3 and 4 show the results of our experiments as percentage of correct responses and MRR, respectively; the error bars of figure 3 correspond to 95% confidence intervals. Our system clearly outperforms Cui et al.'s, despite the fact that the

[12] The reader is reminded that all terms were selected randomly from the index of an on-line encyclopedia.

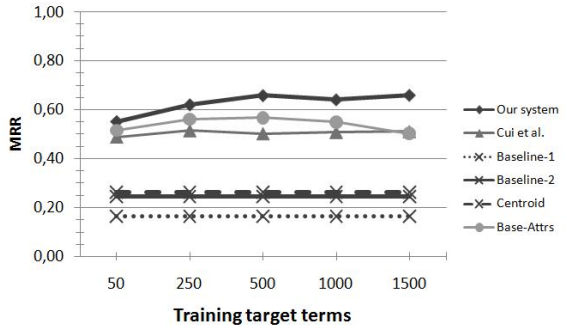

Figure 4: MRR scores, 5 answers per question.

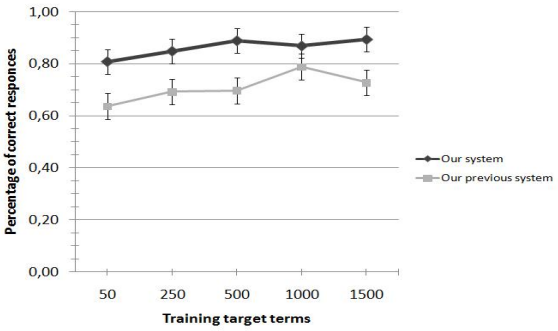

Figure 5: Correct responses of our new and previous system, allowing 5 answers per question.

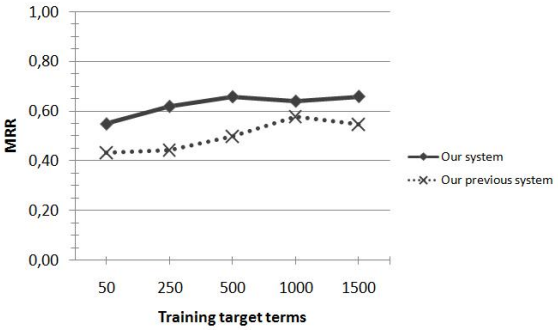

Figure 6: MRR of our new and previous system.

latter uses more linguistic resources (a POS tagger and a chunker). Both systems outperform the baselines, of which the centroid baseline is the best, and both systems perform better as the size of the training set increases. The baselines contain no learning components; hence, their curves are flat. We also show the results (Base-Attrs) of our system when the features that correspond to automatically acquired patterns are excluded. Clearly, these patterns help our system achieve significantly better results; however, our system outperforms Cui et al.'s even without them. Without the automatic patterns, our system also shows signs of saturation as the training data increase.

Figures 5 and 6 show the performance of our new system against our previously published one (Androutsopoulos and Galanis, 2005); the new system clearly outperforms the old one. Additional experiments we conducted with the old system replacing the SVM by the MAXENT classifier (without using ROUGE-W) indicate that the use of MAXENT by itself also improved slightly the results, but the differences are too minor to show; the improvement is mostly due to the use of ROUGE-W instead of our previous measure.

5 Related work

Xu et al. (2004) use an information extraction engine to extract linguistic features from documents relevant to the target term. The features are mostly phrases, such as appositives, and phrases expressing relations. The features are then ranked by their type and similarity to a centroid, and the most highly ranked ones are returned. Xu et al. seem to aim at generating multi-snippet definitions, unlike the single-snippet definitions we seek.

Blair-Goldensohn et al. (2003; 2004) extract sentences that may provide definitional information from documents retrieved for the target term; a decision tree learner and manually tagged training data are used. The sentences are then matched against manually constructed patterns, which operate on syntax trees, to detect sentences expressing the target term's genus, species, or both (genus+species). The system composes its answer by placing first the genus+species sentence that is closer to the centroid of the extracted sentences. The remaining sentences are ranked by their distance from the centroid, and the most highly ranked ones are clustered. The system then selects iteratively the cluster that is closer to the centroid of the extracted sentences and the most recently used cluster. The cluster's most representative sentence, i.e., the sentence closest to the centroid of the cluster's sentences, is added to the response. The iterations stop when a maximum response length is reached. Multi-snippet definitions are generated.

Han et al. (2004; 2006) parse a definition question to locate the head word of the target term. They also use a named entity recognizer to determine the target term's type (person, organization,

etc.). They then extract from documents relevant to the target term sentences containing its head word, as well as sentences the extracted ones refer to (e.g., via pronouns). The resulting sentences are matched against manually constructed syntactic patterns to detect phrases conveying definitional information. The resulting phrases are ranked by criteria like the degree to which the phrase contains words common in definitions of the target term's type, and the highest ranked phrases are included in a multi-snippet summary. Other mechanisms discard phrases duplicating information.

Xu et al. (2005) aim to extract all the definitions in a document collection. They parse the documents to detect base noun phrases (without embedded noun phrases). Base noun phrases are possible target terms; the paragraphs containing them are matched against manually constructed patterns that look for definitions. An SVM then separates the remaining paragraphs into good, indifferent, and bad definitions. Redundant paragraphs, identified by edit distance similarity, are removed.

6 Conclusions and future work

We presented a freely available system that finds short definitions of user-specified terms on Web pages. It employs a MAXENT classifier, which is trained on automatically generated examples; hence, the system is in effect unsupervised. We use ROUGE-W to generate training examples from Web snippets and encyclopedias, a method that outperforms an alternative centroid-based one. Once our system has been trained, it can find short definitions of terms that are not covered by encyclopedias. Experiments show our system outperforms a comparable well-published system and a previously published form of our system.

Our system does not require linguistic processing tools, such as named entity recognizers, POS taggers, chunkers, parsers; hence, it can be easily used in languages where such tools are unavailable. It could be improved by exploiting the HTML markup of Web pages and the Web's hyperlinks. For example, the target term is sometimes written in italics in definitions, and some definitions are provided on pages (e.g., pop-up windows) that occurrences of the target term link to.

The work reported here was conducted in the context of project INDIGO, where an autonomous robotic guide for museum collections is being developed (Galanis et al., 2009). The guide engages the museum's visitors in spoken dialogues, and it describes the exhibits the visitors select by generating spoken natural language descriptions from an ontology. Among other requests, the visitors can ask follow up questions, and we have found that the most common kind of follow up questions are requests to define terms (e.g., names of persons, events, architectural terms, etc.) mentioned in the generated exhibit descriptions. Some of these definition requests can be handled by generating new texts from the ontology, but some times the ontology contains no information for the target terms. We are, thus, experimenting with the possibility of obtaining short definitions from the Web, using the system we presented.

Abstract

This paper explores Chinese semantic role labeling (SRL) for nominal predicates. Besides those widely used features in verbal SRL, various nominal SRL-specific features are first included. Then, we improve the performance of nominal SRL by integrating useful features derived from a state-of-the-art verbal SRL system. Finally, we address the issue of automatic predicate recognition, which is essential for a nominal SRL system. Evaluation on Chinese NomBank shows that our research in integrating various features derived from verbal SRL significantly improves the performance. It also shows that our nominal SRL system much outperforms the state-of-the-art ones.

1. Introduction

Semantic parsing maps a natural language sentence into a formal representation of its meaning. Due to the difficulty in deep semantic parsing, most of previous work focuses on shallow semantic parsing, which assigns a simple structure (such as WHO did WHAT to WHOM, WHEN, WHERE, WHY, HOW) to each predicate in a sentence. In particular, the well-defined semantic role labeling (SRL) task has been drawing more and more attention in recent years due to its importance in deep NLP applications, such as question answering (Narayanan and Harabagiu, 2004), information extraction (Surdeanu et al., 2003), and co-reference resolution (Ponzetto and Strube, 2006). Given a sentence and a predicate (either a verb or a noun) in it, SRL recognizes and maps all the constituents in the sentence into their corresponding semantic arguments (roles) of the predicate. According to the predicate types, SRL could be divided into SRL for verbal predicates (verbal SRL, in short) and SRL for nominal predicates (nominal SRL, in short).

During the past few years, verbal SRL has dominated the research on SRL with the availability of FrameNet (Baker et al., 1998), PropBank (Palmer et al., 2005), and the consecutive CoNLL shared tasks (Carreras and Màrquez, 2004 & 2005) in English language. As a complement to PropBank on verbal predicates, NomBank (Meyers et al., 2004) annotates nominal predicates and their corresponding semantic roles using similar semantic framework as PropBank. As a representative, Jiang and Ng (2006) pioneered the exploration of various nominal SRL-specific features besides the traditional verbal SRL-related features on NomBank. They achieved the performance of 72.73 and 69.14 in F1-measure on golden and automatic syntactic parse trees, respectively, given golden nominal predicates.

For SRL in Chinese, Sun and Jurafsky (2004) and Pradhan et al. (2004) pioneered the research on Chinese verbal and nominal SRLs, respectively, on small private datasets. Taking the advantage of recent release of Chinese PropBank (Xue and Palmer, 2003) and Chinese NomBank (Xue, 2006a), Xue and his colleagues (Xue and Palmer 2005; Xue 2006b; Xue, 2008) pioneered the exploration of Chinese verbal and nominal SRLs, given golden predicates. Among them, Xue and Palmer (2005) studied Chinese verbal SRL using Chinese PropBank and achieved the performance of 91.3 and 61.3 in F1-measure on golden and automatic syntactic parse trees, respectively. Xue (2006b) extended their study on Chinese nominal SRL and attempted to improve the performance of nominal SRL by simply in-

Singapore, 6-7 August 2009.

cluding the Chinese PropBank training instances into the training data for nominal SRL on Chinese NomBank. However, such integration was empirically proven unsuccessful due to the different nature of certain features for verbal and nominal SRLs. Xue (2008) further improved the performance on both verbal and nominal SRLs with a better syntactic parser and new features. Ding and Chang (2008) focused on argument classification for Chinese verbal predicates with hierarchical feature selection strategy. They achieved the classification precision of 94.68% on golden parse trees on Chinese PropBank.

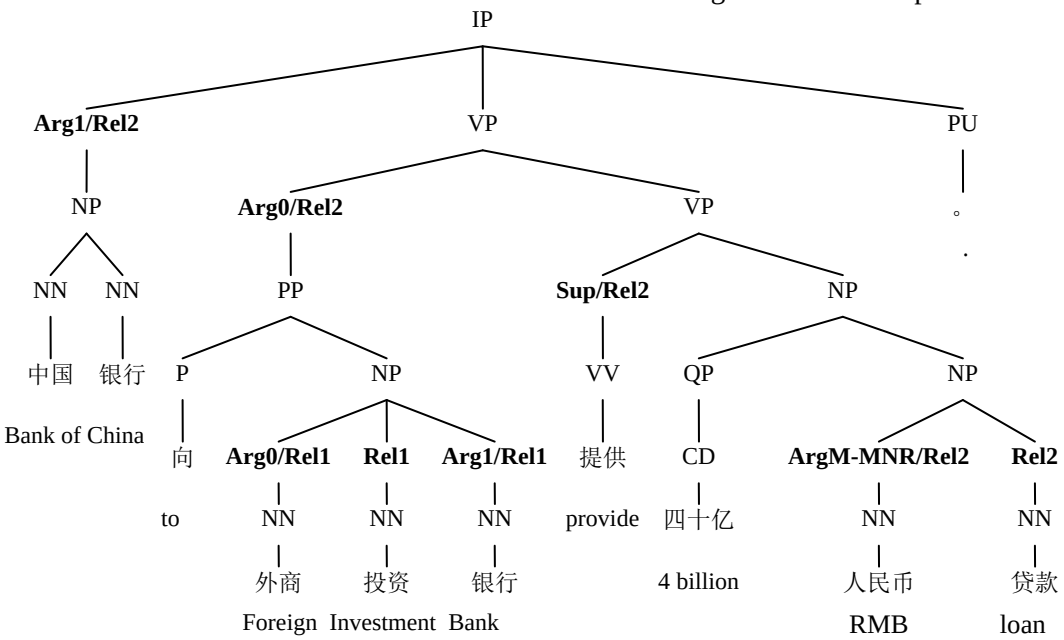
This paper focuses on Chinese nominal SRL. This is done by adopting a traditional verbal SRL architecture to handle Chinese nominal predicates with additional nominal SRL-specific features. Moreover, we significantly enhance the performance of nominal SRL by properly integrating various features derived from verbal SRL. Finally, this paper investigates the effect of automatic nominal predicate recognition on the performance of Chinese nominal SRL. Although previous research (e.g. CoNLL'2008) in English nominal SRL reveals the importance of automatic predicate recognition, there has no reported research on automatic predicate recognition in Chinese nominal SRL.

The rest of this paper is organized as follows: Section 2 introduces Chinese NomBank while the baseline nominal SRL system is described in Section 3 with traditional and nominal SRL-specific features. Then, the baseline nominal SRL system is improved by integrating useful features derived from verbal SRL (Section 4) and extended with automatic recognition of nominal predicates (Section 5). Section 6 gives experimental results and discussion. Finally, Section 7 concludes the paper.

2. Chinese NomBank

Chinese NomBank (Xue, 2006a) adopts similar semantic framework as NomBank, and focuses on Chinese nominal predicates with their arguments in Chinese TreeBank. The semantic arguments include:

1) Core arguments: Arg0 to Arg5. Generally, Arg0 and Arg1 denotes the agent and the patient, respectively, while arguments from Arg2 to Arg5 are predicate-specific.
2) Adjunct arguments, which are universal to all predicates, e.g. ArgM-LOC for locative, and ArgM-TMP for temporal.



Bank of China provides 4 billion RMB loan to Foreign Investment Bank.

Figure 1: Two nominal predicates and their arguments in the style of NomBank.

All the arguments are annotated on parse tree nodes with their boundaries aligning with the spans of tree nodes. Figure 1 gives an example with two nominal predicates and their respective arguments, while the nominal predicate "投资/investment" has two core arguments, "NN(外商/foreign businessman)" as Arg0 and "NN(银行/bank)" as Arg1, and the other nominal predicate "贷款/loan" also has two core arguments, "NP(中国银行/Bank of China)" as Arg1 and

"PP(向外商投资银行/to Foreign Investment Bank)" as Arg0, and 1 adjunct argument, "NN(人民币/RMB)" as ArgM-MNR, denoting the manner of loan. It is worth noticing that there is a (Chinese) NomBank-specific label in Figure 1, Sup (support verb) (Xue, 2006a), in helping introduce the arguments, which occur outside the nominal predicate-headed noun phrase. This is illustrated by the nominal predicate "贷款/loan", whose Arg0 and Arg1 are both realized outside the nominal predicate-headed noun phrase, NP(四十亿人民币贷款/4 billion RMB loan). Normally, a verb is marked as a support verb only when it shares some arguments with the nominal predicate.

3. Baseline: Chinese Nominal SRL

Popular SRL systems usually formulate SRL as a classification problem, which annotates each constituent in a parse tree with a semantic role label or with the non-argument label NULL. Besides, we divide the system into three consecutive phases so as to overcome the imbalance between the training instances of the NULL class and those of any other argument classes.

Argument pruning. Here, several heuristic rules are adopted to filter out constituents, which are most likely non-arguments. According to the argument structures of nominal predicates, we categorize arguments into two types: arguments inside NP (called ***inside arguments***) and arguments introduced via a support verb (called ***outside arguments***), and handle them separately. For the inside arguments, the following three heuristic rules are applied to find *inside argument candidates*:

- All the sisters of the predicate are candidates.
- If a CP or DNP node is a candidate, its children are candidates too.
- For any node X, if its parent is an ancestral node of the predicate, and the internal nodes along the path between X and the predicate are all NPs, then X is a candidate.

For outside arguments, we look for the support verb of the focus nominal predicate, and then adopt the rules as proposed in Xue and Palmer (2005) to find the candidates for the support verb, since *outside argument candidates* are introduced via this support verb. That to say, the argument candidates of the support verb are regarded as *outside argument candidates* of the nominal predicate. However, as support verbs are not annotated explicitly in the testing phase, we identify intervening verbs as alternatives to support verbs in both training and testing phases with the path between the nominal predicate and intervening verb in the form of "VV<VP>[NP>]$^{+}$NN", where "[NP>]$^{+}$" denotes one or more NPs. Our statistics on Chinese NomBank shows that 51.96% of nominal predicates have no intervening verb while 48.04% of nominal predicates have only one intervening verb.

Taken the nominal predicate "贷款/loan" in Figure 1 as an example, NN(人民币/RMB) and QP(四十亿/4 billion) are identified as *inside argument candidates*, while PP(向外商投资银行/to Foreign Investment Bank) and NP(中国银行/Bank of China) are identified as *outside argument candidates* via the support verb VV(提供/provide).

Argument identification. A binary classifier is applied to determine the candidates as either valid arguments or non-arguments. It is worth pointing out that we only mark those candidates that are most likely to be NULL (with probability > 0.90) as non-arguments. Our empirical study shows that this little trick much benefits nominal SRL, since argument identification for nominal predicates is much more difficult than that for verbal predicates and thus many arguments would have been falsely marked as non-arguments if the threshold is set as 0.5.

Argument classification. A multi-class classifier is employed to label identified arguments with specific argument labels (including the NULL class for non-argument).

In the following, we first adapt some traditional features, which have been proven effective in verbal SRL, to nominal SRL, and then introduce several nominal SRL-specific features.

3.1. Traditional Features

Using the feature naming convention as adopted in Jiang and Ng (2006), Table 1 lists the traditional features, where "I" and "C" indicate the features for argument identification and classification, respectively. Among them, the predicate class (b2) feature was first introduced in Xue and Palmer (2005) to overcome the imbalance of the predicate distribution in that some predicates can be only found in the training data while some predicates in the testing data are absent from the training data. In particular, the verb class is classified along three dimensions: the number of arguments, the number of framesets and selected syntactic alternations. For example,

the verb class of "C1C2a" means that it has two framesets, with the first frameset having one argument and the second having two arguments. The symbol "a" in the second frameset represents a type of syntactic alternation.

Feature	Remarks: b1-b5(C, I), b6-b7(C)
b1	Predicate: the nominal predicate itself. (贷款/loan)
b2	Predicate class: the verb class that the predicate belongs to. (C4a)
b3	Head word (b3H) and its POS (b3P). (银行/bank, NN)
b4	Phrase type: the syntactic category of the constituent. (NP)
b5	Path: the path from the constituent to the nominal predicate. (NP<IP>VP>VP>NP>NP>NN)
b6	Position: the positional relationship of the constituent with the predicate. "left" or "right". (left)
b7	First word (b7F) and last word (b7L) of the focus constituent. (中国/China, 银行/bank)
Combined features: b11-b14(C, I), b15(C)	
b11: b1&b4; b12: b1&b3H; b13: b2&b4; b14: b2&b3H; b15: b5&b6	

Table 1: Traditional features and their instantiations for argument identification and classification, with NP(中国银行/Bank of China) as the focus constituent and NN(贷款/loan) as the nominal predicate, regarding Figure 1.

3.2. Nominal SRL-specific Features

To capture more useful information in the predicate-argument structure, we also study additional features which provide extra information. Statistics on Chinese NomBank show that about 40% of pruned inside candidates are arguments. Since inside arguments usually locate near to the nominal predicate, its surroundings are expected to be helpful in SRL. Table 2 shows the features in better capturing the details between inside arguments and nominal predicates. Specially, features ai6 and ai7 are sister-related features, inspired by the features related with the neighboring arguments in Jiang and Ng (2006).

Statistics on NomBank and Chinese NomBank show that about 20% and 22% of arguments are introduced via a support verb, respectively. Since a support verb pivots outside arguments and the nominal predicate on its two sides, support verbs play an important role in labeling these arguments. Here, we also identify intervening verbs as alternatives to support verbs since support verbs are not explicitly in the testing phase. Table 3 lists the intervening verb-related features (ao1-ao4, ao11-ao14) employed in this paper.

Feature	Remarks
ai1	Whether the focus constituent is adjacent to the predicate. Yes or No. (Yes)
ai2	The headword (ai2H) and pos (ai2P) of the predicate's nearest right sister. (银行/bank, NN)
ai3	Whether the predicate has right sisters. Yes or No. (Yes)
ai4	Compressed path of b5: compressing sequences of identical labels into one. (NN<NP>NN)
ai5	Whether the predicate has sisters. Yes or No. (Yes)
ai6	For each sister of the focus constituent, combine b3H&b4&b5&b6. (银行/bank&NN & NN<NP>NN&right)
ai7	Coarse version of ai6, b4&b6. (NN&right)

Table 2: Additional features and their instantiations for inside argument candidates, with "NN(外商/foreign businessman)" as the focus constituent and "NN(投资/investment)" as the nominal predicate, regarding Figure1.

Feature	Remarks
ao1	Intervening verb itself. (提供/provide)
ao2	The verb class that the intervening verb belongs to. (C3b)
ao3	The path from the focus constituent to the intervening verb. (NP<IP>VP>VP>VV)
ao4	The compressed path of ao3: compressing sequences of identical labels into one. (NP<IP>VP>VV)
Combined features: ao11-ao14	
ao11: ao1&ao3; ao12: ao1&ao4; ao13: ao2&ao3; ao14: ao2&ao4.	

Table 3: Additional features and their instantiations for outside argument candidates, with "NP(中国银行/Bank of China)" as the focus constituent and "贷款/loan" as the nominal predicate, regarding Figure1.

Feature selection. Some Features proposed above may not be effective in tasks of identification and classification. We adopt the greedy feature selection algorithm as described in Jiang and Ng (2006) to pick up positive features empirically and incrementally according to their contributions on the development data. The algorithm repeatedly selects one feature each time which contributes most, and stops when adding any of the remaining features fails to improve the performance. As far as the SRL task concerned, the whole feature selection process could be done as follows: 1). Feature selection for argument identification: run the selection algo-

rithm with the basic set of features (b1-b5, b11-b14) to pick up effective features from (ai1-ai7, ao1-ao4, ao11-ao14); 2). Feature selection for argument classification: fix the output returned in step1 as the feature set of argument identification, and run the selection algorithm with the basic set of features (b1-b7, b11-b15) to select positive features from (ai1-ai7, ao1-ao4, ao11-ao14) for argument classification.

4. Integrating Features derived from Verbal SRL

Since Chinese PropBank and NomBank are annotated on the same data set with the same lexical guidelines (e.g. frame files), it may be interesting to investigate the contribution of Chinese verbal SRL on the performance of Chinese nominal SRL. In the frame files, argument labels are defined with regard to their semantic roles to the predicate, either a verbal or nominal predicate. For example, in the frame file of predicate "贷款/loan", the borrower is always labeled with Arg0 and the lender labeled with Arg1. This can be demonstrated by the following two sentences: "贷款/loan" is annotated as a nominal and a verbal predicate in S1 and S2, respectively.

S1 [Arg1 中国银行/Bank of China] [Arg0 向外商投资银行/to Foreign Investment Bank] 提供/provide [Rel 贷款/loan]

S2 [Arg0 中国银行/Bank of China] [Arg1 向外商投资银行/from Foreign Investment Bank] [Rel 贷款/loan]

Therefore, it is straightforward to augment nominal training instances with verbal ones. However, Xue (2006b) found that simply adding the training instances for verbal SRL to the training data for nominal SRL and indiscriminately extracting the same features in both verbal and nominal SRLs hurt the performance. This may be due to that certain features (e.g. the path feature) are much different for verbal and nominal SRLs. This can be illustrated in sentences S1 and S2: the verbal instances in S2 are negative for semantic role labeling of the nominal predicate "贷款/loan" in S1, since "中国银行/Bank of China" takes opposite roles in S1 and S2. So does "向外商投资银行/(from/to) Foreign Investment Bank".

Although several support verb-related features (ao1-ao4, ao11-ao14) have been proposed, one may still ask how large the role support verbs can play in nominal SRL. It is interesting to note that outside arguments and the highest NP phrase headed by the nominal predicate are also annotated as arguments of the support verb in Chinese PropBank. For example, Chinese PropBank marks "中国银行/Bank of China" as Arg0 and "四十亿人民币贷款/4 billion RMB loan" as Arg1 for verb "提供/provide" in Figure1. Let OA be the outside argument, VV be the support verb, and NP be the highest NP phrase headed by the nominal predicate NN, then there exists a pattern "OA VV NN" in the sentence, where the support verb VV plays a certain role in transferring roles between OA and NN. For example, if OA is the agent of VV, then OA is also the agent of phrase VP(VV NN). Like the example in Figure1, supposing a NP is the agent of support verb "提供/provide" as well as VP phrase ("提供四十亿人民币贷款/provide 4 billion RMB loan"), we can infer that the NP is the lender of the nominal predicate "贷款/loan" independently on any other information, such as the NP content and the path from the NP to the nominal predicate "贷款/loan".

Let C be the focus constituent, V be the intervening verb, and NP be the highest NP headed by the nominal predicate. Table 4 shows the features (ao5-ao8, p1-p7) derived from verbal SRL. In this paper, we develop a state-of-the-art Chinese verbal SRL system, similar to the one as shown in Xue (2008), to achieve the goal. Based on golden parse trees on Chinese PropBank, our Chinese verbal SRL system achieves the performance of 92.38 in F1-measure, comparable to Xue (2008) which achieved the performance of 92.0 in F1-measure.

Feature	Remarks
ao5	Whether C is an argument for V. Yes or No
ao6	The semantic role of C for V.
ao7	Whether NP is an argument for V. Yes or No
ao8	The semantic role of NP for V.
Combined features: p1-p7	
p1: ao1&ao5; p2: ao1&ao6; p3: ao1&ao5&b1; p4: ao1&ao6&b1; p5: ao1&apo7; p6: ao1&ao8; p7: ao5&ao7.	

Table 4: Features derived from verbal SRL.

5. Automatic Predicate Recognition

Unlike Chinese PropBank where almost all the verbs are annotated as predicates, Chinese NomBank only marks those nouns having arguments as predicates. Statistics on Chinese NomBank show that only 17.5% of nouns are marked as predicates. It is possible that a noun is a predi-

cate in some cases but not in others. Previous Chinese nominal SRL systems (Xue, 2006b; Xue, 2008) assume that nominal predicates have already been manually annotated and thus are available. To our best knowledge, there is no report on addressing automatic recognition of nominal predicates on Chinese nominal SRL.

Automatic recognition of nominal predicates can be cast as a binary classification (e.g., Predicate vs. Non-Predicate) problem. This paper employs the convolution tree kernel, as proposed in Collins and Duffy (2001), on automatic recognition of nominal predicates.

Given the convolution tree kernel, the key problem is how to extract a parse tree structure from the parse tree for a nominal predicate candidate. In this paper, the parse tree structure is constructed as follows: 1) starting from the predicate candidate's POS node, collect all of its sister nodes (with their headwords); 2). recursively move one level up and collect all of its sister nodes (with their headwords) till reaching a non-NP node. Specially, in order to explicitly mark the positional relation between a node and the predicate candidate, all nodes on the left side of the candidate are augmented with tags 1 and 2 for nodes on the right side. Figure 2 shows an example of the parse tree structure with regard to the predicate candidate "贷款/loan" as shown in Figure 1.

In our extra experiments we found global statistic features (e.g. g1-g5) about the predicate candidate are helpful in a feature vector-based method for predicate recognition. Figure 2 makes an attempt to utilize those features in kernel-based method. We have explored other ways to include those global features. However, the way in Figure 2 works best.

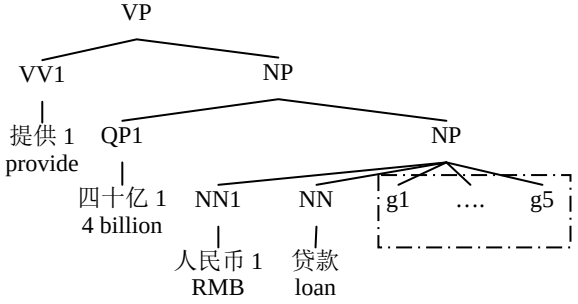


Figure 2: Semantic sub-tree for nominal predicate

Let the predicate candidate be w_0, and its left and right neighbor words be w_{-1} and w_1, respectively. The five global features are defined as follows.

g1 Whether w_0 is ever tagged as a verb in the training data? Yes or No.

g2 Whether w_0 is ever annotated as a nominal predicate in the training data? Yes or No.

g3 The most likely label for w_0 when it occurs together with w_{-1} and w_1.

g4 The most likely label for w_0 when it occurs together with w_{-1}.

g5 The most likely label for w_0 when it occurs together with w_1.

6. Experiment Results and Discussion

We have evaluated our Chinese nominal SRL system on Chinese NomBank with Chinese PropBank 2.0 as its counterpart.

6.1. Experimental Settings

This version of Chinese NomBank consists of standoff annotations on the files (chtb_001 to 1151.fid) of Chinese Penn TreeBank 5.1. Following the experimental setting in Xue (2008), 648 files (chtb_081 to 899.fid) are selected as the training data, 72 files (chtb_001 to 040.fid and chtb_900 to 931.fid) are held out as the test data, and 40 files (chtb_041 to 080.fid) as the development data, with 8642, 1124, and 731 propositions, respectively.

As Chinese words are not naturally segmented in raw sentences, two Chinese automatic parsers are constructed: word-based parser (assuming golden word segmentation) and character-based parser (with automatic word segmentation). Here, Berkeley parser (Petrov and Klein, 2007)[1] is chosen as the Chinese automatic parser. With regard to character-based parsing, we employ a Chinese word segmenter, similar to Ng and Low (2004), to obtain the best automatic segmentation result for a given sentence, which is then fed into Berkeley parser for further syntactic parsing. Both the word segmenter and Berkeley parser are developed with the same training and development datasets as our SRL experiments. The word segmenter achieves the performance of 96.1 in F1-measure while the Berkeley parser gives a performance of 82.5 and 85.5 in F1-measure on golden and automatic word segmentation, respectively[2].

In addition, SVMLight with the tree kernel function (Moschitti, 2004)[3] is selected as our classifier. In order to handle multi-classification

[1] Berkeley Parser. http://code.google.com/p/berkeleyparser/

[2] POSs are not counted in evaluating the performance of word-based syntactic parser, but they are counted in evaluating the performance of character-based parser. Therefore the F1-measure for the later is higher than that for the former.

[3] SVM-LIGHT-TK. http://dit.unitn.it/~moschitt/

problem in argument classification, we apply the *one vs. others* strategy, which builds K classifiers so as to separate one class from all others. For argument identification and classification, we adopt the linear kernel and the training parameter C is fine-tuned to 0.220. For automatic recognition of nominal predicates, the training parameter C and the decay factor λ in the convolution tree kernel are fine-tuned to 2.0 and 0.2, respectively.

6.2. Results with Golden Parse Trees and Golden Nominal Predicates

Effect of nominal SRL-specific features

	Rec.(%)	Pre.(%)	F1
traditional features	62.83	73.58	67.78
+nominal SRL-specific features	69.90	75.11	72.55

Table 5: The performance of nominal SRL on the development data with golden parse trees and golden nominal predicates

After performing the greedy feature selection algorithm on the development data, features {ao1, ai6, ai2P, ai5, ao2, ao12, ao14}, as proposed in Section 3.2, are selected consecutively for argument identification, while features {ai7, ao1, ai1, ao2, ai5, ao4} are selected for argument classification. Table 5 presents the SRL results on the development data. It shows that nominal SRL-specific features significantly improve the performance from 67.78 to 72.55 ($\chi^2; p < 0.05$) in F1-measure.

Effect of features derived from verbal SRL

Features	Rec.(%)	Pre.(%)	F1
baseline	67.86	73.63	70.63
+ao5	68.15	73.60	70.77 (+0.14)
+ao6	67.66	72.80	**70.14 (-0.49)**
+ao7	68.20	75.41	71.62 (+0.99)
+ao8	68.30	75.39	71.67 (+1.04)
+p1	67.91	74.40	71.00 (+0.37)
+p2	67.76	74.20	70.83 (+0.20)
+p3	67.96	74.69	71.16 (+0.53)
+p4	68.01	74.18	70.96 (+0.33)
+p5	68.01	75.01	71.39 (+0.76)
+p6	68.20	75.12	71.49 (+0.86)
+p7	68.40	75.70	71.87 (+1.24)

Table 6: Effect of features derived from verbal SRL on the performance of nominal SRL on the test data with golden parse trees and golden nominal predicates. The first row presents the performance using traditional and nominal SRL-specific features.

	Rec.(%)	Pre.(%)	F1
baseline	67.86	73.63	70.63
+features derived from verbal SRL	68.40	77.51	72.67
Xue (2008)	66.1	73.4	69.6

Table 7: The performance of nominal SRL on the test data with golden parse trees and golden nominal predicates

Table 6 shows the effect of features derived from verbal SRL in an incremental way. It shows that only the feature ao6 has negative effect due to its strong relevance with intervening verbs and thus not included thereafter. Table 7 shows the performance on the test data with or without using the features derived from the verbal SRL system. It shows these features significantly improve the performance ($\chi^2; p < 0.05$) on nominal SRL. Table 7 also shows our system outperforms Xue (2008) by 3.1 in F1-measure.

6.3. Results with Automatic Parse Trees and Golden Nominal Predicates

In previous section we have assumed the availability of golden parse trees during the testing process. Here we conduct experiments on automatic parse trees, using the Berkeley parser. Since arguments come from constituents in parse trees, those arguments, which do not align with any syntactic constituents, are simply discarded. Moreover, for any nominal predicate segmented incorrectly by the word segmenter, all its arguments are unable to be labeled neither. Table 8 presents the SRL performance on the test data by using automatic parse trees. It shows that the performance drops from 72.67 to 60.87 in F1-measure when replacing golden parse trees with word-based automatic ones, partly due to the absence of 6.9% arguments in automatic trees, and wrong POS tagging of nominal predicates. Table 8 also compares our system with Xue (2008). It shows that our system also outperforms Xue (2008) on Chinese NomBank.

	Rec. (%)	Pre. (%)	F1
This paper	56.95(53.55)	66.74(66.69)	60.87(59.40)
Xue (2008)	53.1 (52.9)	62.9 (62.3)	57.6 (57.3)

Table 8: The performance of nominal SRL on the test data with automatic parse trees and golden predicates. Here, the numbers outside the parentheses indicate the performance using a word-based parser, while the numbers inside indicate the performance using a character-based parser[4].

[4] About 1.6% nominal predicates are mistakenly segmented by the character-based parser, thus their arguments are missed directly.

6.4. Results with Automatic Nominal Predicates

So far nominal predicates are assumed to be manually annotated and available. Here we turn to a more realistic scenario in which both the parse tree and nominal predicates are automatically obtained. In the following, we first report the results of automatic nominal predicate recognition and then the results of nominal SRL on automatic recognition of nominal predicates.

Results of nominal predicate recognition

Parses	g1-g5	Rec.(%)	Pre.(%)	F1
golden	no	91.46	88.93	90.18
	yes	92.62	89.36	90.96
word-based	yes	86.39	81.80	84.03
character-based	yes	84.79	81.94	83.34

Table 9: The performance of automatic nominal predicate recognition on the test data

Table 9 lists the predicate recognition results, using the parse tree structure, as shown in Section 5, and the convolution tree kernel, as proposed in Collins and Duffy (2001). The second column (g1-g5) indicates whether the global features (g1-g5) are included in the parse tree structure. We have also defined a simple rule that treats a noun which is ever a verb or a nominal predicate in the training data as a nominal predicate. Based on golden parse trees, the rule receives the performance of 81.40 in F1-measure. This suggests that our method significantly outperforms the simple rule-based one. Table 9 also shows that:

- As a complement to local structural information, global features improve the performance of automatic nominal predicate recognition by 0.78 in F1-measure.
- The word-based syntactic parser decreases the F1-measure from 90.96 to 84.03, mostly due to the POSTagging errors between NN and VV, while the character-based syntactic parser further drops the F1-measure by 0.69, due to automatic word segmentation.

Results with automatic predicates

Parses	Predicates	Rec.(%)	Pre.(%)	F1
golden	golden	68.40	77.51	72.67
	automatic	65.07	74.65	69.53
word-based	golden	55.95	66.74	60.87
	automatic	52.67	59.56	55.90
character-based	golden	53.55	66.69	59.40
	automatic	50.66	59.60	54.77

Table 10: The performance of nominal SRL on the test data with the choices of golden/automatic parse trees and golden/automatic predicates

In order to have a clear performance comparison among nominal SRL on golden/automatic parse trees and golden/automatic predicates, Table 10 lists all the results in those scenarios.

6.5. Comparison

Chinese nominal SRL vs. Chinese verbal SRL

Comparison with Xue (2008) shows that the performance of Chinese nominal SRL is about 20 lower (e.g. 72.67 vs. 92.38 in F1-measure) than that of Chinese verbal SRL, partly due to the smaller amount of annotated data (about 1/5) in Chinese NomBank than that in Chinese PropBank. Moreover, according to Chinese NomBank annotation criteria (Xue 2006a), even when a noun is a true deverbal noun, not all of its modifiers are legitimate arguments or adjuncts of this predicate. Only arguments that can co-occur with both the nominal and verbal forms of the predicate are considered in the NomBank annotation. This means that the judgment of arguments is semantic rather than syntactic. These facts may also partly explain the lower nominal SRL performance, especially the performance of argument identification. This can be illustrated by the statistics on the development data that 96% (40%) of verbal (nominal) predicates' sisters are annotated as arguments. Finally, the predicate-argument structure of nominal predicates is more flexible and complicated than that of verbal predicates as illustrated in Xue (2006a).

Chinese nominal SRL vs. English nominal SRL

Liu and Ng (2007) reported the performance of 77.04 and 72.83 in F1-measure on English NomBank when golden and automatic parse trees are used, respectively. Taking into account that Chinese verbal SRL achieves comparable performance with English verbal SRL on golden parse trees, the performance gap between Chinese and English nominal SRL (e.g. 72.67 vs. 77.04 in F1-measure) presents great challenge for Chinese nominal SRL. Moreover, while automatic parse trees only decrease the performance of English nominal SRL by about 4.2 in F1-measure, automatic parse trees significantly decrease the performance of Chinese nominal SRL by more than 12 in F1-measure due to the much lower performance of Chinese syntactic parsing.

7. Conclusion

In this paper we investigate nominal SRL in Chinese language. In particular, some nominal SRL-specific features are included to improve

the performance. Moreover, various features derived from verbal SRL are properly integrated into nominal SRL. Finally, a convolution tree kernel is adopted to address the issue of automatic nominal predicates recognition, which is essential in a nominal SRL system.

To our best knowledge, this is the first research on

1) Exploring Chinese nominal SRL on automatic parse trees with automatic predicate recognition;
2) Successfully integrating features derived from Chinese verbal SRL into Chinese nominal SRL with much performance improvement.

On the Use of Virtual Evidence in Conditional Random Fields

Xiao Li
Microsoft Research

xiaol@microsoft.com

Abstract

Virtual evidence (VE), first introduced by (Pearl, 1988), provides a convenient way of incorporating prior knowledge into Bayesian networks. This work generalizes the use of VE to undirected graphical models and, in particular, to conditional random fields (CRFs). We show that VE can be naturally encoded into a CRF model as potential functions. More importantly, we propose a novel semi-supervised machine learning objective for estimating a CRF model integrated with VE. The objective can be optimized using the Expectation-Maximization algorithm while maintaining the discriminative nature of CRFs. When evaluated on the *CLASSIFIEDS* data, our approach significantly outperforms the best known solutions reported on this task.

1 Introduction

Statistical approaches to sequential labeling problems rely on necessary training data to model the uncertainty of a sequence of events. Human's prior knowledge about the task, on the other hand, often requires minimum cognitive load to specify, and yet can provide information often complementary to that offered by a limited amount of training data. Whenever prior knowledge becomes available, it is desired that such information is integrated to a probabilistic model to improve learning.

Virtual evidence (VE), first introduced by Pearl (1988), offers a principled and convenient way of incorporating external knowledge into Bayesian networks. In contrast to *standard evidence* (also known as observed variables), VE expresses a prior belief over values of random variables. It has been shown that VE can significantly extend the modeling power of Bayesian networks without complicating the fundamental inference methodology (Bilmes, 2004; Reynolds and Bilmes, 2005).

This work extends the use of VE to undirected graphical models and, in particular, to conditional random fields (CRFs). We show that VE can be naturally encoded into an undirected graphical model as potential functions. More importantly, we discuss a semi-supervised machine learning setting for estimating CRFs with the presence of VE. As the conditional likelihood objective of CRFs is not directly maximizable with respect to unlabeled data, we propose a novel semi-supervised learning objective that can be optimized using the Expectation-Maximization (EM) algorithm while maintaining the discriminative nature of CRFs.

We apply our model to the CLASSIFIEDS data (Grenager et al., 2005). Specifically, we use VE to incorporate into a CRF model two types of prior knowledge specified in previous works. The first is defined based on the notion of *prototypes*, *i.e.*, example words for a given label; and the other assumes that adjacent tokens tend to have the same label. When unlabeled data becomes available, we further extend the sparse prototype information to other words based on distributional similarity. This results in so-called *collocation lists*, each consisting of a relatively large number of noisy "prototypes" for a label. Given the fact that these noisy prototypes are often located close to each other in an input sequence, we create a new type of VE based on word collocation to reduce ambiguity.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1289–1297,
Singapore, 6-7 August 2009.

We compare our CRF model integrated with VE with two state-of-the-art models, *i.e.*, constraint-driven learning (Chang et al., 2007) and generalized expectation criteria (Mann and McCallum, 2008). Experiments show that our approach leads to sequential labeling accuracies superior to the best results reported on this task in both supervised and semi-supervised learning.

2 Related work

There have been various works that make use of prior knowledge in sequential labeling tasks. Grenager et al. (2005) explicitly constrain the transition matrix of a hidden Markov model (HMM) to favor self transitions, assuming that fields tend to consist of consecutive runs of the same label.

Prototype-drive learning (Haghighi and Klein, 2006) specifies prior knowledge by providing a few *prototypes* (*i.e.*, canonical example words) for each label. This sparse prototype information is then propagated to other words based on distributional similarity. The relation between words and their prototypes are then used as features in a Markov random field (MRF) model. Since an MRF model aims to optimize the joint probability $p(\mathbf{x}, \mathbf{y})$ of input and state sequences, it is possible to apply the EM algorithm for unsupervised/semi-supervised learning.

Constraint-driven learning (Chang et al., 2007) expresses several kinds of constraints in a unified form. In inference, a new decision function is proposed to penalize the violation of the desired constraints as follows,

$$\underset{\mathbf{y}}{\text{argmax}}\ \lambda \cdot F(\mathbf{x}, \mathbf{y}) - \sum_k \rho_k d(\mathbf{y}, 1_{C_k}(\mathbf{x})) \quad (1)$$

Here $\lambda \cdot F(\mathbf{x}, \mathbf{y})$ is a linear decision function applicable to a number of sequential models, such as HMMs, MRFs and CRFs. Function d is implemented as the Hamming distance (or its approximation) between a hypothesis sequence and the space of state sequences that satisfy the constraint C_i. Due to the nature of the distance function, their work approximates EM training by finding the top K hypothesis sequences and using them as newly labeled instances to update the model. This process is repeated for a number of iterations in a self-training fashion (Yarowsky, 1995).

Generalized expectation criteria (Mann and McCallum, 2008) represent prior knowledge as *labeled features*, and use such information to regularize semi-supervised learning for CRFs. Formally, their learning objective consists of the standard CRF training objective, plus a Gaussian prior on model parameters and an additional regularization term:[1]

$$\sum_i \log p_\lambda(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}) - \frac{1}{2\sigma^2}\|\lambda\|^2 - \rho D(\hat{p}||\tilde{p}_\lambda) \quad (2)$$

In the last term, $\hat{p}$ and $\tilde{p}_\lambda$ both refer to conditional distributions of labels given a feature. While the former is specified by prior knowledge, and the latter is estimated from unlabeled data.

Our approach incorporates prior knowledge as virtual evidence to express preferences over the values of a set of random variables. The notion of VE was first introduced by Pearl (1998) and further developed by Bilmes (2004), both in the context of Bayesian networks. Different from constraint-driven learning, VE can be formally encoded as part of a graphical model. The fundamental inference methodology, therefore, does not need to be altered. Moreover, VE has the flexibility of representing various kinds of prior knowledge. For example, Reynolds and Bilmes (2005) use VE that explicitly favors self transitions in dynamic Bayesian networks.

This work extends the use of VE to CRFs. In essence, VE herein can be viewed as probabilistic constraints in an undirected graph that allow exact inference. One of the biggest challenges of such a model lies in the semi-supervised machine learning setting. Since the entire state sequence of an unlabeled instance remains hidden, the conditional likelihood objective of CRFs is not directly optimizable. There have been a number of works that address this problem for conditional models. For example, *minimum entropy regularization* (Grandvalet and Bengio, 2004; Jiao et al., 2006), aims to maximize the conditional likelihood of labeled data while minimizing the conditional entropy of unlabeled data:

$$\sum_i \log p_\lambda(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}) - \frac{1}{2\sigma^2}\|\lambda\|^2 - \rho H(\mathbf{y}|\mathbf{x}) \quad (3)$$

This approach generally would result in "sharper" models which can be data-sensitive in practice.

Another approach (Suzuki and Isozaki, 2008) embeds a joint probability model (HMM in their

[1] We slightly modify the notation here to be consistent with the rest of the paper.

case) into a CRF model as a new potential function. Semi-supervised learning is then conducted by iteratively (1) fixing the HMM and updating CRF parameters on labeled data and (2) fixing the CRF model and updating the HMM on unlabeled data.

Additionally, when unlabeled instances have partial labeling information, it is possible to optimize a marginal distribution of the conditional likelihood, *i.e.*, $p_\lambda(\mathbf{y}_o^{(i)}|\mathbf{x})$, on unlabeled data. Here $\mathbf{y}_o^{(i)}$ is a subvector of $\mathbf{y}^{(i)}$ that denotes the set of observed state variables. The optimization can be done in a similar fashion as training a hidden-state CRF model (Quattoni et al., 2007).

3 Task

We consider the problem of extracting fields from free-text advertisements. We use the CLASSIFIEDS data (Grenager et al., 2005) which consists of 8767 ads for apartment rental. 302 of the ads in the CLASSIFIEDS data have been manually-labeled with 12 fields, including *size*, *rent*, *neighborhood* and so on. The labeled data has been divided into train/dev/test sets with 102/100/100 ads respectively. The evaluation metric is the token-level accuracy where tokens include both words and punctuations.

Our goal in this work is two folds: (1) leverage both the training data and the prior knowledge specified for this task for supervised learning, and (2) additionally use the unlabeled data for semi-supervised learning. We exploit two types of prior knowledge:

- K1: *label consistency with prototypes*;
- K2: *label consistency within a sentence*.

K1 involves a set of prototype lists. Each list is attached with a label and consists of a set of example words for that label. In this work, we use the prototype lists originally defined by Haghighi and Klein (2006) (HK06) and subsequently used by Chang et al. (2005) (CRR07) and Mann and McCallum (2008) (MM08). The labels as well as their prototypes are shown in the first two columns of Table 1. Our model is desired to be consistent with such prototype information. Secondly, K2 means that tokens tend to have consistent labels within a sentence. A similar type of prior knowledge is implemented by CRR07 as a constraint in inference.

4 Conditional Random Fields

Conditional random fields are a probabilistic model that directly optimizes the conditional probability of a state (label) sequence given an input sequence (Lafferty et al., 2001). Formally, we let $\mathbf{x} = (x_1, x_2, \ldots, x_T)$ denote an input sequence of T tokens, and $\mathbf{y} = (y_1, y_2, \ldots, y_T)$ the corresponding state sequence. We further augment $\mathbf{y}$ with two special states, *Start* and *End*,[2] represented by y_0 and y_{T+1} respectively. A linear-chain CRF model is an undirected graphical model as depicted in Figure 1(a), with the conditional probability given by

$$p_\lambda(\mathbf{y}|\mathbf{x}) = \frac{1}{Z_\lambda(\mathbf{x})} \prod_t \psi_\lambda^{(t)}(\mathbf{x}, y_{t-1}, y_t) \qquad (4)$$

The partition function $Z_\lambda(\mathbf{x})$ normalizes the exponential form to be a probability distribution. $\psi_\lambda^{(t)}$ are a set of potential functions defined on the *maximum cliques* of the graph, *i.e.*, $(\mathbf{x}, y_{t-1}, y_t)$ in the case of a linear-chain CRF model. The potential functions are typically in the form of

$$\psi_\lambda^{(t)}(\mathbf{x}, y_{t-1}, y_t) = \exp\Big(\lambda \cdot f(\mathbf{x}, y_{t-1}, y_t, t)\Big) \qquad (5)$$

where λ is a weight vector and f is a feature vector of arbitrary functions of the corresponding clique.

Given a set of labeled examples $\{\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\}_{i=1}^m$, we can estimate model parameters in a supervised machine learning setting. The objective is to estimate λ that maximizes the conditional likelihood while regularizing the model size:

$$\mathcal{L}_1 = \sum_{i=1}^m \log p_\lambda(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}) - \frac{1}{2\sigma^2}\|\lambda\|^2 \qquad (6)$$

In this work, we optimize $\mathcal{L}_1$ using stochastic gradient descent and use the accuracy on the development set as the stopping criterion.

5 CRFs with Virtual Evidence

A canonical way of using virtual evidence (VE) in Bayesian networks is to have a directed edge from a hidden variable h to a VE variable v. The variable v will always be observed with a particular value, *e.g.*, $v = 1$, but the actual value itself does not matter. The prior knowledge about h is

[2] *Start* and *End* are with regard to a document, which are different from start and end of a sentence.

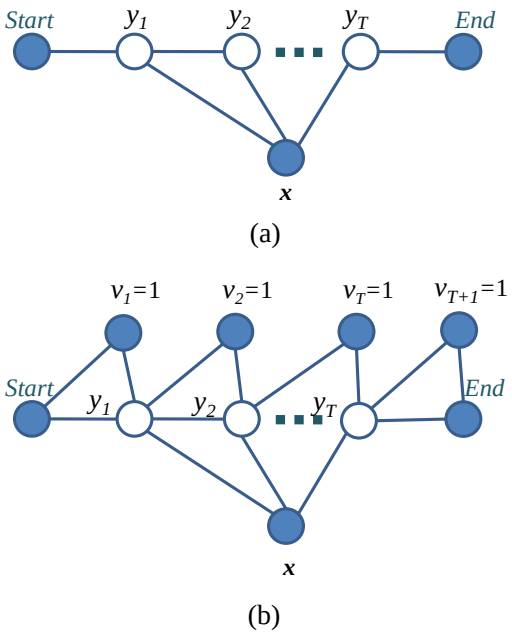

Figure 1: Graphical model representations of (a) a CRF model and (b) a CRF model integrated with virtual evidence. Solid and empty nodes denote observed and hidden variables respectively.

expressed via the conditional probability $p(v = 1|h)$. For example, by setting $p(v = 1|h = a) > p(v = 1|h = b)$, we know that $h = a$ is more likely a event than $h = b$. This conditional distribution is not learned from data, Instead, it is predefined in such a way that reflects a prior belief over the value of h.

VE can be encoded in an undirected graphical model in a similar fashion. For our task, we modify the structure of a linear-chain CRF model as depicted in Figure 1(b) — we create a sequence of VE variables, denoted by $v_1, v_2, \ldots, v_{T+1}$, in parallel to the state variables. Each v_t is assigned a constant 1 (one), and is connected with y_{t-1} and y_t, forming a new set of maximum cliques (y_{t-1}, y_t, v_t), $t = 1, \ldots, T + 1$. We create cliques of size 3 because it is the minimum size required to represent the prior knowledge used in our task, as will be discussed shortly. However, it is possible to have a different graph structure to incorporate other types of prior knowledge, *e.g.*, using large cliques to represent constraints that involve more variables.

Next, in analogy to Equation (5), we define the corresponding potential functions as follows,

$$\phi^{(t)}(y_{t-1}, y_t, v_t) = \exp\Big(\omega \cdot s(y_{t-1}, y_t, v_t, t)\Big) \tag{7}$$

s is a vector of VE feature functions and ω is the corresponding weight vector with pre-defined values. Given the new graphical model in Figure 1(b). It is natural to model the conditional probability of the state sequence given *both* the standard evidence and the VE as follows,

$$p_\lambda(\mathbf{y}|\mathbf{x}, \mathbf{v}) = \frac{1}{Z_\lambda(\mathbf{x}, \mathbf{v})} \prod_t \psi_\lambda^{(t)}(\mathbf{x}, y_{t-1}, y_t)\phi^{(t)}(y_{t-1}, y_t, v_t) \tag{8}$$

Analogous to using $p(v = 1|h)$ in Bayesian networks, we can utilize $\phi^{(t)}(y_{t-1}, y_t, \mathbf{v} = \mathbf{1})$ to express preferences over state hypotheses in a CRF model. In general, the function form of $\phi^{(t)}$ may or may not depend on the input $\mathbf{x}$. Even when $\phi^{(t)}$ does depend on $\mathbf{x}$, the relation is completely determined by external knowledge/systems (as opposed to by data). Thus we do not explicitly connect $\mathbf{v}$ with $\mathbf{x}$ in the graph.

5.1 Incorporating prior knowledge

Now we show how to represent the prior knowledge introduced in Section 3 using the VE feature functions. Unless otherwise stated, we assume $v_t = 1$ for all $t = 1, \ldots, T$ and simply use v_t instead of $v_t = 1$ in all equations. First, we define a VE function s_1 that represents K1: *label consistency with prototypes*. We let P_l denote a prototype list associated with the label l. If x_t belongs to P_l, we should prefer $y_t = l$ as opposed to other values. To this end, for cases where $x_t \in P_l$, we set s_1 as

$$s_1(y_t, v_t, t) = \begin{cases} 1 & \text{if } y_t = l \\ 0 & \text{otherwise} \end{cases} \tag{9}$$

On the other hand, if x_t is not a prototype, we will always have $s_1(y_t, v_t, t) = 0$ for all hypotheses of y_t. The impact of this prior knowledge is controlled by the weight of s_1, denote by ω_1. At one extreme where $\omega_1 = 0$, the prior knowledge is completely ignored in training. At the other extreme where $\omega_1 \to +\infty$, we constrain the values of state variables to agree with the prior knowledge. Note that although s_1 is implicitly related to $\mathbf{x}$, we do not write s_1 as a function of $\mathbf{x}$ for consistency with the general definition of VE.

To represent K2: *label consistency within a sentence*, we define a second VE feature function s_2 with weight ω_2. Assume that we have an external system that detects sentence boundaries. If it is determined that x_t is *not* the start of a sentence, we set s_2 as

$$s_2(y_{t-1}, y_t, v_t, t) = \begin{cases} 1 & \text{if } y_{t-1} = y_t \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

It is easy to see that this would penalize state transitions within a sentence. On the other hand, if x_t is a sentence start, we set $s_2(y_{t-1}, y_t, v_t, t) = 0$ for all possible (y_{t-1}, y_t) pairs. In this work, we use a simple heuristics to detect sentence boundaries: we determine that x_t is the start of a sentence if its previous token x_{t-1} is a period (.), a semi-colon (;) or an acclamation mark (!), *and* if x_t is not a punctuation.

5.2 Semi-supervised learning

When a large amount of unlabeled data is available, it is often helpful to leverage such data to improve learning. However, we cannot directly optimize $p(\mathbf{y}|\mathbf{x}, \mathbf{v})$ since the correct state sequences of the unlabeled data are hidden. One heuristic approach is to adapt the *self-training* algorithm (Yarowsky, 1995) to our model. More specifically, for each input in the unlabeled dataset $\{\mathbf{x}^{(i)}\}_{i=m+1}^{n}$, we decode the best state sequence,

$$\hat{\mathbf{y}}^{(i)} = \underset{\mathbf{y}^{(i)}}{\text{argmax}}\ p(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}, \mathbf{v}^{(i)}) \quad (11)$$

Then we use $\{(\mathbf{x}^{(i)}, \hat{\mathbf{y}}^{(i)})\}_{i=m+1}^{n}$ in addition to the labeled data to train a supervised CRF model. This approach, however, does not have a theoretical guarantee on optimality unless certain nontrivial conditions are satisfied (Abney, 2004).

On the other hand, it is well known that unlabeled data can be naturally incorporated using a generative approach that models a joint probability (Nigam et al., 2000). This is achieved by maximizing a marginal distribution of the joint probability over hidden variables. Inspired by the generative approach, we propose to explicitly model $p(\mathbf{y}, \mathbf{v}|\mathbf{x})$. In contrast to Equation (8), here we jointly model $\mathbf{y}$ and $\mathbf{v}$ but the probability is still conditioned on $\mathbf{x}$. This "joint" distribution should be chosen such that it results in the same conditional distribution $p(\mathbf{y}|\mathbf{x}, \mathbf{v})$ as defined in Equation (8). To this end, we define $p_\lambda(\mathbf{y}, \mathbf{v}|\mathbf{x})$ as

$$p_\lambda(\mathbf{y}, \mathbf{v}|\mathbf{x}) = \frac{1}{Z'_\lambda(\mathbf{x})} \prod_t \psi_\lambda^{(t)}(\mathbf{x}, y_{t-1}, y_t)\phi^{(t)}(y_{t-1}, y_t, v_t) \quad (12)$$

Here $Z'_\lambda(\mathbf{x})$ is a normalization function obtained by summing the numerator over both $\mathbf{y}$ and $\mathbf{v}$. By applying the Bayes rule, it is easy to see that $p(\mathbf{y}|\mathbf{x}, \mathbf{v})$ is exactly equal to Equation (8).

Given unlabeled data $\{\mathbf{x}^{(i)}\}_{i=m+1}^{n}$, we aim to optimize the following objective,[3]

$$\mathcal{L}_2 = \sum_{i=1}^{m+n} \log p_\lambda(\mathbf{v}^{(i)}|\mathbf{x}^{(i)}) - \frac{1}{2\sigma^2}\|\lambda\|^2 \quad (13)$$

This is essentially the marginal distribution of $p(\mathbf{y}, \mathbf{v}|\mathbf{x})$ over hidden variables $\mathbf{y}$. Here we ignore the labels of the dataset $\{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\}_{i=1}^{m}$, but we do use the label information in initializing the model which will described in Section 6. To optimize such an objective, we apply the EM algorithm in the same fashion as is used in a generative approach. In other words, we iteratively optimize $Q(\lambda) = \sum_{\mathbf{y}} p_{\lambda^g}(\mathbf{y}|\mathbf{x}, \mathbf{v}) \log p_\lambda(\mathbf{y}, \mathbf{v}|\mathbf{x})$ where λ^g denotes the model estimated from the previous iteration. The gradient of the Q function is straightforward to compute with the result given by

$$\frac{\partial Q(\lambda)}{\partial \lambda_k} = \sum_t \sum_{y_{t-1}, y_t} f_k(y_{t-1}, y_t, \mathbf{x}, t) \cdot \Big(p_\lambda(y_{t-1}, y_t|\mathbf{x}, \mathbf{v}) - p_\lambda(y_{t-1}, y_t|\mathbf{x}) \Big) \quad (14)$$

We keep two sets of accumulators in running the Forward-Backward algorithm, one for computing $p_\lambda(y_{t-1}, y_t|\mathbf{x}, \mathbf{v})$ and the other for computing $p_\lambda(y_{t-1}, y_t|\mathbf{x})$. Loosely speaking, the model will converge to a local optimum if the difference between these two posterior probabilities becomes trivial.

5.3 Collocation based virtual evidence

Prior knowledge represented by prototypes is typically sparse. This sparse information, however, can be propagated across all data based on distributional similarity (Haghighi and Klein, 2006). Following the same idea, we extend the prototype lists as follows. (1) We merge all prototypes in P_l into a single word type w_l. (2) For each word

[3] In Equation (13), the fact that $\mathbf{v}$ is assigned a constant 1 does not mean $p(\mathbf{v} = \mathbf{1}|\mathbf{x}) = 1$ (Bilmes, 2004)

Table 1: Field labels (except *other*) for the CLASSIFIEDS task, their respective prototype lists specified by prior knowledge, and collocation lists mined from unlabeled data.

in the corpus, we collect a context vector of the counts of all words (excluding stop words) that occur within a window of size k in either direction, where the window is applied only within sentence boundaries. (3) Latent semantic analysis (Deerwester et al., 1990) is performed on the constructed context vectors. (4) In the resulting latent semantic space, all words (except stop words) that have a high enough dot product with w_l will be grouped to form a new set, denoted as C_l, which is a superset of P_l. In this regard, C_l can be viewed as lists of noisy "prototypes". As observed in HK06, another consequence of this method is that many neighboring tokens will share the same prototypes.

Differently from previous works, we use C_l directly as virtual evidence. We could apply s_1 in Equation (9) when $x_t \in C_l$ (as opposed to when $x_t \in P_l$). This, however, would contaminate our model since C_l are often noisy. For example, "water" is found to be distributionally similar to the prototypes of *utilities*. Although in most cases "water" indeed means *utilities*, it can mean *features* in the context of "water front view". To maximally reduce ambiguity, we propose to apply s_1 in Equation (9) if *both* of the following conditions hold,

(1) $x_t \in C_l$

(2) There exists τ s.t. $|\tau - t| < k$, and $x_\tau \in C_l$

In other words, we will impose a non-uniform prior on y_t if $x_t \in C_l$ "collocates", within k tokens, with another word that belongs to C_l. Based on K2, it is reasonable to believe that neighboring tokens tend to share the same label. Therefore, knowing that two tokens close to each other both belong to C_l would strengthen our belief that either word is likely to have label l. We thus refer to this type of virtual evidence as *collocation-based VE*, and refer to C_l as *collocation lists*.

6 Evaluation

We use the CLASSIFIEDS data provided by Grenager et al. (2005) and compare with results reported by CRR07 (Chang et al., 2007) and MM08 (Mann and McCallum, 2008) for both supervised and semi-supervised learning. Following all previous works conducted on this task, we tokenized both words and punctuations, and created a number of regular expression tokens for phone numbers, email addresses, URLs, dates, money amounts and so on. However, we did not tokenize newline breaks, as CRR07 did, which might be useful in determining sentence boundaries. Based on such tokenization, we extract n-grams, $n = 1, 2, 3$, from the corpus as features for CRFs.

As described in Section 3, we integrate the prior knowledge K1 and K2 in our CRF model. The prototypes that represent K1 are given in Table 1. CRR07 used the same two kinds of prior knowledge in the form of constraints, and they implemented another constraint on the minimum number of words in a field chunk. MM08 used almost the same set of prototypes as labeled features, but they exploited two sets of 33 additional features for some experiments. In this regard, the comparison between CRR07, MM08 and the method presented here cannot be exact. However, we show that while our prior knowledge is no more than that used in previous works, our approach is able

Supervised model	# labeled examples 10	25	100
CRR07: HMM	61.6	70.0	76.3
+ Constr in decoding	66.1	73.7	80.4

+ Col-VE in decoding	**78.8**	**79.5**	**82.9**

Table 3: Token-level accuracy of semi-supervised learning methods. "+ Col-VE" refers to cases where collocation-based VE is integrated in the CRF model in addition to the VE representing K1 and K2.

to achieve the state-of-art performance.

6.1 Decoding settings

Depending on whether VE is used at test time, we explore two decoding settings in all experiments:

1. Find $\mathbf{y}$ that maximizes $p_\lambda(\mathbf{y}|\mathbf{x})$ as in standard CRF decoding, ignoring virtual evidence.
2. Find $\mathbf{y}$ that maximizes $p(\mathbf{y}|\mathbf{x}, \mathbf{v})$. We use "+ VE in decoding" to represent this setting.

These two scenarios are analogous to those in CRR07 which conducted HMM decoding without/with constraints applied. We use "+ constr. in decoding" to represent the latter scenario of their work. MM08, on the other hand, found no accuracy improvement when adding constraints at test time.

Note that in our second decoding setting, the weights for the VE feature functions, *i.e.*, ω_1 and ω_2, are tuned on the development set. This is done by a greedy search that first finds the best ω_1, and then finds the best ω_2 while fixing the value of ω_1, both with a step size 0.5.

6.2 Supervised learning results

First, we experimented with a standard CRF model with VE applied neither in training nor in decoding. As shown in Table 2, our CRF implementation performed slightly worse than the implementation by MM08, probably due to slight difference in tokenization. Secondly, we used the same CRF model but additionally applied VE in decoding, corresponding to the second setting in Section 6.1. This method gave a significant boost to the tagging performance, yielding the best supervised learning results (shown as bolded in the table). This proves that the prior knowledge is indeed complementary to the information offered by the training data.

Similar to the second decoding setting that incorporates VE, we can have a counterpart setting at training time. In other words, we can optimize $p_\lambda(\mathbf{y}|\mathbf{x}, \mathbf{v})$ instead of $p_\lambda(\mathbf{y}|\mathbf{x})$ during learning. In deciding $\omega = (\omega_1, \omega_2)$, it is possible to learn ω from data in the same way as how we learn λ. This, however, might undermine the role of other useful features since we do not always have sufficient training data to reliably estimate the weight of prior knowledge. As shown in Table 2, we experimented with learning ω automatically (shown as "auto weights"). While applying VE with such weights in both training and decoding worked reasonably well, applying VE only in training but not in decoding yielded very poor performance (probably due to excessively large estimates of ω_1 and ω_2). Additionally, we repeated the above experiment with manually specified weights, but did not find further accuracy improvement over the best supervised learning results.

6.3 Semi-supervised learning results

One natural way of leveraging the unlabeled data (more than 8K examples) is to perform semi-supervised learning in a self-training fashion. To this end, we used our best supervised model in Table 2 to decode the unlabeled examples as well as the test-set examples (by treating them as unlabeled). Note that by doing this our comparison with CRR07 and MM08 cannot be exact as they

sampled the unlabeled examples, with different rates, for semi-supervised learning, while we used as much data as possible. We applied the same ω that was used for the supervised model, and then combined the newly labeled examples, in addition to the manually labeled ones, as training data to learn a supervised CRF model. On this particular dataset, we did not find it helpful by selecting automatically labeled data based on a confidence threshold. We simply used all data available in self-training. This paradigm is referred to as "CRF + VE (self-train)" in Table 3. When no VE is applied at test time, this semi-supervised CRF model significantly outperformed the best model in Table 2. When applying VE at test time, however, the improvement over its supervised counterpart became trivial.

Next, following Section 5.3, we collected context vectors on the unlabeled data using a window size $k = 3$, and extracted the top 50 singular vectors therefrom.[4] We created collocation lists that contain words close to the merged prototype words in the latent semantic space. Some examples are given in the last column of Table 1. We then augmented the prototype-based VE based on the following rules: If x_t belongs to any prototype list P_l, we directly apply s_1 in Equation (9); otherwise, we apply s_1 if x_t *and* at least one neighbor (within 3 tokens from x_t) belong to the same collocation list C_l. In our experiments, we let "Col-VE" represent such collocation-based VE. We conducted self-training using a CRF model integrated with Col-VE, where ω was tuned *a priori* by testing the same model on the development set. As shown in the table, "CRF + Col-VE (self-train)" gave significant accuracy improvement over "CRF + VE", while adding Col-VE at test time further boosted the performance. The accuracies were already on par with the best results previously reported on this task.

Finally, we implemented the EM algorithm proposed in Section 5.2 that iteratively optimizes $p(\mathbf{v}|\mathbf{x})$ on all data. The model was initialized by the one obtained from "CRF + Col-VE (self-train)". After the model was initialized, we performed the EM algorithm until the model reached a maximum accuracy on the development set. Note that in some cases, we observed a development-set accuracy degradation after the first iteration of the EM, but the accuracy quickly recovered from the second iteration and kept increasing until a maximum accuracy was reached.[5] As shown in the last two rows in Table 3, this method is clearly advantageous over self-training, leading to the best tagging accuracies in both decoding settings. Our model achieved $2.6\% - 5.7\%$ absolute accuracy increases in the three training settings compared with MM08 which had the best results without using any constraints in decoding. When applying VE at test time, our model was $1.2\% - 4.1\%$ better than CRR07 which had the best overall results. Additionally, when compared with supervised learning results, our best semi-supervised model trained on only 10 labeled examples performed almost as well as a standard supervised CRF model trained on 100 labeled examples.

[4]The same configuration is used in HK06.

7 Conclusions

We have presented the use of virtual evidence as a principled way of incorporating prior knowledge into conditional random fields. A key contribution of our work is the introduction of a novel semi-supervised learning objective for training a CRF model integrated with VE. We also found it useful to create so-called collocation-based VE, assuming that tokens close to each other tend to have consistent labels. Our evaluation on the CLASSIFIEDS data showed that the learning objective presented here, combined with the use of collocation-based VE, yielded remarkably good accuracy performance. In the future, we would like to see the application of our approach to other tasks such as (Li et al., 2009).

Abstract

This paper proposes a novel method to refine the grammars in parsing by utilizing semantic knowledge from HowNet. Based on the hierarchical state-split approach, which can refine grammars automatically in a data-driven manner, this study introduces semantic knowledge into the splitting process at two steps. Firstly, each part-of-speech node will be annotated with a semantic tag of its terminal word. These new tags generated in this step are semantic-related, which can provide a good start for splitting. Secondly, a knowledge-based criterion is used to supervise the hierarchical splitting of these semantic-related tags, which can alleviate overfitting. The experiments are carried out on both Chinese and English Penn Treebank show that the refined grammars with semantic knowledge can improve parsing performance significantly. Especially with respect to Chinese, our parser achieves an F_1 score of 87.5%, which is the best published result we are aware of.

1 Introduction

At present, most high-performance parsers are based on probabilistic context-free grammars (PCFGs) in one way or another (Collins, 1999; Charniak and Johnson, 2005; Petrov and Klein, 2007). However, restricted by the strong context-free assumptions, the original PCFG model which simply takes the grammars and probabilities off a treebank, does not perform well. Therefore, a variety of techniques have been developed to enrich and generalize the original grammar, ranging from lexicalization to symbol annotation.

*Corresponding author: Xihong Wu.

Lexicalized PCFGs use the structural features on the lexical head of phrasal node in a tree, and get significant improvements for parsing (Collins, 1997; Charniak, 1997; Collins, 1999; Charniak, 2000). However, they suffer from the problem of fundamental sparseness of the lexical dependency information. (Klein and Manning, 2003).

In order to deal with this limitation, a variety of unlexicalized parsing techniques have been proposed. Johnson (1998) annotates each node by its parent category in a tree, and gets significant improvements compared with the original PCFGs on the Penn Treebank. Then, some manual and automatic symbol splitting methods are presented, which get comparable performance with lexicalized parsers (Klein and Manning, 2003; Matsuzaki et al., 2005). Recently, Petrov et al. (2006) introduces an automatic hierarchical state-split approach to refine the grammars, which can alternately split and merge the basic nonterminals by the Expectation-Maximization (EM) algorithm. In this method, the nonterminals are split to different degrees, as appropriate to the actual complexity in the data. The grammars refined in this way are proved to be much more accurate and compact than previous work on automatic annotation. This data-driven method still suffers from the overfitting problem, which may be improved by integrating other external information.

In this paper, we propose a novel method that combines the strengths of both data-driven and knowledge-driven strategies to refine grammars. Based on the work proposed by Petrov et al. (2006), we use the semantic knowledge from HowNet (Dong and Dong, 2000) to supervise the hierarchical state-split process at the part-of-speech(POS) level. At first, we define the most general hypernym in HowNet as the semantic class of a word, and then use this semantic class to initialize the tag of each POS node. In this way, a new set of semantic-related tags is generated, and

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1298–1307,
Singapore, 6-7 August 2009.

a good starting annotation is provided to reduce the search space for the EM algorithm in the splitting process. Then, in order to mitigate the overfitting risk, the hierarchical hypernym-hyponym relation between hypernyms in HowNet is utilized to supervise the splitting of these new semantic-related tags. By introducing a knowledge-based criterion, these new tags are decided whether or not to split into subcategories from a semantic perspective. To investigate the effectiveness of the presented approach, several experiments are conduced on both Chinese and English. They reveal that the semantic knowledge is potentially useful to parsing.

The remainder of this paper is organized as follows. Section 2 reviews some closely related works, including the lexical semantic related parsing and the hierarchical state-split unlexicalized parsing. In section 3, the presented method for grammar refining is described in detail, and several experiments are carried out for evaluation in Section 4. Conclusions are drawn in Section 5.

2 Background

This paper tries to refine the grammars through an improved hierarchical state-split process integrated with semantic knowledge. The related works are reviewed as follows.

2.1 Lexical Semantic Related Parsing

Semantic knowledge is useful to resolving syntactic ambiguities, and a variety of researches focus on how to utilize it. Especially in recent years, a conviction arose that semantic knowledge could be incorporated into the lexicalized parsing.

Based on the lexicalized grammars, Bikel (2000) attempts at combining parsing and word sense disambiguation in a unified model, using a subset of SemCor (Miller et al., 1994). Bikel (2000) evaluates this model in a parsing context with sense information from WordNet, but does not get improvements on parsing performance.

Xiong et al. (2005) combines word sense from CiLin and HowNet (two Chinese semantic resources) in a generative parsing model, which generalizes standard bilexical dependencies to word-class dependencies, and indeed help to tackle the sparseness problem in lexicalized parsing. The experiments show that the parse model combined with word sense and the most special hypernyms achieves a significant improvement on Penn Chinese Treebank. This work only considers the most special hypernym of a word, rather than other hypernyms at different levels of the hypernym-hyponym hierarchy.

Then, Fujita et al. (2007) uses the Hinoki treebank as training data to train a discriminative parse selection model combining syntactic features and word sense information. Instead of utilizing the most special hypernym, the word sense information in this model is embodied with more general concepts. Based on the hand-craft sense information, this model is proved to be effective for parse selection.

Recently, Agirre et al. (2008) train two lexicalized models (Charniak, 2000; Bikel, 2004) on preprocessed inputs, where content words are substituted with semantic classes from WordNet. By integrating the word semantic classes into the process of parser training directly, these two models obtain significant improvements in both parsing and prepositional phrase attachment tasks. Zhang (2008) does preliminary work on integrating POS with semantic class of words directly, which can not only alleviate the confusion in parsing, but also infer syntax and semantic information at the same time.

2.2 The Hierarchical State-split Parsing

In order to alleviate the context-free assumptions, Petrov et al. (2006) proposes a hierarchical state-split approach to refine and generalize the original grammars, and achieves state-of-the-art performance. Starting with the basic nonterminals, this method repeats the split-merge (SM) cycle to increase the complexity of grammars. That is, it splits every symbol into two, and then re-merges some new subcategories based on the likelihood computation.

Splitting

In each splitting stage, the previous syntactic symbol is split into two subcategories, and the EM algorithm is adopted to learn probability of the rules for these latent annotations to maximize the likelihood of trees in the training data. Finally, each symbol generates a series of new subcategories in a hierarchical fashion. With this method, the splitting strategy introduces more context information, and the refined grammars cover more linguistic information which helps resolve the syntactic ambiguities.

However, it is worth noting that the EM algorithm does not guarantee a global optimal solution, and often gets stuck in a suboptimal configuration. Therefore, a good starting annotation is expected to help alleviate this problem, as well as reduce the search space for EM.

Merging

It is obvious that using more derived subcategories can increase accuracy, but the refined grammars fit tighter to the training data, and may lead to overfitting to some extent. In addition, different symbols should have their specific numbers of subcategories. For example, the comma POS tag should have only one subcategory, as it always produces the terminal comma. On the contrary, the noun POS tag and the verb POS tag are expected to have much more subcategories to express their context dependencies. Therefore, it is not reasonable to split them in the same way.

The symbol merging stage is introduced to alleviate this defect. This approach splits symbols only where needed, and it is implemented by splitting each symbol first and then measure the loss in likelihood incurred when removing this subcategory. If the loss is small, it means that this subcategory does not take enough information and should be removed. In general it is hard to decide the threshold of the likelihood loss, and this merging stage is often executed by removing a certain proportion of subcategories, as well as giving priority to the most informative subcategories.

By splitting and merging alternately, this method can refine the grammars step by step to mitigate the overfitting risk to some extent. However, this data-driven method can not solve this problem completely, and we need to find other external information to improve it.

Analysis

The hierarchical state-split approach is used to split all the symbols in the same way. Table 1 cites the subcategories for several POS tags, along with their two most frequent words. Results show that the words in the same subcategory of POS tags are semantic consistent in some cases. Therefore, it is expected to optimize the splitting and merging process at the POS level with semantic knowledge.

3 Integration with Semantic Knowledge

In this paper, the semantic knowledge is used to refine grammars by improving the automatic hierarchical state-split approach. At first, in order to provide good starting annotations to reduce the search space for the EM algorithm, we try to annotate the tag of each POS node with the most general hypernym of its terminal word. In this way, we generate a new set of semantic-related tags. And then, instead of splitting and merging all symbols together automatically, we propose a knowledge-based criterion with hierarchical semantic knowledge to supervise the splitting of these new semantic-related tags.

3.1 HowNet

The semantic knowledge resource we use is HowNet, which is a common sense knowledge base unveiling concepts and inter-conceptual relations in Chinese and English.

As a knowledge base of graph structure, HowNet is devoted to demonstrating the properties of concepts through sememes and relations between sememes. Broadly speaking, a sememe refers to the smallest basic semantic unit that cannot be reduced further, which can be represented in English and their Chinese equivalents, such as the sememe *institution*|*机构*. The relations explicated in HowNet include hypernym-hyponym relations, location-event relations, time-event relations and so on. In this work, we mainly focus on

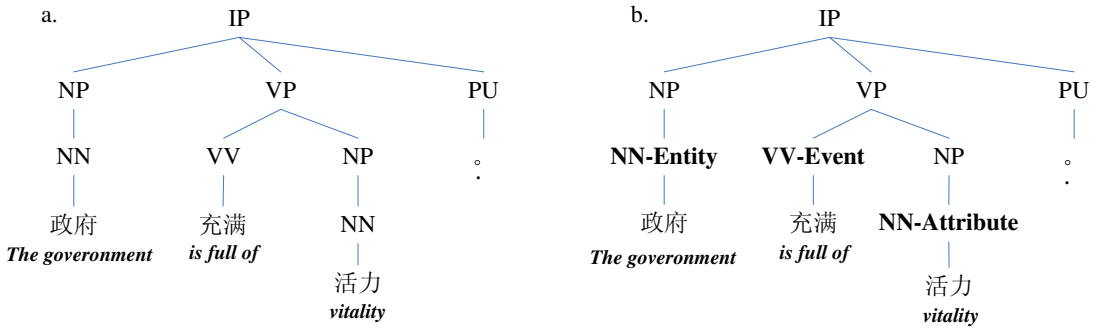

Figure 1: The two syntax trees of the sentence "*The government is full of vitality*". a. is the original syntax tree, b. is the syntax tree in which each tag of the POS node is annotated with the most general hypernym of its terminal word.

the hypernym-hyponym relations. Take the word 政府(government) as an example, its hypernyms with the hierarchical hypernym-hyponym relations are listed below from speciality to generality, which we call hierarchical semantic information in this paper.

institution|机构→group|群体→thing|万物→entity|实体

It is clear that this word 政府(government) has hypernyms from the most special hypernym *institution|机构* to the most general hypernym *entity|实体* in a hierarchical way.

In HowNet(Update 2008), there are 173535 concepts, with 2085 sememes. The sememes are categorized into entity, event, attribute, attribute value, etc., each corresponding to a sememe hierarchy tree.

3.2 Annotating the Training Data

One of the original motivations for the grammar refinement is that the original symbols, especially the POS tags, are usually too general to distinguish the context dependencies. Take the sentence in Figure 1 for example, the word 政府(government) should have different context dependencies compared with the word 活力(vitality), although both of them have the same POS tag "NN". In fact, the two words are defined in HowNet with different hypernyms. The word 政府(government) is defined as a kind of objective things, while the word 活力(vitality) is defined as a property that is often used to describe things. It is obvious that the different senses can represent their different syntax structures, and we expect to refine the POS tags with semantic knowledge.

In the automatic hierarchical state-split approach introduced above, the EM algorithm is used to search for the maximum of the likelihood during the splitting process, which can generate subcategories for POS tags to express the context dependencies. However, this method often gets stuck in a suboptimal configuration, which varies depending on the start point. Therefore, a good start of the annotations is very important. As it is displayed in Figure 1, we annotate the tag of each POS node with the hypernym of its terminal word as the starting annotation. There are two problems that we have to consider in this process: a) how to choose the appropriate semantic granularity, and b) how to deal with the polysemous words.

As mentioned above, the semantic information of each word can be represented as hierarchical hypernym-hyponym relations among its hypernyms. In general, it is hard to decide the appropriate level of granularity to represent the word. The semantic class is only used as the starting annotations of POS tags to reduce the search space for EM in our method. It is followed by the hierarchical state-split process to further refine the starting annotations based on the structural information. If more special kinds of semantic classes are chosen, it will make the structural information weaker. As annotations with the special hypernym always defeat some of the advantage of automatically latent annotations learning, we annotate the training data with the most general hypernym. For example, as shown in Figure 1, the POS tag "NN" of 政府(government) is annotated as "NN-Entity", and "NN" of 活力(energy) is annotated as "NN-Attribute".

Another problem is how to deal with the polysemous words in HowNet. In fact, when we choose the most general hypernym as the word's semantic

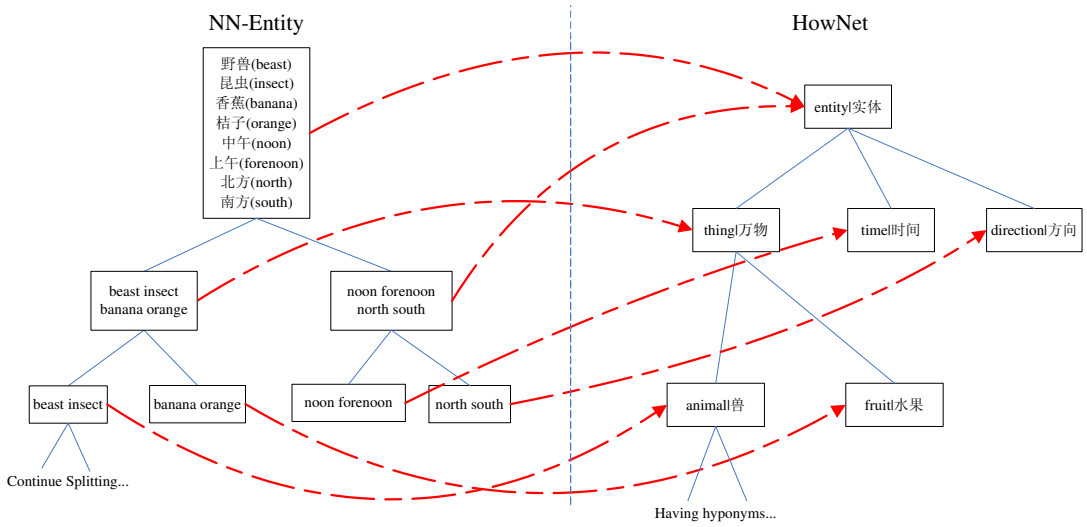

Figure 2: A schematic figure for the hierarchical state-split process of the semantic-related tag "NN-Entity". Each subcategory of this tag has its own word set, and corresponds to one hypernym at the appropriate level in HowNet.

representation, this problem has been alleviated to a large extent. In this paper we adopt the first sense option as our word sense disambiguation (WSD) strategy to determine the sense of each token instance of a target word. That is to say, all token instances of a given word are tagged with the sense that occurs most frequently in HowNet. In addition, we keep the tag of the POS node whose terminal word is not defined in HowNet unchanged.

3.3 Supervising the Hierarchical State-split Process

With the method proposed above, we can produce a good starting annotation with semantic knowledge, which is of great use to constraining the automatic splitting process. Our parser is trained on the good starting annotations with the automatic hierarchical state-split process, and gets improvements compared with the original training data. However, during this process, only the most general hypernyms are used as the semantic representation of words, and the hierarchical semantic knowledge is not explored. In addition, the automatic process tries to refine all symbols together through a data-driven manner, which suffers the overfitting risk.

After annotating the training data with hypernyms, a new set of semantic-related tags such as "NN-Entity" is produced. We treat the refining process of these semantic-related tags as the specializing process of hypernym with hierarchical semantic knowledge. Each subcategory of these tags corresponds to a appropriate special level of hypernym in the HowNet. For example, every subcategory of "NN-Entity" could corresponds to a appropriate hyponym of *entity|实体*.

We integrate the hierarchical semantic knowledge into the original hierarchical state-split process to refine these semantic-related tags. First of all, it is necessary to establish the mapping from each subcategory of these semantic-related tags to the hypernym at the appropriate level in HowNet. Then, instead of likelihood judgment, a knowledge-based criterion is proposed, to decide whether or not to remove the new subcategories of these tags. That is to say, once the parent tag of this new subcategory is mapped onto the most special hypernym without any hyponym, it should be removed immediately.

The schematic Figure 2 demonstrates this semantically supervised splitting process. The left part of this figure is the subcategories of the semantic-related tag "NN-Entity", which is split hierarchically. As expressed by the dashed line, each subcategory corresponds to one hypernym in the right part of this figure. If the hypernym node has no hyponym, the corresponding subcategory will stop splitting.

The mapping from each subcategory of these semantic-related tags to the hypernym at the appropriate level is implemented with the word set related to this subcategory. As it is shown in Fig-

TestSet	Articles 271-300	Section 23

Table 2: Experimental setup.

ure 2, the original tag "NN-Entity" treats all the words it products as its word set. Once the original category is split into two subcategories, its word set is also split, through forcedly dividing each word in the word set into one subcategory which is most frequent with this word. And then, each subcategory is mapped onto the most specific hypernym that contains its related word set entirely in HowNet. On this basis, a new knowledge-based criterion is introduced to enrich and generalize these semantic-related tags, with purpose of fitting to the hierarchical semantic structure rather than the training data.

4 Experiments

In this section, we designed several experiments to investigate the validity of refining grammars with semantic knowledge.

4.1 Experimental Setup

We did experiments on Chinese and English. In order to make a fair comparison with previous works, we split the standard corpora as shown in Table 2. Our parsers were evaluated by the EVALB parseval reference implementation[1]. The Berkeley parser[2] was used to train the models with the original automatic hierarchical state-split process. The semantic resource we used to improve parsing was HowNet, which has been introduced in Subsection 3.1. Statistical significance was checked using Dan Bikel's randomized parsing evaluation comparator with the default setting of 10,000 iterations[3].

4.2 Semantic Representation Experiments

First of all, we ran experiments with different semantic representation methods on Chinese. The polysemous words in the training set were annotated with the WSD strategy of first sense option, which was proved to be useful in Agirre et al. (2008).

As mentioned in Subsection 3.1, the semantic information of each word can be represented as a hierarchical relation among its hypernyms from specialty to generalization in HowNet. In order to choose the appropriate level of granularity to represent words, we annotated the training set with different levels of granularity as semantic representation. In our experiments, the automatic hierarchical state-split process is used to train models on these training sets with different level of semantic representation.

We tried two kinds of semantic representations, one is using the most general hypernym, and the other is using the most special hypernym. Results in Figure 3 proved the effectiveness of our method in Subsection 3.2. When we annotated the tag of each POS node with the most general hypernym of its terminal word, the parser performs much better than both the baseline and the one annotated with the most special hypernym. Moreover, the F_1 score starts dropping after 3 training iterations on the training set annotated with the most special hypernyms, while it is still improving with the most general one, indicating overfitting.

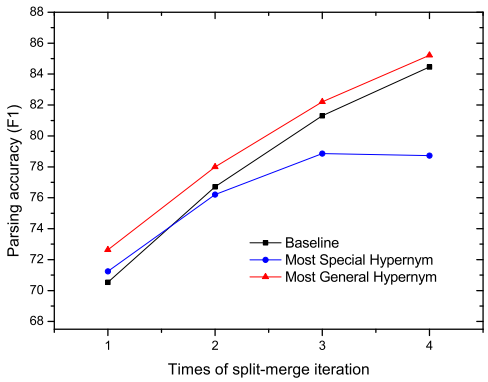

Figure 3: Performances on Chinese with different semantic representations: the training set without semantic representation, the training set annotated with the most special hypernyms, and the training set annotated with the most general hypernyms.

When the training set was annotated with the most general hypernyms, there were only 57 new semantic-related tags such as "NN-Entity", "NN-Attribute" and so on. However, when the training set was annotated with the most special hypernyms, 4313 new tags would be introduced. Ob-

[3] http://www.cis.upenn.edu/ dbikel/software.html.

viously, it introduces too many tags at once and is difficult to refine appropriate grammars in the subsequent step starting with this over-splitting training set.

4.3 Grammar Refinement Experiments

Several experiments were carried out on Chinese and English to verify the effectiveness of refining grammars with semantic knowledge. We took the most general hypernym as the semantic representation, and the polysemous words in the training set were annotated with the WSD strategy of first sense option.

In our experiments, three kinds of method were compared. The baseline was trained on the raw training set with the automatic hierarchical state-split approach. Then, we improved it with the semantic annotation, which annotated the raw training set with the most general hypernyms as semantic representations, while keeping the training approach used in the baseline unchanged. Further, our knowledge-based criterion was introduced to supervise the automatic hierarchical state-split process with semantic knowledge.

In this section, since most of the parsers (including the baseline parser and our advanced parsers) had the same behavior on development set that the accuracy continued increasing in the five beginning iterations and then dropped at the sixth iteration, we chose the results at the fifth iteration as our final test set parsing performance.

Performances on Chinese

Figure 4 shows that refining grammars with semantic knowledge can help improve parsing performance significantly on Chinese (sentences of length 40 or less). Benefitting from the good starting annotations, our parser achieved significant improvements compared with the baseline (86.8% vs. 86.1%, p<.08). It proved that the good starting annotations with semantic knowledge were effective in the splitting process. Further, we supervised the splitting of the new semantic-related tags from the semantic annotations, and achieved the best results at the fifth iteration. The best F_1 score reached 87.5%, with an error rate reduction of 10.1%, relative to the baseline (p<.004).

Table 3 compared our methods with the best previous works on Chinese. The result showed that refining grammars integrated with semantic knowledge could resolve syntactic ambiguities remarkably and achieved the state-of-the-art performance on Chinese.

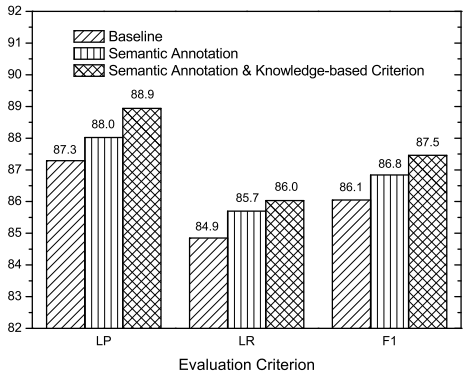

Figure 4: Performances at the fifth iteration on Chinese (sentences of length 40 or less) with three methods: the baseline, the parser trained on the semantic annotations with automatic method, and the parser trained on the semantic annotations with knowledge-based criterion.

This Paper	**88.9**	**86.0**	**87.5**	**86.0**	**83.1**	**84.5**

Table 3: Our final parsing performance compared with the best previous works on Chinese.

Performances on English

In order to verify the effectiveness of our method on other languages, we carried out some experiments on English. HowNet is a common sense knowledge base in Chinese and English, therefore, it was still utilized as the knowledge source in these experiments.

The same three methods were compared on English (sentences of length 40 or less), and the results were showed in Table 4. Compared with the baseline (90.1%), the parsers trained with the semantic annotation, while using different splitting methods introduced in Section 3, achieved an F_1 score of 90.2% and 90.3% respectively. The results showed that our methods could get a small but stable improvements on English (p<.08).

PN-Event-0	**援外(aid foreign)**, **予(donate)**
PN-AttributeValue-2	以上(the above), 那些(those), 彼(that), 其他(other), 以下(below)

Table 5: Several subcategories that generated from the original training set and the good starting annotations respectively.

Method	F_1
Baseline	90.1
Semantic Annotations	90.2
Semantic Annotations & Knowledge-based Criterion	**90.3**

Table 4: Performances at the fifth iteration on English (sentences of length 40 or less) with three methods: the baseline, the parser trained on the semantic annotations with automatic method, and the parser trained on the semantic annotations with knowledge-based criterion.

These results on English were preliminary, and we did not introduce any language dependent operation such as morphological processing. Since only the lemma of English words can be found in HowNet, we just annotated two kinds of POS tags "VB"(Verb, base form) and "NN"(Noun, singular or mass) with semantic knowledge, on the contrary, we annotated almost all POS tags whose corresponding words could be found in HowNet on Chinese. This might be the reason that the improvement on the English Treebank was much smaller than that of Chinese. It is expected to achieve more improvements through some morphological analysis in the future.

4.4 Results and Analysis

So far, a new strategy has been introduced to refine the grammars in two steps, and achieved significant improvements on parsing performance. In this section, we analyze the grammars learned at different steps, attempting to explain how the semantic knowledge works.

It is hard to inspect all the grammars by hand. Since the semantic knowledge is mainly used for generating and splitting new semantic-related tags in our method, we focus on the refined subcategories of these tags.

First, we examine the refined subcategories of POS tags, which are generated from the original training set and the good starting annotations respectively. Several subcategories are listed and compared in Table 5, along with their frequent words. It can be seen that the subcategories refined with semantic knowledge are more consistent than the previous one. For example, the subcategory "PN-0", which is refined from the original training set, produces a lot of words without semantic consistence. In contrast, we refine the subcategories "PN-0", "PN-Event-0" and "PN-AttributeValue-2" from the good starting annotations. Each of them produces a small but semantic consistent word set.

In order to inspect the difference between the automatic splitting process and the semantic based one, we compare the numbers of subcategories refined in these two processes. Since it is hard to list all the semantic-related tags here, three parts of the semantic-related tags were selected and listed in Table 6, along with the number of their subcategories. The first part is the noun and verb related tags, which are most heavily split in both two processes. It is clear that the semantic based splitting process can generate more subcategories than the automatic one, because the semantic structures of noun and verb are sophisticated. The second part lists the tags that have much more subcategories (≥ 4) from the automatic splitting process than the semantic based one, and the third part vice verse. It can be seen that most of the subcategories in the second part are functional categories, while most of the subcategories in the third part are content categories. It means that the semantic based splitting process is prone to generating less subcategory for the functional categories, but more subcategories for the content categories. This tendency is in accordance with the linguistic intuition. We believe that it is the main effect

Semantic-related tag	Automatic split number	Semantic based split numebr

of our knowledge-based criterion, because it adjusts the splitting results dynamically with semantic knowledge, which can alleviate the overfitting risk.

5 Conclusions

In this paper, we present a novel approach to integrate semantic knowledge into the hierarchical state-split process for grammar refinement, which yields better accuracies on Chinese than previous methods. The improvements are mainly owing to two aspects. Firstly, the original treebank is initialized by annotating the tag of each POS node with the most general hypernym of its terminal word, which reduces the search space for the EM algorithm and brings an initial restrict to the following splitting step. Secondly, the splitting process is supervised by a knowledge-based criterion with the new semantic-related tags. Benefitting from the hierarchical semantic knowledge, the proposed approach alleviates the overfitting risk in a knowledge-driven manner. Experimental results reveal that the semantic knowledge is of great use to syntactic disambiguation. The further analysis on the refined grammars shows that, our method tends to split the content categories more often than the baseline method and the function classes less often.

{dliu, gildea}@cs.rochester.edu

Abstract

We examine the problem of overcoming noisy word-level alignments when learning tree-to-string translation rules. Our approach introduces new rules, and re-estimates rule probabilities using EM. The major obstacles to this approach are the very reasons that word-alignments are used for rule extraction: the huge space of possible rules, as well as controlling overfitting. By carefully controlling which portions of the original alignments are re-analyzed, and by using Bayesian inference during re-analysis, we show significant improvement over the baseline rules extracted from word-level alignments.

1 Introduction

Non-parametric Bayesian methods have been successfully applied to directly learn phrase pairs from a bilingual corpus with little or no dependence on word alignments (Blunsom et al., 2008; DeNero et al., 2008). Because such approaches directly learn a generative model over phrase pairs, they are theoretically preferable to the standard heuristics for extracting the phrase pairs from the many-to-one word-level alignments produced by the IBM series models (Brown et al., 1993) or the Hidden Markov Model (HMM) (Vogel et al., 1996). We wish to apply this direct, Bayesian approach to learn better translation rules for syntax-based statistical MT (SSMT), by which we specifically refer to MT systems using Tree-to-String (TTS) translation templates derived from syntax trees (Liu et al., 2006; Huang et al., 2006; Galley et al., 2006; May and Knight, 2007), as opposed to *formally syntactic* systems such as Hiero (Chiang, 2007). The stumbling block preventing us from taking this approach is the extremely large space of possible TTS templates when no word alignments are given. Given a sentence pair and syntax tree over one side, there are an exponential number of potential TTS templates and a polynomial number of phrase pairs. In this paper, we explore methods for restricting the space of possible TTS templates under consideration, while still allowing good templates to emerge directly from the data as much as possible. We find an improvement in translation accuracy through, first, using constraints to limit the number of new templates, second, using Bayesian methods to limit which of these new templates are favored when re-analyzing the training data with EM, and, third, experimenting with different renormalization techniques for the EM re-analysis.

We introduce two constraints to limit the number of TTS templates that we extract directly from tree/string pairs without using word alignments. The first constraint is to limit direct TTS template extraction to the part of the corpus where word alignment tools such as GIZA++ do poorly. There is no reason not to re-use the good alignments from GIZA++, which holds a very competitive baseline performance. As already mentioned, the noisy alignments from GIZA++ are likely to cross the boundaries of the tree constituents, which leads to comparatively big TTS templates. We use this fact as a heuristic to roughly distinguish noisy from good word alignments.[1] Here we define *big templates* as those with more than 8 symbols in their right hand sides (RHSs). The word alignments in big templates are considered to be noisy and will be recomposed by extracting smaller TTS templates. Another reason to do extraction on big templates is that the applicability of big templates to new sentences is very limited due to their size, and the portion of the training data from which they are extracted is effectively wasted. The second constraint, after choosing the

[1] Precisely differentiating the noisy/good word alignments is as hard as correctly aligning the words.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1308–1317,
Singapore, 6-7 August 2009.

extraction site, is to extract the TTS templates all the way down to the leaves of the hosting templates. This constraint limits the number of possible left hand sides (LHSs) to be equal to the number of tree nodes in the hosting templates. The entire extraction process can be summarized in 3 steps:

1. Compute word alignments using GIZA++, and generate the basic TTS templates.

2. Select big templates from the basic TTS templates in step 1, and extract smaller TTS templates all the way down to the bottom from big templates, without considering the pre-computed word alignments.

3. Combine TTS templates from step 1 and step 2 and estimate their probabilities using Variational Bayes with a Dirichlet Process prior.

In step 2, since there are no constraints from the pre-computed word alignments, we have complete freedom in generating all possible TTS templates to overcome noisy word alignments. We use variational EM to approximate the inference of our Bayesian model and explore different normalization methods for the TTS templates. A two-stage normalization is proposed by combining LHS-based normalization with normalization based on the root of the LHS, and is shown to be the best model when used with variational EM.

Galley et al. (2006) recompose the TTS templates by inserting unaligned target words and combining small templates into bigger ones. The recomposed templates are then re-estimated using the EM algorithm described in Graehl and Knight (2004). This approach also generates TTS templates beyond the precomputed word alignments, but the freedom is only granted over unaligned target words, and most of the pre-computed word alignments remain unchanged. Other prior approaches towards improving TTS templates focus on improving the word alignment performance over the classic models such as IBM series models and Hidden Markov Model (HMM), which do not consider the syntactic structure of the aligning languages and produce syntax-violating alignments. DeNero and Klein (2007) use a syntax-based distance in an HMM word alignment model to favor syntax-friendly alignments. Fossum et al. (2008) start from the GIZA++ alignment and incrementally delete bad links based on a discriminative model with syntactic features. This approach can only find a better subset of the GIZA++ alignment and requires a parallel corpus with gold-standard word alignment for training the discriminative model. May and Knight (2007) factorize the word alignment into a set of re-orderings represented by the TTS templates and build a hierarchical syntax-based word alignment model. The problem is that the TTS templates are generated by the word alignments from GIZA++, which limits the potential of the syntactic re-alignment. As shown by these prior approaches, directly improving the word alignment either falls into the framework of many-to-one alignment, or is substantially confined by the word alignment it builds upon.

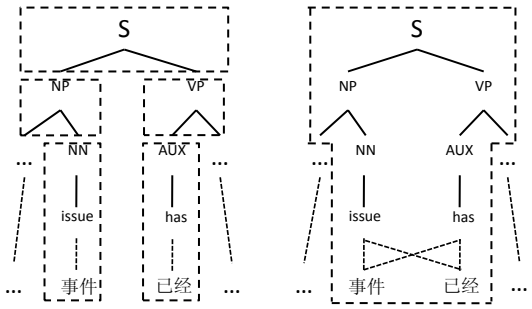

Figure 1: 5 small TTS templates are extracted based on the correct word alignments (left), but only 1 big TTS template (right) can be extracted when the cross-boundary noisy alignments are added in.

The remainder of the paper focuses on the Bayesian approach to learning TTS templates and is organized as follows: Section 2 describes the procedure for generating the candidate TTS templates; Section 3 describes the inference methods used to learn the TTS templates; Section 4 gives the empirical results, Section 5 discusses the characteristics of the learned TTS templates, and Section 6 presents the conclusion.

2 Extracting Phrasal TTS Templates

The Tree-to-String (TTS) template, the most important component of a SSMT system, usually contains three parts: a fragment of a syntax tree in its left hand side (LHS), a sequence of words and variables in its right hand side (RHS), and a probability indicating how likely the template is to be used in translation. The RHS of a TTS template shows one possible translation and reordering of its LHS. The variables in a TTS template are further transformed using other TTS templates, and the recursive process continues until there are no variables left. There are two ways

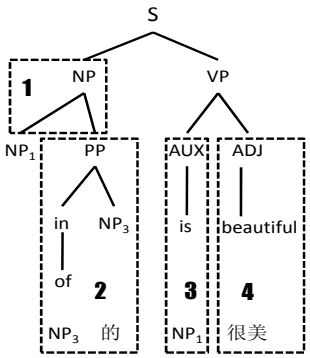

Figure 2: Examples of valid and invalid templates extracted from a big Template. Template 1, invalid, doesn't go all the way down to the bottom. Template 2 is valid. Template 3, invalid, doesn't have the same set of variables in its LHS/RHS. Template 4, invalid, is not a phrasal TTS template.

that TTS templates are commonly used in machine translation. The first is *synchronous parsing* (Galley et al., 2006; May and Knight, 2007), where TTS templates are used to construct synchronous parse trees for an input sentence, and the translations will be generated once the synchronous trees are built up. The other way is the TTS *transducer* (Liu et al., 2006; Huang et al., 2006), where TTS templates are used just as their name indicates: to transform a source parse tree (or forest) into the proper target string. Since synchronous parsing considers all possible synchronous parse trees of the source sentence, it is less constrained than TTS transducers and hence requires more computational power. In this paper, we use a TTS transducer to test the performance of different TTS templates, but our techniques could also be applied to SSMT systems based on synchronous parsing.

2.1 Baseline Approach: TTS Templates Obeying Word Alignment

TTS templates are commonly generated by decomposing a pair of aligned source syntax tree and target string into smaller pairs of tree fragments and target string (i.e., the TTS templates). To keep the number of TTS templates to a manageable scale, only the non-decomposable TTS templates are generated. This algorithm is referred to as GHKM (Galley et al., 2004) and is widely used in SSMT systems (Galley et al., 2006; Liu et al., 2006; Huang et al., 2006). The word alignment used in GHKM is usually computed independent of the syntactic structure, and as DeNero and Klein (2007) and May and Knight (2007) have noted,

Ch-En	En-Ch	Union	Heuristic
28.6%	33.0%	45.9%	20.1%

Table 1: Percentage of corpus used to generate big templates, based on different word alignments

	9-12	13-20	≥21
Ch-En	18.2%	17.4%	64.4%
En-Ch	15.9%	20.7%	63.4%
Union	9.8%	15.1%	75.1%
Heuristic	24.6%	27.9%	47.5%

Table 2: In the selected big templates, the distribution of words in the templates of different sizes, which are measured based on the number of symbols in their RHSs

is not the best for SSMT systems. In fact, noisy word alignments cause more damage to a SSMT system than to a phrase based SMT system, because the TTS templates can only be derived from tree constituents. If some noisy alignments happen to cross over the boundaries of two constituents, as shown in Figure 2, a much bigger tree fragment will be extracted as a TTS template. Even though the big TTS templates still carry the original alignment information, they have much less chance of getting matched beyond the syntax tree where they were extracted, as we show in Section 4. In other words, a few cross-boundary noisy alignments could disable a big portion of a training syntax tree, while for a phrase-based SMT system, their effect is limited to the phrases they align. As a rough measure of how the training corpus is affected by the big templates, we calculated the distribution of target words in big and non-big TTS templates. The word alignment is computed using GIZA++[2] for the selected 73,597 sentence pairs in the FBIS corpus in both directions and then combined using union and heuristic diagonal growing (Koehn et al., 2003). Table 1 shows that big templates consume 20.1% to 45.9% of the training corpus depending on different types of word alignments. The statistics indicate that a significant portion of the training corpus is simply wasted, if the TTS templates are extracted based on word alignments from GIZA++. On the other hand, it shows the potential for improving an SSMT system if we can efficiently re-use the wasted training corpus. By further examining the selected big templates, we find that the most common form of big templates is a big skeleton template starting

[2]GIZA++ is available at http://www.fjoch.com/GIZA++.html

from the root of the source syntax tree, and having many terminals (words) misaligned in the bottom. Table 2 shows, in the selected big templates, the distribution of words in the templates of different sizes (measured based on the number of symbols in their RHS). We can see that based on either type of word alignment, the most common big templates are the TTS templates with more than 20 symbols in their RHSs, which are generally the big skeleton templates. The advantage of such big skeleton templates is that they usually have good marginal accuracy[3] and allow accurate smaller TTS templates to emerge.

2.2 Liberating Phrasal TTS Templates From Noisy Word Alignments

To generate better TTS templates, we use a more direct way than modifying the underlying word alignment: extract smaller phrasal TTS templates from the big templates without looking at their pre-computed word alignments. We define *phrasal* TTS templates as those with more than one symbol (word or non-terminal) in their LHS. The reason to consider only phrasal TTS templates is that they are more robust than the word-level TTS templates in addressing the complicated word alignments involved in big templates, which are usually not the simple type of one-to-many or many-to-one. Abandoning the pre-computed word alignments in big templates, an extracted smaller TTS template can have many possible RHSs, as long as the two sides have the same set of variables. Note that the freedom is only given to the alignments of the words; for the variables in the big templates, we respect the pre-computed word alignments. To keep the extracted smaller TTS templates to a manageable scale, the following two constraints are applied:

1. The LHS of extracted TTS templates should go all the way down to the bottom of the LHS of the big templates. This constraint ensures that at most N LHSs can be extracted from one big Template, where N is the number of tree nodes in the big Template's LHS.

2. The number of leaves (including both words and variables) in an extracted TTS template's LHS should not exceed 6. This constraint limits the size of the extracted TTS templates.

[3]Here, marginal accuracy means the correctness of the TTS template's RHS corresponding to its LHS.

Figure 3: All valid templates that can be extracted from the example in Figure 2.1

```
for all template t do
    if size(t.rhs) > 8 then
        for all tree node s in t.lhs do
            subt = subtree(s, t.lhs);
            if leaf_num(subt) ≤ 6 then
                for i=1:size(t.rhs) do
                    for j=i:size(t.rhs) do
                        if valid(subt, i, j) then
                            create_template(subt, i, j);
```

Figure 4: Algorithm that liberates smaller TTS Templates from big templates

As we show in Section 4, use of bigger TTS templates brings very limited performance gain.

Figure 2.2 describes the template liberating algorithm running in $O(NM^2)$, where N denotes the number of tree nodes in the LHS of the input big Template and M denotes the length of the RHS. In the algorithm, function *valid* returns *true* if there are the same set of variables in the left/right hand side of an extracted TTS template; *subtree(x, y)* denotes the sub-tree in *y* which is rooted at *x* and goes all the way down to *y*'s bottom. Figure 2.1 shows valid and invalid TTS templates which can be extracted from an example hosting TTS template. Note that, in order to keep the example simple, the hosting TTS template only has 4 symbols in its RHS, which does not qualify as a big template according to our definition. Figure 2.2 shows the complete set of valid TTS templates which can be extracted from the example TTS template. The subscripts of the non-terminals are used to differentiate identical non-terminals in different positions. The extraction process blindly releases smaller TTS templates from the big templates, among which only a small fraction are correct TTS templates. Therefore, we need an inference method to raise the weight of the correct templates and decrease the weight of the noisy templates.

3 Estimating TTS Template Probability

The Expectation-Maximization (EM) algorithm (Dempster et al., 1977) can be used to estimate the TTS templates' probabilities, given a generative model addressing how a pair of source syntax tree and target string is generated. There are two commonly used generative models for syntax-based MT systems, each of which corresponds to a normalization method for the TTS templates. The LHS-based normalization (LHSN) (Liu et al., 2006; Huang et al., 2006), corresponds to the generative process where the source syntax subtree is first generated, and then the target string is generated given the source syntax subtree. The other one is normalization based on the root of the LHS (ROOTN) (Galley et al., 2006), corresponding to the generative process where, given the root of the syntax subtree, the LHS syntax subtree and the RHS string are generated simultaneously. By omitting the decomposition probability in the LHS-based generative model, the two generative models share the same formula for computing the probability of a training instance:

$$Pr(T,S) = \sum_{R} Pr(T,S,R) = \sum_{R} \left(\prod_{t \in R} Pr(t) \right)$$

where T and S denote the source syntax tree and target string respectively, R denotes the decomposition of (T,S), and t denotes the TTS template. The expected counts of the TTS templates can then be efficiently computed using an inside-outside-like dynamic programming algorithm (May and Knight, 2007).

LHSN, as shown by Galley et al. (2006), cannot accurately restore the true conditional probabilities of the target sentences given the source sentences in the training corpus. This indicates that LHSN is not good at predicting unseen sentences or at translating new sentences. But this deficiency does not affect its ability to estimate the expected counts of the TTS templates, because the posteriors of the TTS templates only depend on the comparative probabilities of the different derivations of a training instance (a pair of tree and string). In fact, as we show in Section 4, LHSN is better than ROOTN in liberating smaller TTS templates out of the big templates, since it is less biased to the big templates in the EM training.[4] Because the two normalization methods have their own strength and weakness, both of them are used in our EM algorithm: LHSN is used in all EM iterations except the last one to compute the expected counts of the TTS templates, and ROOTN is used in the last EM iteration to compute the final probabilities of the TTS templates. This two-stage normalization method is denoted as MIXN in this paper.

E-step:
for all pair of syntax tree T and target string S **do**
  for all TTS Template t **do**
    $EC(t) += \frac{\sum_{R:t \in R} Pr(T,S,R)^{\beta}}{\sum_{R'} Pr(T,S,R')^{\beta}}$;
Increase β;

M-step:
for all TTS Template t **do**
  if it is the last iteration **then**
    $Pr(t) = \frac{EC(t)}{\sum_{t':t'.root=t.root} EC(t')}$;
  else
    $Pr(t) = \frac{EC(t)}{\sum_{t':t'.lhs=t.lhs} EC(t')}$;

Figure 5: EM Algorithm For Estimating TTS Templates

Deterministic Annealing (Rose et al., 1992) is is used in our system to speed up the training process, similar to Goldwater et al. (2006). We start from a high temperature and gradually decrease the temperature to 1; we find that the initial high temperature can also help small templates to survive the initial iterations. The complete EM framework is sketched in Figure 3, where β is the inverse of the specified temperature, and *EC* denotes the expected count.

3.1 Bayesian Inference with the Dirichlet Process Prior

Bayesian inference plus the Dirichlet Process (DP) have been shown to effectively prevent MT models from overfitting the training data (DeNero et al., 2008; Blunsom et al., 2008). A similar approach can be applied here for SSMT by considering each TTS template as a cluster, and using DP to adjust the number of TTS templates according to the training data. Note that even though there is a size limitation on the liberated phrasal TTS templates, standard EM will still tend to overfit the training data by pushing up the probabilities of the big templates from the noisy word alignments. The complete generative process, integrating the DP prior and the generative models described in

[4] Based on LHSN, the difference between the probability of a big Template and the product of the probabilities of its decomposing TTS templates is much less than the one based on ROOTN, thus LHSN gives comparably more expected counts to the smaller TTS templates than ROOTN.

for all TTS Template t **do**
  if it is the last iteration **then**
    $Pr(t) = \frac{\exp(\psi(EC(t)+\alpha G_0(t)))}{\exp\left(\psi\left(\left(\sum_{t':t'.root=t.root} EC(t')\right)+\alpha\right)\right)}$;
  else
    $Pr(t) = \frac{\exp(\psi(EC(t)+\alpha G_0(t)))}{\exp\left(\psi\left(\left(\sum_{t':t'.lhs=t.lhs} EC(t')\right)+\alpha\right)\right)}$;

Figure 6: M-step of the Variational EM

Section 3.1, is given below:

$$\begin{aligned} \theta^r \mid \{\alpha_r, G_0^r\} &\sim DP(\alpha_r, G_0^r) \\ t \mid \theta^{t.root} &\sim \theta^{t.root} \\ (T,S) \mid \{SG, \{t\}, \theta\} &\sim SG(\{t\}, \theta) \end{aligned}$$

where G_0 is a base distribution of the TTS templates, t denotes a TTS template, $\theta^{t.root}$ denotes the multinomial distribution over TTS templates with the same root as t, SG denotes the generative model for a pair of tree and string in Section 3.1, and α is a free parameter which adjusts the rate at which new TTS templates are generated.

It is intractable to do exact inference under the Bayesian framework, even with a conjugate prior such as DP. Two methods are commonly used for approximate inference: Markov chain Monte Carlo (MCMC) (DeNero et al., 2008), and Variational Bayesian (VB) inference (Blunsom et al., 2008). In this paper, the latter approach is used because it requires less running time. The E-step of VB is exactly the same as standard EM, and in the M-step the digamma function ψ and the base distribution G_0 are used to increase the uncertainty of the model. Similar to standard EM, both LHS- and root-based normalizations are used in the M-step, as shown in Figure 3.1. For the TTS templates, which are also pairs of subtrees and strings, a natural choice of G_0 is the generative models described in Section 3.1. Because G_0 estimates the probability of the new TTS templates, the root-based generative model is superior to the LHS-based generative model and used in our approach.

3.2 Initialization

Since the EM algorithm only converges to a local minimum, proper initializations are needed to achieve good performance for both standard EM and variational EM. For the baseline templates derived from word alignments, the initial counts are set to the raw counts in the training corpus. For the templates blindly extracted from big templates, the raw count of a LHS tree fragment is distributed among their RHSs based on the likelihood of the template, computed by combining

for all big template t **do**
  for all template g extracted from t **do**
    $g.count$ = $g.lhs.count$ = 0;
  for all template g extracted from t **do**
    $g.count$ += w_in(g)×w_out(g, t);
    $g.lhs.count$ += w_in(g)×w_out(g, t);
  for all template g extracted from t **do**
    $g.init$ += $\frac{g.count}{g.lhs.count}$;

Figure 7: Compute the initial counts of the liberated TTS templates

the word-based inside/outside scores. The algorithm is sketched in Figure 3.2, where the inside score *w_in(g)* is the product of the IBM Model 1 scores in both directions, computed based on the words in g's LHS and RHS. The outside score *w_out(g, t)* is computed similarly, except that the IBM Model 1 scores are computed based on the words in the hosting template t's LHS/RHS excluding the words in g's LHS/RHS. The initial probabilities of the TTS templates are then computed by normalizing their initial counts using LHSN or ROOTN.

4 Experiments

We train an English-to-Chinese translation system using the FBIS corpus, where 73,597 sentence pairs are selected as the training data, and 500 sentence pairs with no more than 25 words on the Chinese side are selected for both the development and test data.[5] Charniak (2000)'s parser, trained on the Penn Treebank, is used to generate the English syntax trees. Modified Kneser-Ney trigram models are trained using SRILM (Stolcke, 2002) upon the Chinese portion of the training data. The trigram language model, as well as the TTS templates generated based on different methods, are used in the TTS transducer. The model weights of the transducer are tuned based on the development set using a grid-based line search, and the translation results are evaluated based on a single Chinese reference[6] using BLEU-4 (Papineni et al., 2002). Huang et al. (2006) used character-based BLEU as a way of normalizing inconsistent Chinese word segmentation, but we avoid this problem as the training, development, and test data are from the same source.

[5]The total 74,597 sentence pairs used in experiments are those in the FBIS corpus whose English part can be parsed using Charniak (2000)'s parser.

[6]BLEU-4 scores based on a single reference are much lower than the ones based on multiple references.

	E2C	C2E	Union	Heuristic

	≤ 5	≤ 6	≤ 7	≤ 8	$\leq \infty$
BLEU-4	14.27	14.42	14.43	14.45	14.55

Table 4: BLEU-4 scores (test set) of the *union* alignment, using TTS templates up to a certain size, in terms of the number of leaves in their LHSs

4.1 Baseline Systems

GHKM (Galley et al., 2004) is used to generate the baseline TTS templates based on the word alignments computed using GIZA++ and different combination methods, including *union* and the diagonal growing heuristic (Koehn et al., 2003). We also tried combining alignments from GIZA++ based on intersection, but it is worse than both single-direction alignments, due to its low coverage of training corpus and the incomplete translations it generates. The baseline translation results based on ROOTN are shown in Table 4.1. The first two columns in the table show the results of the two single direction alignments. *e2c* and *c2e* denote the many English words to one Chinese word alignment and the many Chinese words to one English word alignment, respectively. The two rows show the results with and without the big templates, from which we can see that removing the big templates does not affect performance much; this verifies our postulate that the big templates have very little chance of being used in the translation. Table 4.1, using the *union* alignments as the representative and measuring a template's size by the number of leaves in its LHS, also demonstrates that using big TTS templates brings very limited performance gain.

The result that the union-based combination outperforms either single direction alignments and even the heuristic-based combination, combined with the statistics of the disabled corpus in Section 2.2, shows that more disabled training corpus actually leads to better performance. This can be explained by the fact that the *union* alignments have the largest number of noisy alignments gathered together in the big templates, and thus have the least amount of noisy alignments which lead to small and low-quality TTS templates.

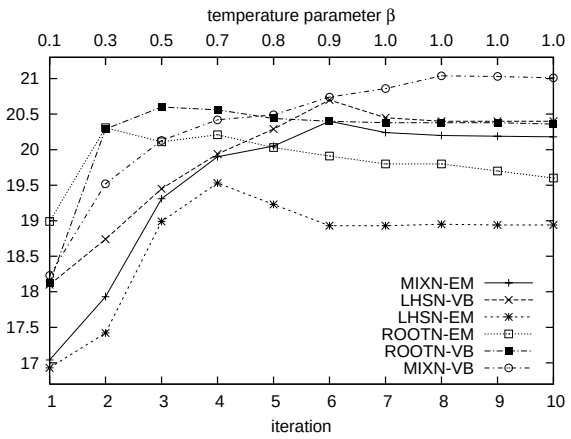

Figure 8: BLEU-4 scores (development set) of annealing EM and annealing VB in each iteration.

4.2 Learning Phrasal TTS Templates

To test our learning methods, we start with the TTS templates generated based on *e2c*, *c2e*, and *union* alignments using GHKM. This gives us 0.98M baseline templates. We use the big templates from the *union* alignments as the basis and extract 10.92M new phrasal TTS templates, which, for convenience, are denoted by NEW-PHR. Because based on Table 1 and Table 2 the *union* alignment has the greatest number of alignment links and therefore produces the largest rules, this gives us the greatest flexibility in realigning the input sentences. The baseline TTS templates as well as NEW-PHR are initialized using the method in Section 3.3 for both annealing EM and annealing VB. To simplify the experiments, the same Dirichlet Process prior is used for all multinomial distributions of the TTS templates with different roots. G_0 in the Dirichlet prior is computed based on the 1-level TTS templates selected from the baseline TTS templates, so that the big templates are efficiently penalized. The training algorithms follow the same annealing schedule, where the temperature parameter β is initialized to 0.1, and gradually increased to 1.

We experiment with the two training algorithms, annealing EM and annealing VB, with different normalization methods. The experimental results based on the development data are shown in Figure 4.2, where the free parameter α of annealing VB is set to 1, 100, and 100 respectively for ROOTN, LHSN, and MIXN. The results verify that LHSN is worse than ROOTN in predicting the translations, since MIXN outperforms LHSN with both annealing EM and VB. ROOTN is on par with MIXN and much better

	Max Likelihood		Annealing EM		Annealing VB	
	w/o new-phr	with new-phr	w/o new-phr	with new-phr	w/o new-phr	with new-phr
LHSN	14.05	13.16	14.31	15.33	14.82	16.15
ROOTN	14.50	13.49	14.90	16.06	14.76	16.12
MIXN	NA	NA	14.82	16.37	14.93	**16.84**

Table 5: BLEU-4 scores (test set) of different systems.

	Initial Template		Final Template	
	number	new-phr%	number	new-phr%
ROOTN	11.9M	91.8%	408.0K	21.9%
LHSN	11.9M	91.8%	557.2K	29.8%
MIXN	11.9M	91.8%	500.5K	27.6%

Table 6: The total number of templates and the percentage of NEW-PHR, in the beginning and end of annealing VB

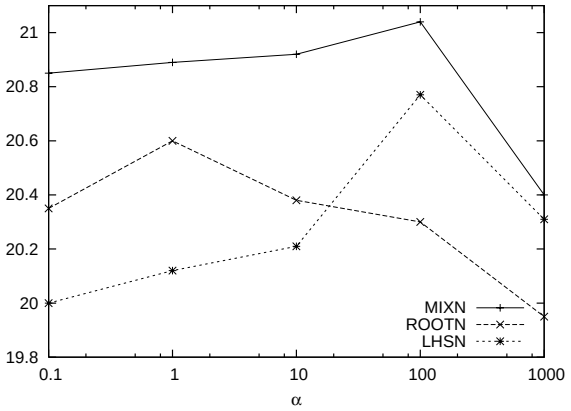

Figure 9: BLEU-4 scores (development set) of annealing VB with different α.

than LHSN when annealing EM is used; but with annealing VB, it is outperformed by MIXN by a large margin and is even slightly worse than LHSN. This indicates that ROOTN is not giving large expected counts to NEW-PHR and leaves very little space for VB to further improve the results. For all the normalization methods, annealing VB outperforms annealing EM and maintains a longer ascending path, showing better control of overfitting for the Bayesian models. Figure 4.2 shows the optimized results of the development set based on annealing VB with different α. The best performance is achieved as α approaches 1, 100, and 100 for ROOTN, LHSN and MIXN respectively. The α parameter can be viewed as a weight used to balance the expected counts and the probabilities from G_0. Thus it is reasonable for LHSN and MIXN to have bigger optimal α than ROOTN, since ROOTN gives lower expected counts to NEW-PHR than LHSN and MIXN do.

To see the contribution of the phrasal template extraction in the performance gain, MT experiments are conducted by turning this component on and off. Results on the test set, obtained by using parameters optimized on the development set, are shown in Table 4.2. The template counts used in the Max-Likelihood training are the same as the ones used in the initialization of annealing EM and VB. Results show that for annealing EM and VB, use of NEW-PHR greatly improves performance, while for the Max-Likelihood training, use of NEW-PHR hurts performance. This is not surprising, because Max-Likelihood training cannot efficiently filter out the noisy phrasal templates introduced in the initial NEW-PHR. Another observation is that annealing VB does not always outperform annealing EM. With NEW-PHR turned on, annealing VB shows consistent superiority over annealing EM; while without NEW-PHR, it only outperforms annealing EM based on LHSN and MIXN, and the improvement is not as big as when NEW-PHR is turned on. This indicates that without NEW-PHR, there is less need to use VB to shrink down the size of the template set. Table 4.2 shows the statistics of the initial template set including NEW-PHR and the final TTS template set after annealing VB is conducted, where we can see annealing VB efficiently reduces NEW-PHR to a relatively small size and results in much more compact systems than the system based on the baseline templates from GIZA++ alignments. Comparing with the best GIZA++-based system *union*, our best system, utilizing NEW-PHR and the two-stage template normalization, demonstrates the strength of annealing VB by an absolute improvement of 2.29% in BLEU-4 score, from 14.55 to 16.84. This improvement is significant at $p < 0.005$ based on 2000 iterations of paired bootstrap re-sampling of the test set (Koehn, 2004).

5 Discussion

Our experimental results are obtained based on a relatively small training corpus, the improved performance may be questionable when a larger training corpus is used. Someone may wonder if the performance gain primarily comes from the

Figure 10: Examples of the learned TTS templates

reduced out of vocabulary (OOV) ratio. We examined the OOV ratio of the test set with/without the learned TTS templates, and found the difference was very small. In fact, our method is designed to learn the phrasal TTS templates, and explictly avoids lexical pairs. To further understand the characteristics of the learned TTS templates, we list some representative templates in Figure 4.2 classified in 3 groups. The group *Many-to-one Alignment* and *Many-to-many Alignment* show the TTS templates based on complicated word alignments, which are difficult to compute based on the existing word alignment models. These templates do not have rare English words, whose translation cannot be found outside the big templates. The difficulty lies in the non-literal translation of the source words, which are unlikely to learnt by soly increasing the size of the training corpus. One other interesting observation is that our learning method is tolerant to noisy Chinese word segmentation, as shown in group *Allowance of Bad Word Segmentation*.

6 Conclusion

This paper proposes a Bayesian model for extracting the Tree-to-String templates directly from the data. By limiting the extraction to the big templates from the pre-computed word alignments and applying a set of constraints, we restrict the space of possible TTS templates under consideration, while still allowing new and more accurate templates to emerge from the training data. The empirical results demonstrate the strength of our approach, which outperforms the GIZA++-based systems by a large margin. This encourages a move from word-alignment-based systems to systems based on consistent, end-to-end probabilistic modeling. Because our Bayesian model employs a very simple prior, more sophisticated generative models provide a possible direction for further experimentation.

Human-competitive tagging using automatic keyphrase extraction

Abstract

This paper connects two research areas: automatic tagging on the web and statistical keyphrase extraction. First, we analyze the quality of tags in a collaboratively created folksonomy using traditional evaluation techniques. Next, we demonstrate how documents can be tagged automatically with a state-of-the-art keyphrase extraction algorithm, and further improve performance in this new domain using a new algorithm, "Maui", that utilizes semantic information extracted from Wikipedia. Maui outperforms existing approaches and extracts tags that are competitive with those assigned by the best performing human taggers.

1 Introduction

Tagging is the process of labeling web resources based on their content. Each label, or *tag*, corresponds to a topic in a given document. Unlike metadata assigned by authors, or by professional indexers in libraries, tags are assigned by end-users for organizing and sharing information that is of interest to them. The organic system of tags assigned by all users of a given web platform is called a *folksonomy*.

In contrast to traditional taxonomies painstakingly constructed by experts, a user can add any tags to a folksonomy. This leads to the greatest downside of tagging, inconsistency, which originates in the synonymy and polysemy of human language, as well as in the varying degrees of specificity used by taggers (Golder and Huberman, 2006). In traditional libraries, *consistency* is the primary evaluation criterion of indexing (Rolling, 1981). Much work has been done on describing the statistical properties of folksonomies, such as tag distribution and co-occurrences (Halpin *et al.*, 2007; Sigurbjörnsson *et al.*, 2008; Sood *et al.*, 2007), but to our knowledge there has been none on assessing the actual quality of tags. How well do human taggers perform? How consistent are they with each other?

One potential solution to inconsistency in folksonomies is to use suggestion tools that automatically compute tags for new documents (e.g. Mishne, 2006; Sood *et al.*, 2007; Heymann *et al.*, 2008). Interestingly, the blooming research on automatic tagging has so far not been connected to work on keyphrase extraction (e.g. Frank *et al.*, 1999; Turney, 2003; Hulth, 2004), which can be used as a tool for the same task (note: we use *tag* and *keyphrase* as synonyms). Instead of simple heuristics based on term frequencies and co-occurrence of tags, keyphrase extraction methods apply machine learning to determine typical distributions of properties common to manually assigned phrases, and can include analysis of semantic relations between candidate tags (Turney, 2003). How well do state-of-the-art keyphrase extraction systems perform compared to simple tagging techniques? How consistent are they with human taggers? These are questions we address in this paper.

Until now, keyphrase extraction methods have primarily been evaluated using a single set of keyphrases for each document, thereby largely ignoring the subjective nature of the task. Collaboratively tagged documents, on the other hand, offer multiple tag assignments by independent users, a unique basis for evaluation that we capitalize upon in this paper.

The experiments reported in this paper fill these gaps in the research on automatic tagging and keyphrase extraction. First, we analyze tagging consistency on the *CiteULike.org* platform for organizing academic citations. Methods traditionally used for the evaluation of professional indexing will provide insight into the quality of this folksonomy. Next, we extract a high quality corpus from CiteULike, containing documents that have been tagged consistently by the best human taggers.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1318–1327,
Singapore, 6-7 August 2009.

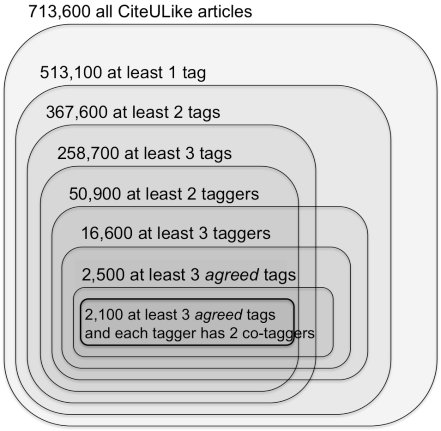

Figure 1. Quality control of CiteULike data

Following that, our goal is to build a system that matches the performance of these taggers. We first apply an existing approach proposed by Brooks and Montanez (2006) and compare it to the keyphrase extraction algorithm Kea (Frank *et al.*, 1999). Next we create a new algorithm, called Maui, that enhances Kea's successful machine learning framework with semantic knowledge retrieved from Wikipedia, new features, and a new classification model. We evaluate Maui using tag sets assigned to the same documents by several users and show that it is as consistent with CiteULike users as they are with each other.

Most of the computation required for automatic tagging with this method can be performed offline. In practice, it can be used as a tag suggestion tool that provides users with tags describing the main topics of newly added documents, which can then be corrected or enhanced by personal tags if required. This will improve consistency in the folksonomy without compromising its flexibility.

2 Collaboratively-tagged Data

CiteULike.org is a bookmarking service that resembles the popular *del.icio.us*, but concentrates on scholarly papers. Rather than replicating the full text of tagged papers it simply points to them on the web (e.g. PubMed, CiteSeer, ScienceDirect, Amazon) or in journals (e.g. HighWire, Nature). This avoids violating copyright but means that the full text of articles is not necessarily available. When entering new resources, users are encouraged to assign tags describing their content or reflecting their own grouping of the information. However, the system does not suggest tags. Moreover, users do not see other users' tags and are thus not biased in their tag choices.

2.1 Extracting a high quality tagged corpus

The CiteULike data set is freely available and contains information about which documents were tagged with what tags by which users (although identities are not provided).

CiteULike's 22,300 users have tagged 713,600 documents with 2.4M "tag assignments"— single applications of a tag by a user to a document. The two most popular tags, *bibtex-import* and *no-tag*, indicate an information source and a missing tag respectively. Most of the remainder describe particular concepts relevant to the documents. We exclude non-content tags from our experiments, e.g. personal tags like *to-read* or *todo*. Note that spam entries have been eliminated from the data set.

Because CiteULike taggers are not professional indexers, high quality of the assigned topics cannot be guaranteed. In fact, manual assessment of users' tags by human evaluators shows precision of 59% (Mishne, 2006) and 49% (Sood *et al.*, 2006). However, why is the opinion of human evaluators valued more than the opinion of taggers? We propose an alternative way of determining ground truth using an automatic approach to determine reliable tags: We concentrate on a subset of CiteULike containing documents that have been indexed with at least three tags on which at least two users have agreed.

In order to be able to measure the tagging consistency between the users, and then compare it to the algorithm's consistency, we need taggers who have tagged documents that some others had tagged. We say that two users are "co-taggers" if they have both tagged at least one common document. As well as restricting the document set, we only include taggers who have at least two co-taggers.

Figure 1 shows the proportions of CiteULike documents that are discarded in order to produce our high quality data set. The final set contains only 2,100 documents (0.3% of the original). Unfortunately, many of these are unavailable for download—for example, books at Amazon.com and ArXiv.org references cannot be crawled. We further restrict attention to two sources: HighWire and Nature, both of which provide easily-accessible PDFs of the full text.

The result is a set of 180 documents indexed by 332 taggers. A total of 4,638 tags were assigned by all taggers to documents in this set; however, the number of tags on which at least two users agreed is significantly smaller, namely 946. Still, this results in accurate tag sets that contain an average of five tags per document.

Table 1. Consistency of the most prolific and most consistent taggers

Note that traditionally much smaller data sets are used to assess consistency of human indexers, because such sets need to be created specifically for the experiment. Collaborative tagging platforms like CiteULike can be mined for large collections of this kind in natural settings.

Most documents in the extracted set relate to the area of bioinformatics. To give an example, a document entitled *Initial sequencing and comparative analysis of the mouse genome* was tagged by eight users with a total of 22 tags. Four of them agreed on the tag *mouse*, but one used the broader term *rodents*. Three agreed on the tag *genome*, but one added *genome paper*, and another used the more specific *comparative genomics*. There are also cases when tags are written together, e.g. *genomepaper*, or with a prefix *key genome*, or in a different grammatical form: *sequence* vs. *sequencing*. This example shows that many inconsistencies in tags are not caused by personalized tag choices as Chirita *et al.* (2007) suggest, but rather stem from the lack of guidelines and uniform tag suggestions that a bookmarking service could provide.

2.2 Measuring tagging consistency

Traditional indexers aim for consistency, on the basis that this will enhance document retrieval (Leonard, 1975). Consistency is measured using experiments in which several people index the same documents—usually a small set of a few dozen documents. It is computed for pairs of indexers, by formulae such as Rolling's (1981):

$$Consistency(I_1, I_2) = \frac{2C}{A + B},$$

where C is the number of tags (index terms) indexers I_1 and I_2 have in common and A and B is the size of their tag sets respectively.

In our experiments, before computing the number of terms in common, we stem each tag with the Porter (1980) stemmer. For example, the overlap C between the tag sets {*complex systems, network, small world*} and {*theoretical, small world, networks, dynamics*} consist of the two tags {*network, small world*}, and the consistency is 2×2/(3+4) = 0.57.

To compute the overall consistency of a particular indexer, this figure is averaged over all documents and co-indexers. There were no cases where the same user reassigned tags to the same articles, so computing intra-tagger consistency, although interesting, was not impossible.

To our knowledge, traditional indexing consistency metrics have not yet been applied to collaboratively tagged data. However, experiments on determining tagging quality do follow the same idea. For example, Xu *et al.* (2006) define an authority metric that assigns high scores to those users who match other users' choices on the same documents, in order to eliminate spammers.

2.3 Consistency of CiteULike taggers

In the collection of 180 documents tagged by 332 users described in Section 3.1, each tagger has 18 co-taggers on average, ranging from 2 to 129, and has indexed 1 to 25 documents. For each user we compute the consistency with all other users who tagged the same document. Consistency is then averaged across documents. We found that the distribution of per-user consistency resembles a power law with a few users achieving high consistency values and a long tail of inconsistent taggers. The maximum consis-

tency in this group is 92.3% and the average is 18.5%. The average consistency of the most prolific 70 indexers—those who have indexed at least five documents—is in the same range, namely 18.4%. The consistency of traditional approaches to free indexing is reported to be between 4% and 67%, with an average of 27% depending on what aids are used (Leininger, 2000).

It is instructive to consider the group of best taggers. We define these as the ones who (a) exhibit greater than average consistency with all others, and (b) are sufficiently prolific, i.e. have tagged at least five documents. There are 36 such taggers; Table 1 lists their consistency within this group. The average consistency they achieve as a group is 37.7%, which is the similar to the average consistency of professionals (Leininger, 2000).

The above consistency analysis provides insight into the tagging quality of the best CiteULike users, based on HighWire and Nature articles. For the purposes of this paper, it shows how the tagging community can be restricted to a best-performing group of taggers by measuring their consistency. This is helpful for testing the performance of automatic tagging (Section 4.4).

3 Automatic tagging with Maui

Maui is a general algorithm for automatic topical indexing based on the Kea system (Frank *et al.*, 1999).[1] It works in two stages: candidate selection and machine learning based filtering. In this paper, we apply it to automatic tagging. In the candidate selection stage, Maui first determines textual sequences defined by orthographic boundaries and splits these sequences into tokens. Then all n-grams up to a maximum length of 3 words that do not begin or end with a stopword are extracted as candidate tags. To reduce the number of candidates, all those that appear only once are discarded. This speeds up the training and the extraction process without impacting the results. In the filtering stage several features are computed for each candidate, which are then input to a machine learning model to obtain the probability that the candidate is indeed a tag.

Maui's architecture resembles that of many other supervised keyphrase extraction systems (Turney, 2000; Hulth 2004; Medelyan *et al.*, 2008). However, this architecture has not previously been applied to the task of automatic tagging.

3.1 Features indicating significance

We now describe the features used in the classification model to determine whether a phrase is likely to be a tag. We begin with three baseline features used in Kea (Frank *et al.*, 1999), and extend the set with three features that have been found useful in previous work. We also add three new features that have not been evaluated before: *spread*, *semantic relatedness* and inverse *Wikipedia linkage*. All Wikipedia-based features are computed using the WikipediaMiner toolkit.[2]

1. TF×IDF combines the frequency of a phrase in a particular document with its inverse occurrence frequency in general use (Salton and McGill, 1983). This score is high for rare phrases that appear frequently in a document and therefore are more likely to be significant.

2. Position of the first occurrence is computed as the relative distance of the first occurrence of the candidate tag from the beginning of the document. Candidates with very high or very low values are likely to be tags, because they appear either in the opening document parts such as title, abstract, table of contents, and introduction, or in the document's final sections such as conclusion and reference lists.

3. Keyphraseness quantifies how often a candidate phrase appears as a tag in the training corpus. Automatic tagging approaches utilize the same information: Mishne (2006) and Sood *et al.* (2006) automatically suggest tags previously assigned to similar documents. However, in Maui (as in Kea) this feature is just one component of the overall model. Thus if a candidate never appears as a keyphrase in the training corpus, it can still be extracted if its other feature values are significant enough.

4. Phrase length is measured in words. Generally speaking, the longer the phrase, the more specific it is. Training captures and quantifies the specificity preference in a given training corpus.

5. Node degree quantifies the semantic relatedness of a candidate tag to other candidates. Turney (2003) computes semantic relatedness using search engine statistics. Instead, following Medelyan *et al.* (2008), we utilize Wikipedia hyperlinks for this task. We first map each candidate phrase to its most common Wikipedia page. For example, the word *Jaguar* appears as a link anchor in Wikipedia 927 times. In 466 cases it links to the article *Jaguar cars*, thus the commonness of this mapping is 0.5. In 203 cases it links to the animal description, a commonness of

[1] Maui is open-source and available for download at *http://maui-indexer.googlecode.com*

[2] http://wikipedia-miner.sourceforge.net/

0.22. We compute the node degree of the corresponding Wikipedia article as the number of hyperlinks that connect it to other Wikipedia pages that have been identified for other candidate tags from the same document. A document that describes a particular topic will cover many related concepts, so high node degree—which indicates strong connectivity to other phrases in the same document—means that a candidate is more likely to be significant.

6. Wikipedia-based keyphraseness is the likelihood of a phrase being a link in the Wikipedia corpus. It divides the number of Wikipedia pages in which the phrase appears in the anchor text of a link by the total number of Wikipedia pages containing it. We multiply this number by the phrase's document frequency.

The new features proposed in this paper are the following:

7. Spread of a phrase is the distance between its first and last occurrences in a document. Both values are computed relative to the length of the document (see feature 2). High values help to determine phrases that are mentioned both in the beginning and at the end of a document.

8. Semantic relatedness of a phrase has already been captured as the node degree (see feature 5). However, recent research allows us to compute semantic relatedness with better techniques than mere hyperlink counts. Milne and Witten (2008) propose an efficient Wikipedia based approach that is nearly as accurate as human subjects at quantifying the relationship between two given concepts. Given a set of candidate phrases we determine the most likely Wikipedia articles that describe them (as explained in feature 5), and then determine the total relatedness of a given phrase to all other candidates. The higher the value, the more likely is the phrase to be a tag.

9. Inverse Wikipedia linkage is another feature that utilizes Wikipedia as a source of language usage statistics. Here, again given the most likely Wikipedia article for a given phrase, we count the number of other Wikipedia articles that link to it and normalize this value as in inverse document frequency:

$$IWL = -\log_2 \frac{linksTo(A_P)}{N}$$

where $linksTo(A_P)$ is the number of incoming links to the article A representing the candidate phrase P, and N is the total number of links in our Wikipedia snapshot (52M). This feature highlights those phrases that refer to concepts commonly used to describe other concepts.

3.2 Machine learning in Maui

In order to build the model, we use the subset of the CiteULike collection described in Section 3.1. For each document we know a set of tags that at least two users have agreed on. This is used as ground truth for building the model. For each training document, candidate phrases (i.e. n-grams) are identified and their feature values are calculated as described above.

Each candidate is then marked as a positive or negative example, depending on whether users have assigned it as a tag to the corresponding document. The machine-learning model is constructed automatically from these labeled training examples using the WEKA machine learning workbench. Kea (Frank *et al.*, 1999) uses the Naïve Bayes classifier, which implicitly assumes that the features are independent of each other given the classification. However, Kea uses only two or three features, whereas Maui combines nine features amongst which there are many obvious relationships, e.g. first occurrence and spread, or node degree and semantic relatedness. Consequently, we also consider bagged decision trees, which can model attribute interactions and do not require parameter tuning to yield good results. Bagging learns an ensemble of classifiers and uses them in combination, thereby often achieving significantly better results than the individual classifiers (Breiman, 1996). Different trees are generated by sampling from the original dataset with replacement. Like Naïve Bayes, bagged trees yield probability estimates that can be used to rank candidates.

To select tags from a new document, Maui determines candidate phrases and their feature values, and then applies the classifier built during training. This classifier determines the probability that a candidate is a tag based on relative frequencies observed from the training data.

4 Evaluation

Here we describe the data used in the experiments and the results obtained, addressing the following questions:

1. How does a state-of-the-art keyphrase extraction method perform on collaboratively tagged data, compared to a baseline automatic tagging method?
2. What is the performance of Maui with old and new features?
3. How consistent are Maui's tags compared to those assigned by human taggers?

		P	R	F
1	Top words based on TF×IDF	16.8	17.3	17.0
2	Top phrases based on TF×IDF	14.4	16.0	15.2
3	Kea (TF×IDF, 1st occur)	20.4	22.3	21.3
4	Kea (+keyphraseness)	**41.1**	**43.1**	**42.1**

Table 2. Baseline auto-tagging approach vs. Kea

4.1 Evaluation method

The evaluation was performed using a set of 180 documents, described in Section 3.1, each tagged with at least three tags on which two users have agreed. In the following, unless explicitly stated otherwise, these are the only tags we use. We consider them to be ground truth. There are on average five such tags per document, and our goal is to extract tag sets that contain them all.

We regard a predicted tag as "correct" if it matches one of the ground truth tags after using the Porter stemmer. We measure performance by computing Precision (the percentage of correct extracted tags out of all extracted), Recall (the percentage of correct extracted tags out of all correct) and F-Measure (the harmonic mean of the two). Given the set {*yeast* (4), *network* (3), *regulation* (2), *metabolic* (2)} of ground truth tags, where the numbers in parenthesis show how many users have assigned each one, and the set {*network*, *metabolic*, *regulatory*, *ChIP-chip*, *transcription*} of predicted tags, three out of five predicted terms are correct, yielding a precision of 60%, and three out of four ground-truth terms are extracted, a recall of 75%. The F-measure combining the two values is 67%.

The reported precision and recall values are averaged over all test documents. We use 10-fold cross-validation for evaluation, which allows us to use all 180 documents as test documents without introducing optimistic bias in the performance measures obtained.

The results obtained in Sections 4.2 and 4.3 using this evaluation provide answers to the first two questions above. To answer the third we compare the indexing consistency of Maui to that of CiteULike users in Section 4.4. Here, we consider the assigned tag sets individually and compute the consistency of Maui with each tagger as described in Section 3.2. We compare Maui both to all 332 users who tagged these documents, and to the 36 best taggers identified in Section 3.3.

4.2 Keyphrase extraction vs. auto-tagging

As noted earlier, Brooks and Montanez (2006) automatically determine tags by extracting terms with the highest TF×IDF values for each post and argue that their quality is perhaps better than

		P	R	F
1	TFxIDF	14.4	16	15.2
2	1st occurrence	5.4	5.4	5.4
3	Keyphraseness	25.2	26.3	25.5
4	Length	2.1	2.1	2.1
5	Node degree	8.3	9.0	8.6
6	Wikipedia keyphraseness	16.9	18.3	17.6
7	Spread	12.1	13.0	12.5
8	Semantic relatedness	7.1	7.3	7.2
9	Inverse Wikipedia linkage	7.3	6.8	7.0

Table 3. Evaluation of individual features

that of manual tags. Note that they only use one-word tags. We evaluate this approach using our 180 test documents and cross-validation, and compare the top five extracted tags with those assigned manually. Comparing the first two rows of Table 2 shows that using multi-word phrases as candidate tags (Section 4) is less accurate than using single words, which gives an overall F-Measure of 17%. Multi-words have higher TF×IDF values, but single words are the majority among the users' tags. The length feature applied in the next section helps to capture this characteristic, without compromising Maui's ability to assign correct multi-words tags.

Adding a second feature, the position of the first occurrence, and using Kea's Naïve Bayes model to learn their conditional distribution, improves the results by 5 percentage points (row 3). Adding the keyphraseness feature (row 4) nearly doubles the F-Measure, from 21.3 to 42.1%. This shows that CiteULike users tend to re-assign existing tags.

4.3 Maui with additional features

To evaluate Maui let us first consider the individual performance of old and new features, as shown in Table 3. Rows 1 to 3 evaluate the standard features used by Frank *et al.* (1999); Rows 4 to 6 evaluate features that were previously used in Kea for controlled indexing (Medelyan *et al.*, 2006) and which we have adapted in Maui for free indexing. Rows 7 to 9 evaluate the three new features of Maui. The values can be compared to keyphrase extraction by chance (F-Measure = 1%) and to the multi-word TF×IDF baseline in Table 2, row 2 (F-Measure = 15.2%). The strength of these features varies from 2.1 to 25.5% (F-Measure). The strongest ones are keyphraseness, Wikipedia keyphraseness, TF×IDF and spread.

Table 4 demonstrates Maui's performance when the features are combined and shows how the two different classifiers, Naïve Bayes (left) and bagged decision trees (right), compare to

		Naïve Bayes			Bagged decision trees		
		P	R	F	P	R	F
1	Features 1 – 3	**41.1**	**43.1**	**42.1**	40.3	42.2	41.2
2	Features 1 – 6	38.9	41.1	40.0	40.3	42.6	41.4
3	Features 1 – 3, 7 – 9	39.3	41.1	40.2	43.7	46.2	44.9
4	Features 1 – 9	37.6	39.6	38.6	**45.7**	**48.6**	**47.1**

Table 4. Combining all features in Maui

each other. The baseline in row 1 (left) shows Kea's performance, using TF×IDF, first occurrence, keyphraseness and Naïve Bayes to combine them (same as row 4 in Table 2). Using decision trees with these three features does not improve the performance (row 1, right). The following row combines the three original features with length, node degree and Wikipedia-based keyphraseness. In contrast to previous research (Medelyan *et al.*, 2008), in this setting we do not observe an improvement with either Naïve Bayes or bagged decision trees. In row 3 we combine the three original features with the three new ones introduced in this work. While Naïve Bayes' values are lower than the baseline, with bagged decision trees Maui's F-Measure improves from 41.2 to 44.9%. The best results are obtained by combining all nine features, again using bagged decision trees, giving in row 4 (right) a notably improved F-Measure of 47.1%. The recall of 48.6% shows that we match nearly half of all tags on which at least two human taggers have agreed.

Given this best combination of features, we eliminate each feature one by one starting from the individually weakest feature, in order to determine the contribution of each feature to this overall result. Table 5 compares the values and only bagged decision trees are used this time. The 'Difference' column quantifies the difference between the best F-Measure achieved with all 9 features and excluding the one that is examined in that row. Interestingly, one of the strongest features, TF×IDF, is the one that contributes the least when all features are combined, while the contribution of the strongest feature—keyphraseness—is, as expected, the highest, adding 16.9 points. The second most important feature is Wikipedia keyphraseness, contributing 4 percentage points to the overall result.

Features	F-Measure	Difference
All 9 Features	47.1	
– Length	45	2.1
– 1st occurrence	45.6	1.5
– Inverse Wikip linkage	45.1	2
– Semantic relatedness	45.4	1.7
– Node degree	46	1.1
– Spread	46.4	0.7
– TFxIDF	46.8	0.3
– Wikip keyphraseness	43.1	4
– Keyphraseness	30.2	16.9
Non-Wikip features	41.7	5.4

Table 5. Evaluation using feature elimination

Since some of the features in the best performing combination rely on Wikipedia as a knowledge source, it is interesting to determine Wikipedia's exact contribution. The last row of Table 5 combines the following features: TF×IDF, first occurrence, keyphraseness, length and spread. The F-Measure is 5.4 points lower than that of Maui with all 9 features combined. Therefore, the contribution of Wikipedia-based features is significant.

4.4 Maui's consistency with human taggers

In Section 2.3 we discussed the indexing consistency of CiteULike users on our data. There are a total of 332 taggers and their consistency with each other is 18.5%. Now, we use results obtained with Maui during the cross-validation, when all 9 features and bagged decision trees are used (Table 4, row 4, right; see examples in Table 5), and compute how consistent Maui is with each human user, based on whatever document this user has tagged. Then we average the results to obtain the overall consistency with all 332 users.

Maui's consistency with the 332 human taggers ranges from 0 to 80%, with an average of 23.8%. The only cases where very low consistency was achieved are those where the human has only assigned a few tags per document (one to three), or has some idiosyncratic tagging behavior (for example, one tagger adds the word *key* in front of most tags). Still, with an average of 23.8%, Maui's performance is over 5 points higher than that of an average CiteULike tagger (18.5%)—and note this group only includes taggers who have at least two co-taggers.

In Section 2.3 we were also able to determine a smaller group of users who perform best and are most prolific. This group consists of 36 taggers whose consistency exceeds the average of the original 332 users. These 36 taggers have tagged a total of 143 documents with an average consistency of 37.6%. Maui's consistency with

Table 6. Tags assigned by CiteULike taggers and Maui to four sample documents

these taggers ranges from 11.5% to 56%, with an average of 35%. This places it only 2.6 percentage points behind the average performance of the best CiteULike taggers. In fact, it outperforms 17 of them (cf. Table 1).

4.5 Examples

Table 6 compares Maui with some of CiteULike's best human taggers on four randomly chosen test documents. Boldface in the taggers' row indicates a tag that has been chosen by at least two other human taggers; the remaining tags have been chosen by just one human. Boldface in Maui's row shows tags that match human tags. For each document Maui extracts several tags assigned by at least two humans. The other tags it chooses are generally chosen by at least one human tagger, and even if not, they are still related to the main theme of the document.

5 Discussion and related work

It is possible to indirectly compare the results of several previously published automatic tagging approaches with Maui's. For each paper, we compute Maui's results in settings closest to the reported ones.

Brooks and Montanez (2006) extract terms with the highest TF×IDF values as tags for posts on *technorati.com*. They do not report precision and recall values for their system, but our reimplementation resulted in precision of 16.8% and recall of 17.3% for the top five assigned tags, compared to those agreed to by at least two CiteULike users on 180 documents. Adding eight additional features and combining them using machine learning gives a clear improvement—Maui achieves 45.7% and 48.7% precision and recall respectively.

Mishne (2006) uses TF×IDF-weighted terms as full-text queries to retrieve posts similar to the one being analyzed. Tags assigned to these posts are analyzed to retrieve the best ones using clustering and heuristic ranking; tags assigned by the given user receive extra weight. Mishne performs manual evaluation on 30 short articles and reports precision and recall for the top ten tags of 38% and 47% respectively. We matched Maui's top ten terms to all tags assigned to 180 documents automatically and obtained precision and recall of 44% and 29% respectively. (We believe that manual rather than automatic evaluation would be likely to give a far more favorable assessment of our system.)

Chirita *et al.* (2007) aim to extract personalized tags. Given a web page, they first retrieve

similar documents stored on the user's desktop and then determine keywords for these documents. They evaluate different term scoring techniques, such as term and document frequency, lexical dispersion, sentence scoring, and term co-occurrence. Like the Kea algorithm, the best formula combines term frequency with the position of the first occurrence of the term, normalized by page length. It yields a precision of 80% for the top four tags assigned to 30 large websites (32Kbytes), again evaluated manually. Our documents are considerably longer (47Kbytes) and thus more difficult to work with, nevertheless Maui achieves only slightly lower values, from 66% to 80%, when evaluating automatically against user-assigned tags. (The above caveat regarding automatic and manual assessment applies here too.)

Budura *et al.* (2008) develop a scoring formula that combines three features (tag frequency, tag co-occurrence and document similarity) and manually evaluate it on ten CiteULike documents. Their precision for the top three to five tags ranges from 66% to 77%, slightly worse than in our paper (66% to 80%).

The only reported automatic evaluation of tags was found in Sood *et al.* (2006), where TagAssist was tested on 1000 blog posts. This algorithm is similar to Mishne's (2006), but uses centroid-based clustering. Exact matching of TagAssist's tags against existing ones yielded precision and recall of 13.1% and 22.8% respectively. This is substantially lower than Maui's 45.75% and 48.7% obtained with best settings (Section 4.3).

Note that this indirect comparison does not reveal the true ranking of approaches, because their task definitions and test sets are slightly different. It would be interesting to compare other systems on the multiple tagger set described in this paper, as we believe this would more objectively reflect the performance of humans and algorithms.

6 Conclusions

This paper has introduced a systematic way of evaluating automatic tagging techniques without the need for manual inspection. We have shown how documents with multiple tag sets can be used in conjunction with a standard consistency measure to identify a robust test corpus for these techniques. Based on the evaluation methodology developed, we have shown that machine-learning-based automatic keyphrase extraction produces tag sets that exhibit consistency on a par with that achieved by the best human taggers. Our results also show a substantial improvement on an existing automatic tagging approach based on TF×IDF, and the results compare well to other systems.

The success of automatic keyphrase extraction depends primarily on the quality of the features that are provided to the machine learning algorithm involved. In this paper we have evaluated nine different features, including two novel Wikipedia-based semantic features, and found that their combination used in conjunction with bagged decision trees produces the best performance.

Abstract

The work presented in this paper explores a supervised method for learning a probabilistic model of a lexicon of VerbNet classes. We intend for the probabilistic model to provide a probability distribution of verb-class associations, over known and unknown verbs, including polysemous words. In our approach, training instances are obtained from an existing lexicon and/or from an annotated corpus, while the features, which represent syntactic frames, semantic similarity, and selectional preferences, are extracted from unannotated corpora. Our model is evaluated in type-level verb classification tasks: we measure the prediction accuracy of VerbNet classes for unknown verbs, and also measure the dissimilarity between the learned and observed probability distributions. We empirically compare several settings for model learning, while we vary the use of features, source corpora for feature extraction, and disambiguated corpora. In the task of verb classification into all VerbNet classes, our best model achieved a 10.69% error reduction in the classification accuracy, over the previously proposed model.

1 Introduction

Lexicons are invaluable resources for semantic processing. In many cases, lexicons are necessary to restrict a set of semantic classes to be assigned to a word. In fact, a considerable number of works on semantic processing implicitly or explicitly presupposes the availability of a lexicon, such as in word sense disambiguation (WSD) (McCarthy et al., 2004), and in token-level verb class disambiguation (Lapata and Brew, 2004; Girju et al., 2005; Li and Brew, 2007; Abend et al., 2008). In other words, those methods are heavily dependent on the availability of a semantic lexicon. Therefore, recent research efforts have invested in developing semantic resources, such as WordNet (Fellbaum, 1998), FrameNet (Baker et al., 1998), and VerbNet (Kipper et al., 2000; Kipper-Schuler, 2005), which greatly advanced research in semantic processing. However, the construction of such resources is expensive, and it is unrealistic to presuppose the availability of full-coverage lexicons; this is the case because unknown words always appear in real texts, and word-semantics associations may vary (Abend et al., 2008).

This paper explores a method for the supervised learning of a probabilistic model for the VerbNet lexicon. We target the automatic classification of arbitrary verbs, including polysemous verbs, into all VerbNet classes; further, we target the estimation of a probabilistic model, which represents the saliences of verb-class associations for polysemous verbs. In our approach, an existing lexicon and/or an annotated corpus are used as the training data. Since VerbNet classes are designed to represent the distinctions in the syntactic frames that verbs can take, features, representing the statistics of syntactic frames, are extracted from the unannotated corpora. Additionally, as the classes represent semantic commonalities, semantically inspired features, like distributionally similar words, are used. These features can be considered as a generalized representation of verbs, and we expect that the obtained probabilistic model predicts VerbNet classes of the unknown words.

Our model is evaluated in two tasks of type-level verb classification: one is the classification of monosemous verbs into a small subset of the classes, which was studied in some previous works (Joanis and Stevenson, 2003; Joanis et al., 2008). The other task is the classification of all verbs into the full set of VerbNet classes, which has not yet

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1328–1337,
Singapore, 6-7 August 2009.

been attempted. In the experiments, training instances are obtained from VerbNet and/or SemLink (Loper et al., 2007), while features are extracted from the British National Corpus or from Wall Street Journal. We empirically compare several settings for model learning by varying the set of features, the source domain and the size of a corpus for feature extraction, and the use of the token-level statistics obtained from a manually disambiguated corpus. We also provide the analysis of the remaining errors, which will lead us to further improve the supervised learning of a probabilistic semantic lexicon.

Supervised methods for automatic verb classification have been extensively investigated (Stevenson et al., 1999; Stevenson and Merlo, 1999; Merlo and Stevenson, 2001; Stevenson and Joanis, 2003; Joanis and Stevenson, 2003; Joanis et al., 2008). However, their focus has been limited to a small subset of verb classes, and a limited number of monosemous verbs. The main contributions of the present work are: i) to provide empirical results for the automatic classification of all verbs, including polysemous ones, into all VerbNet classes, and ii) to empirically explore the effective settings for the supervised learning of a probabilistic lexicon of verb semantic classes.

2 Background

2.1 Verb lexicon

Levin's (1993) work on verb classification has broadened the field of computational research that concerns the relationships between the syntactic and semantic structures of verbs. The principal idea behind the work is that the meanings of verbs can be identified by observing possible syntactic frames that the verbs can take. In other words, with the knowledge of syntactic frames, verbs can be semantically classified. This idea provided the computational linguistics community with criteria for the definition and the classification of verb semantics; it has subsequently resulted in the research of the induction of verb classes (Korhonen and Briscoe, 2004), and the construction of a verb lexicon based on Levin's criteria.

VerbNet (Kipper et al., 2000; Kipper-Schuler, 2005) is a lexicon of verbs organized into classes that share the same syntactic behaviors and semantics. The design of classes originates from Levin (1993), though the design has been considerably reorganized and extends beyond the original classification. The classes therefore cover more English verbs, and the classification should be more consistent (Korhonen and Briscoe, 2004; Kipper et al., 2006).

Figure 2: Syntactic frames for VerbNet classes

The current version of VerbNet includes 270 classes.[1] Figure 1 shows a part of the classes of VerbNet. The top-level categories, e.g. **Emission** and ***Destroy***, represent a coarse classification of verb semantics. They are further classified into verb classes, each of which expresses a group of verbs sharing syntactic frames. Figure 2 shows an excerpt from VerbNet, which represents the possible syntactic frames for the **Sound Emission** class, including "*chime*" and "*jangle*," and the **Modes of Being with Motion** class, including "*jiggle*" and "*waft*." In this figure, each line represents a syntactic frame, where `Agent`,

[1] Throughout this paper, we refer to VerbNet 2.3. Subclasses are ignored in this work, following the setting of Abend et al. (2008).

...the walls still shook;VN=47.3 and an evacuation alarm blared;VN=43.2 outside.

Suddenly the woman begins;VN=55.1 swaying ;VN=47.3 and then ...

Figure 3: An excerpt from SemLink

Theme, and Location indicate the thematic roles, V denotes a verb, and P specifies a preposition. P:loc defines locative prepositions such as: "*in*" and "*at*." For example, the second syntactic frame of **Sound Emission**, i.e., Theme V P:loc Location, corresponds to the following sentence:

1. The coins *jangled* in my pocket.

Theme corresponds to "*the coins*," V to "*jangled*," P:loc to "*in*," and Location to "*my pocket*."

While VerbNet provides associations between verbs and semantic classes, SemLink (Loper et al., 2007) additionally provides mappings among VerbNet, FrameNet (Baker et al., 1998), PropBank (Palmer et al., 2005), and WordNet (Fellbaum, 1998). Since FrameNet and PropBank include annotated instances of sentences, SemLink can be considered as a corpus annotated with VerbNet classes. Figure 3 presents some annotated sentences obtained from SemLink. For example, the annotation "blared;VN=43.2" indicates that the occurrence of "blare" in this context is classified as **Sound Emission**.

2.2 Related work

There has been much research effort invested in the automatic classification of verbs into lexical semantic classes, in a supervised or unsupervised way. The present work inherits the spirit of the supervised approaches to verb classification (Stevenson et al., 1999; Stevenson and Merlo, 1999; Merlo and Stevenson, 2001; Stevenson and Joanis, 2003; Joanis and Stevenson, 2003; Joanis et al., 2008). Our learning framework basically follows the above listed works: features are obtained from an unannotated (automatically parsed) corpus, and gold verb-class associations are used as training instances for machine learning classifiers, such as decision trees and support vector machines. However, those works targeted a small subset of Levin classes, and a limited number of monosemous verbs; for example, Merlo and Stevenson (2001) studied three classes and 59 verbs, and Joanis et al. (2008) focused on 14 classes and 835 verbs. Although these works provided a theoretical framework for supervised verb classification, their results were not readily available for practical applications, because of the limitation in the coverage of the targeted classes/verbs on real texts. On the contrary, we target the classification of arbitrary verbs, including polysemous verbs, into all VerbNet classes (270 in total). In this realistic situation, we will empirically compare settings for model learning, in order to explore effective conditions to obtain better models.

Another difference from the aforementioned works is that we aim at obtaining a probabilistic model, which represents *saliences* of classes of polysemous verbs. Lapata and Brew (2004) and Li and Brew (2007) focused on this issue, and described methods for inducing probabilities of verb-class associations. The obtained probabilistic model was intended to be incorporated into a token-level disambiguation model. Their methods claimed to be unsupervised, meaning that the induction of a probabilistic lexicon did not require any hand-annotated corpora. In fact, however, their methods relied on the existence of a full-coverage lexicon, both in training and running time. In their methods, a lexicon was necessary for restricting possible classes to which each word belongs. Since most verbs are associated with only a couple of classes, such a restriction significantly reduces the search space, and the problem becomes much easier to solve. This presupposition is implicitly or explicitly used in other semantic disambiguation tasks (McCarthy et al., 2004), but it is unrealistic for practical applications.

Clustering methods have also been extensively researched for verb classification (Stevenson and Merlo, 1999; Schulte im Walde, 2000; McCarthy, 2001; Korhonen, 2002; Korhonen et al., 2003; Schulte im Walde, 2003). The extensive research is in large part due to the intuition that the set of classes could not be fixed beforehand. In particular, it is often problematic to define a static set of semantic classes. However, it is reasonable to assume that the set of VerbNet classes is fixed, because Levin-type classes are more static than ontological classes, like in WordNet synsets. Therefore, we can apply supervised classification methods to our task. It is true that the current VerbNet classes are imperfect and require revisions, but in this work we adopt them as they are, because as

time advances, more stable classifications will become available.

The problem focused in this work has a close relationship with automatic thesaurus/ontology expansion. In fact, we evaluate our method in the task of automatic verb classification, which can be considered as lexicon expansion. The most prominent difference of the present work from thesaurus/ontology expansion is that the number of classes is much smaller in our problem, and the set of verb classes can be assumed to be fixed. These characteristics indicate that our problem is easier and more well-defined than is the case for automatic thesaurus/ontology expansion.

Supervised approaches to token-level verb class disambiguation have recently been addressed (Girju et al., 2005; Abend et al., 2008), largely owing to SemLink. Their approaches fundamentally follow traditional supervised WSD methods: extracting features representing the context in which the target word appears, and training a classification model with an annotated corpus. While those works achieved an impressive accuracy (more than 95%), the results may not necessarily indicate the method's effectiveness; rather, it may imply the importance of a lexicon. In fact, these works restrict their target to verb tokens, in which the correct class exists in a given lexicon, and they only consider candidate classes that are registered in the lexicon. This setting reduces the ambiguity significantly, and the problem becomes much easier to handle; for example, approximately half of verb tokens are monosemous in their setting. Thus, a simple baseline achieves very high accuracy figures. However, in our preliminary experiment on token-level verb classification with unknown verbs, we found that the accuracy for unknown verbs (i.e., lemmas not included in the VerbNet lexicon) is catastrophically low. This indicates that VerbNet and SemLink are insufficient for unknown verbs, and that we cannot expect the availability of a full-coverage lexicon in the real world. Instead of a static lexicon, our probabilistic model is intended to be used as a prior distribution for the token-level disambiguation, as in Lapata and Brew (2004)'s model.

3 A probabilistic model for verb semantic classes

In this work, supervised learning is applied to the probabilistic modeling of a lexicon of verb semantic classes. We do not presuppose the existence of a full-coverage lexicon; instead, we use an existing lexicon for the training data. Combined with features extracted from unannotated corpora, a probabilistic model is learned from the existing lexicon. Like other supervised learning applications, our probabilistic lexicon can predict classes for words that are not included in the original lexicon.

Our model is defined in the following way. We assume that the set, C, of verb classes is fixed, while a set of verbs is unfixed. With this assumption, probabilistic modeling can be reduced to a classification problem. Specifically, the goal is to obtain a probability distribution, $p(c|v)$, of verb class $c \in C$ for a given verb (lemma) v. We can therefore apply well-known supervised learning methods to estimate $p(c|v)$.

This probability is modeled in the form of a log-linear model.

$$p(c|v) = \frac{1}{Z} \exp\left(\sum_i \lambda_i f_i(c, v)\right),$$

where $f_i(c, v)$ are features that represent characteristics of c and v, and λ_i are model parameters that express weights of the corresponding features.

Model parameters can be estimated when *training instances*, i.e., pairs $\langle c, v\rangle$, and *features*, $f_i(c, v)$, for each instance are given. Therefore, what we have to do is to prepare the training instances $\langle c, v\rangle$, and effective features $f_i(c, v)$ that contribute to the better estimation of probabilities. In token tagging tasks, both training instances and features are extracted from annotated corpora. However, since our goal is the probabilistic modeling of a lexicon, we have to determine how to derive the training instances and features for lexicon entries, to be discussed in the next section.

For the parameter estimation of log-linear models, we applied the stochastic gradient descent method. A hyperparameter for l_2-regularization was tuned to minimize the KL-divergence (see Section 4.4) for the development set.

4 Experiment design

In this work, we empirically compare several settings for the learning of the above probabilistic model, in the two tasks of automatic verb classification. In what follows, we explain the training/test data, corpora for extracting features, and the design of the features and evaluation tasks. The measures for evaluation are also introduced.

1	sound_emission-43.2	chime
0.5	sound_emission-43.2	blare
0.5	manner_speaking-37.3	blare
0.5	modes_of_being_with_motion-47.3	sway
0.5	urge-58.1	sway

1	sound_emission-43.2	chime
0.7	sound_emission-43.2	blare
0.3	manner_speaking-37.3	blare
0.6	modes_of_being_with_motion-47.3	sway
0.4	urge-58.1	sway

Figure 4: Training instances obtained from VerbNet (upper) and VerbNet+SemLink (lower)

4.1 Data

As our goal is the supervised learning of a lexicon of verb semantic classes, VerbNet is used as the training/test data. In addition, since we aim at representing the saliences of verb-class associations with probabilities, the gold probabilities are necessary. For this purpose, we count the occurrences of each verb-class association in the VerbNet-PropBank token mappings in the subset of the SemLink corresponding to sections 2 through 21 of Penn Treebank (Marcus et al., 1994). Frequency counts are normalized for each lemma, with the Laplace smoothing (the parameter is 0.5).

In this work, we compare the two settings for creating training instances. By comparing the results of these settings, we evaluate the necessity of an annotated corpus for learning a probabilistic lexicon of verb semantic classes.

VerbNet We collect all $\langle c, v \rangle$ pairs registered in VerbNet. For each v, all of the associated classes are assigned equal weights (see the upper part of Figure 4).

VerbNet+SemLink Each pair $\langle c, v \rangle$ in VerbNet is weighted by the normalized frequency obtained from SemLink (see the lower part of Figure 4).

Because VerbNet classes represent groups of syntactic frames, and it is impossible to guess the verb class by referring to only one occurrence in a text, it is necessary to have statistics over a sufficient amount of a corpus. Hence, features are extracted from a large unannotated corpus. In this paper, we use the following two corpora:

WSJ Wall Street Journal newspaper articles (around 40 million words).

BNC British National Corpus, which is a balanced corpus of around 100 million words.

In addition to the variance of the corpus domains, we vary the size of the corpus to observe the effect of increasing the corpus size. These corpora are automatically parsed by Enju 2.3.1 (Miyao and Tsujii, 2008), and the features are extracted from the parsing results.

4.2 Features

Levin-like classes, including VerbNet, are designed to represent distinctions in syntactic frames and alternations. Hence, if we were given the perfect knowledge of the possible syntactic frames, verbs can be classified into the correct classes almost perfectly (Dorr and Jones, 1996). Previous works thus proposed features that express the corpus statistics of syntactic frames. However, class boundaries are subtle in some cases; several classes share syntactic frames with each other to a large extent.

For example, the classes shown in Figure 2 have very similar syntactic frames. The difference is indicated in the last two frames of **Sound Emission**, although they appear much less frequently in real texts. Therefore, it is difficult to accurately capture the distinctions between these classes, if we are only provided with the statistics of the syntactic frames that appear in real texts. In this case, however, it is easy to observe that the verbs of these classes have different selectional preferences; that is, the `Theme` of **Sound Emission** verbs would be objects that make sounds, while the `Theme` of **Modes of Being with Motion** is likely to be objects that move.[2] Although Levin's classification initially focused on syntactic alternations, the resulting classes represent some semantic commonalities. Hence, it would be reasonable to design features that capture such semantic characteristics.

In this work, we re-implemented the following features proposed by Joanis et al. (2008) as the starting point.

Syntactic slot Features to count the occurrences of each syntactic slot, such as subject, object, and prepositional phrases. For the subject slot, we also count its transitive and intransitive usages separately. Additionally, we count the appearances of reflexive pronouns and semantically empty constituents (*it* and

[2] Syntactic frames in VerbNet include specifications of selectional preferences, such as *animate* and *place*, although we do not explicitly use them, because it is not apparent to determine the members of these semantic classes.

Syntactic slot	`subj:0.885` `intrans-subj:0.578`
Slot overlap	`overlap-subj-obj:0.299` `overlap-obj-in:0.074`
Tense, voice, aspect	`pos-VBG:0.307` `pos-VBD:0.290`
Animacy	`anim-subj:0.244` `anim-obj:0.057`
Slot POS	`subj-PRP:0.270` `subj-NN:0.270`
Syntactic frame	`NP_V:0.326` `NP_V_NP:0.307`
Similar word	`sim-rock:0.090` `sim-swing:0.083`
Slot class	`subj-C82:0.219` `obj-C12:0.081`

Figure 5: Example of features for "sway"

there). Differently from Joanis et al. (2008), we consider non-nominal arguments, such as sentential and adjectival complements.

Slot overlap Features to measure the overlap in words (lemmas) between two syntactic slots of the verb. They are intended to approximate argument alternations, such as the ergative alternation. For example, for the alternation "*The sky cleared*"/"*The clouds cleared from the sky*," a feature to indicate the overlap between the subject slot and the *from* slot is added (Joanis et al., 2008). The value of this feature is computed by the method of Merlo and Stevenson (2001).

Tense, voice, aspect Features to approximate the tendency of the tense, voice, and aspect of the target verb. The Penn Treebank POS tags for verbs (VB, VBP, VBZ, VBG, VBD, and VBN) are counted. In addition, included are the frequency of the co-occurrences with an adverb or an auxiliary verb, and the count of usages as a noun or an adjective.

Animacy Features to measure the frequency of animate arguments for each syntactic slot. Personal pronouns except *it* are counted as animate, following Joanis et al. (2008), while named entity recognition was not used.

Examples of these features are shown in Figure 5. For details, refer to Joanis et al. (2008).

The above features mainly represent syntactic behaviors of target verbs. Since our target classes are broader than in the previous works, we further enhance the syntactic features. Additionally, as discussed above, semantically motivated features may present strong clues to distinguish among syntactically similar classes. We therefore include the following four types of feature; the first two are syntactic, while the other two are intended to capture semantic characteristics:

Slot POS In addition to the syntactic slot features, we add features that represent a combination of a syntactic slot and the POS of its head word. Since VerbNet includes extended classes that take verbal and adjectival arguments, the POSs of arguments would provide a strong clue to discriminate among these syntactic frames.

Syntactic frame The number of arguments and their syntactic categories. This feature was mentioned as a baseline in Joanis et al. (2008), but we include it in our model.

Similar word Similar words (lemmas) to the target verb. Similar words are automatically obtained from a corpus (the same corpus as used for feature extraction) by Lin (1998)'s method. This feature is motivated by the hypothesis that distributionally similar words tend to be classified into the same class. Because Lin's method is based on the similarity of words in syntactic slots, the obtained similar words are expected to represent a verb class that share selectional preferences.

Slot class Semantic classes of the head words of the arguments. This feature is also intended to approximate selectional preferences. The semantic classes are obtained by clustering nouns, verbs, and adjectives into 200, 100, and 50 classes respectively, by using the k-medoid method with Lin (1998)'s similarity.

Figure 5 shows an example of the features for "sway," extracted from the BNC corpus.[3] Feature values are defined as relative frequencies for each lemma; while, for similar word features, feature values are weighted by Lin's similarity measure.

4.3 Tasks

We evaluate our model in the tasks of automatic verb classification (a.k.a. lexicon expansion): given gold verb-class associations for some set of verbs, we predict the classes for unknown

[3] "C82" and "C12" are automatically assigned cluster names.

Verb class	Levin class number
Recipient	13.1, 13.3
Admire	31.2
Amuse	31.1
Run	51.3.2
Sound Emission	43.2
Light and Substance Emission	43.1, 43.4
Cheat	10.6
Steal and *Remove*	10.5, 10.1
Wipe	10.4.1, 10.4.2
Spray/Load	9.7
Fill	9.8
Other Verbs of Putting	9.1–6
Change of State	45.1–4
Object Drop	26.1, 26.3, 26.7

Table 1: 14 classes used in Joanis et al. (2008) and their corresponding Levin class numbers

verbs. While our main target is the full set of VerbNet classes, we also show results for the task studied in the previous work.

14-class task The task to classify (almost) monosemous verbs into 14 classes. Refer to Table 1 for the definition of the 14 classes. Following Joanis et al. (2008)'s task definition, we removed verbs that belong to multiple classes in these 14 classes, and also removed *overly polysemous* verbs (in our experiment, verb-class associations that have the relative frequency that is less than 0.5 in SemLink are removed). For each class, member verbs are randomly split into 50% (training), 25% (development), and 25% (final test) sets.

All-class task The task to classify all target verbs into 268 classes.[4] Any verbs that did not occur at least 100 times in the BNC corpus were removed.[5] The remaining verbs (2517 words) are randomly split into 80% (training), 10% (development), and 10% (final test) sets, under the constraint that at least one instance for each class is included in the training set.[6]

4.4 Evaluation measures

For the 14-class task, we simply measure the classification accuracy. However, the evaluation in the all-class task is not trivial, because verbs may be assigned multiple classes.

Since our purpose is to obtain a probabilistic model rather than to classify monosemous verbs, the evaluation criterion should be sensitive to the probabilistic distribution on the test data. In this paper, we adopt two evaluation measures. One is the *top-N weighted accuracy*; we count the number of correct pairs $\langle c, v \rangle$ in the N-best outputs from the model (where N is the number of gold classes for each lemma), where each count is weighted by the relative frequency (i.e., the counts in SemLink) of the pair in the test set. For example, in the case for "blare" in Figure 4, if the model states that **Sound Emission** has the largest probability, we get 0.7 points. If **Manner Speaking** has the largest probability, we instead obtain 0.3 points. Intuitively, the score is higher when the model presents larger probabilities to classes with higher relative frequencies. This measure is similar to the top-N precision in information retrieval; it evaluates the ranked output by the model. It is intuitively interpretable, but is insufficient for evaluating the quality of probability distributions.

The other measure is *KL-divergence*, which is popularly used for measuring the dissimilarity between two probability distributions. This is defined as follows:

$$KL(p||q) = \sum_x p(x)\log(p(x)) - p(x)\log(q(x)).$$

In the experiments, this measure is applied, with the assumption that p is the relative frequency of $\langle c, v \rangle$ in the test set, and that q is the estimated probability distribution. Although the KL-divergence is not a true distance metric, it is sufficient for measuring the fitting of the estimated model to the true distribution. We report the KL-divergence averaged over all verbs in the test set. Since this measure indicates a dissimilarity, a smaller value is better. When p and q are equivalent, $KL(p||q) = 0$.

5 Experimental results

Table 2 shows the accuracy obtained for the 14-class task. The first column denotes the incorporated features ("Joanis et al.'s features" or "All features"), and the sources of the features ("WSJ" or "BNC"). The two baseline results are also given: "Baseline (*random*)" indicates that classes are randomly output, and "Baseline (*majority*)" indicates

[4] Two classes (**Being Dressed** and **Debone**) are not used in the experiments because no lemmas belonged to these classes after filtering by the frequency in BNC.

[5] This is the same preprocessing as Joanis et al. (2008), although we use VerbNet, while Joanis et al. (2008) used the original Levin classifications.

[6] Because polysemous verbs belong to multiple classes, the class-wise data split was not adopted for the all-class task.

	Accuracy
Baseline (*random*)	7.14
Baseline (*majority*)	26.47
Joanis et al.'s features/WSJ	56.86
Joanis et al.'s features/BNC	64.22
All features/WSJ	60.29
All features/BNC	68.14

Table 2: Accuracy for the 14-class task

	Accuracy	KL
Baseline (*random*)	0.37	—
Baseline (*majority*)	8.69	—
Joanis et al.'s features/WSJ	30.26	3.65
Joanis et al.'s features/BNC	35.66	3.32
All features/WSJ	34.07	3.37
All features/BNC	42.54	2.99

Table 3: Accuracy and KL-divergence for the all-class task (the VerbNet+SemLink setting)

that the majority class (i.e., the class that has the largest number of member verbs) is output to every lemma. While these figures cannot be compared directly to the previous works due to the difference in the preprocessing, Joanis et al. (2008) achieved 58.4% accuracy for the 14-class task. Table 3 and 4 present the results for the all-class task. Table 3 gives the accuracy and KL-divergence achieved by the model trained with the VerbNet+SemLink training instances, while Table 4 presents the same measures by the training instances created from VerbNet only.

Our models performed substantially better on both tasks than the baseline models. The results also proved that the features we proposed in this paper contributed to the further improvement of the model from Joanis et al. (2008). In the all-class task with the VerbNet+SemLink setting, our features achieved 10.69% error reduction in the accuracy over Joanis et al. (2008)'s features. Another interesting fact is that the model with BNC consistently outperformed the model with WSJ. This outcome is somewhat surprising, provided that the relative frequencies in the training/test sets are created from the WSJ portion of SemLink. The reason for this is independent of the corpus size, as will be shown below. When comparing Table 3 and 4, we can see that using SemLink statistics resulted in a slightly better model. This result is predictable, because the evaluation measures are sensitive to the relative frequencies estimated from SemLink. However, the difference remained small. In both of the tasks and the evaluation measures, the best model was achieved when we use

	Accuracy	KL
Baseline (*random*)	0.37	—
Baseline (*majority*)	8.69	—
Joanis et al.'s features/WSJ	29.65	3.67
Joanis et al.'s features/BNC	35.78	3.34
All features/WSJ	34.53	3.40
All features/BNC	42.38	3.02

Table 4: Accuracy and KL-divergence for the all-class task (the VerbNet only setting)

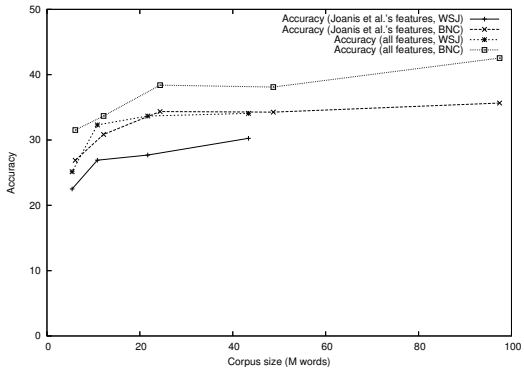

Figure 6: Corpus size vs. accuracy

all the features extracted from BNC, and create training instances from VerbNet+SemLink.

Figure 6 and 7 plot the accuracy and KL-divergence against the size of the unannotated corpus used for feature extraction. The result clearly indicates that the learning curve still grows at the corpus size with 100 million words (especially for the all features + BNC setting), which indicates that better models are obtained by increasing the size of the unannotated corpora.

Therefore, we can claim that the differences between the domains and the size of the unannotated corpora are more influential than the availability of the annotated corpora. This indicates that learning only from a lexicon would be a viable solution, when a token-disambiguated corpus like SemLink is unavailable.

Table 5 shows the contribution of each feature group. BNC is used for feature extraction, and VerbNet+SemLink is used for the creation of training instances. The results demonstrated the effectiveness of the slot POS features, and in particular, for the all-class task, most likely because VerbNet covers verbs that take non-nominal arguments. Additionally, the similar word features contributed equally or more in both of the tasks. This result suggests that we were reasonable in hypothesizing that distributionally similar words tend to be clas-

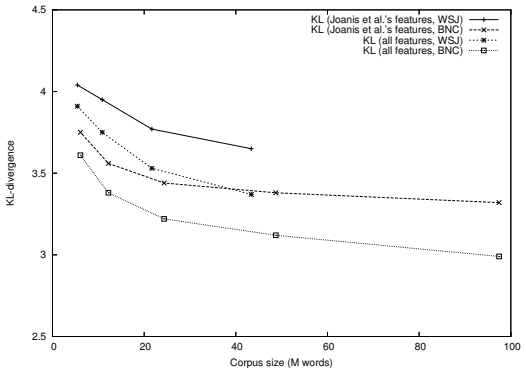

Figure 7: Corpus size vs. KL-divergence

	14-classes Accuracy	All classes Accuracy	KL
Baseline (*random*)	7.14	0.37	—
Baseline (*majority*)	26.47	8.69	—
Joanis et al.'s features	64.22	35.66	3.32
+ Slot POS	66.67	38.77	3.18
+ Syntactic frame	64.71	35.99	3.29
+ Similar word	68.14	37.88	3.10
+ Slot class	64.71	36.51	3.26
All features	68.14	42.54	2.99

Table 5: Contribution of features

sified into the same class. Slot classes also contributed to a slight improvement, indicating that selectional preferences are effective clues for predicting VerbNet classes. The result of the "All features" model for the all-class task attests that these features worked collaboratively, and using them all resulted in a considerably better model.

From the analysis of the confusion matrix for the outputs by our best model, we identified several reasons for the remaining misclassification errors. A major portion of the errors were caused by confusing the classes that take the same prepositions. Examples of these errors include:

- **Other Change of State** verbs were misclassified into the ***Butter*** class: "embalm," "laminate." (they take "with" phrases)
- **Judgement** verbs were misclassified into the **Characterize** class: "acclaim," "hail." (they take "as" phrases)

Since prepositions are strong features for automatic verb classification (Joanis et al., 2008), the classes that take the same prepositions remained confusing. The discovery of the features to discriminate among these classes would be crucial for further improvement.

Another major error is in classifying verbs into **Other Change of State**. Examples include:

- ***Amuse*** verbs: "impair," "recharge."
- ***Herd*** verbs: "aggregate," "mass."

Because **Other Change of State** is one of the biggest classes, supervised learning tends to place a high probability to this class. Therefore, when strong clues do not exist, verbs tend to be misclassified into this class. In addition, this class is not syntactically/semantically homogeneous, and is likely to introduce noise in the machine learning classifier. A possible solution to this problem would be to exclude this class from the classification, and to process the class separately.

6 Conclusions

We presented a method for the supervised learning of a probabilistic model for a lexicon of VerbNet classes. By combining verb-class associations from VerbNet and SemLink, and features extracted from a large unannotated corpus, we could successfully train a log-linear model in a supervised way. The experimental results attested to our success that features proposed in this paper worked effectively in obtaining a better probability distribution. Not only syntactic features, but also semantic features were shown to be effective. While each of these features could increase the accuracy, they collaboratively contributed to a large improvement. In the all-class task, we obtained 10.69% error reduction in the classification accuracy over Joanis et al. (2008)'s model. We also observed the trend that a larger corpus for feature extraction led to a better model, indicating that a better model will be obtained by increasing the size of an unannotated corpus.

We could identify the effective features and settings for this problem, but the classification into all VerbNet classes remained challenging. One possible direction for this research topic would be to use our model for the semi-automatic construction of verb lexicons, with the help of human curation. However, there is also a demand for exploring other types of features that can discriminate among confusing classes.

Abstract

The use of lexical semantic knowledge in information retrieval has been a field of active study for a long time. Collaborative knowledge bases like Wikipedia and Wiktionary, which have been applied in computational methods only recently, offer new possibilities to enhance information retrieval. In order to find the most beneficial way to employ these resources, we analyze the lexical semantic relations that hold among query and document terms and compare how these relations are represented by a measure for semantic relatedness. We explore the potential of different indicators of document relevance that are based on semantic relatedness and compare the characteristics and performance of the knowledge bases Wikipedia, Wiktionary and WordNet.

1 Introduction

Today we face a rapidly growing number of electronic documents in all areas of life. This demands for more effective and efficient ways of searching these documents for information. Especially user-generated content on the web is a growing source of huge amounts of data that poses special difficulties to IR. The precise wording is often difficult to predict and current information retrieval (IR) systems are mainly based on the assumption that the meaning of a document can be inferred from the occurrence or absence of terms in it. In order to yield a good retrieval performance, i.e., retrieving all relevant documents without retrieving non-relevant documents, the query has to be formulated by the user in an appropriate way. Blair and Maron (1985) showed that with larger growing document collections, it gets impossible for the user to anticipate the terms that occur in all relevant documents, but not in non-relevant ones.

The use of semantic knowledge for improving IR by compensating non-optimal queries has been a field of study for a long time. First experiments on query expansion by Voorhees (1994) using lexical-semantic relations extracted from a linguistic knowledge base (LKB), namely WordNet (Fellbaum, 1998), showed sginificant improvements in performance only for manually selected expansion terms. The combination of WordNet with thesauri built from the underlying document collections by Mandala et al. (1998) improved the performance on several test collections. Mandala et al. (1998) identified missing relations, especially cross part of speech relations and insufficient lexical coverage as reasons for the low performance improvement when using only WordNet.

In recent work, collaborative knowledge bases (CKB) like Wikipedia have been used in IR for judging the document relevance by computing the semantic relatedness (SR) of queries and documents (Gurevych et al., 2007; Egozi et al., 2008; Müller and Gurevych, 2008) and have shown promising results. These resources have a high coverage of general and domain-specific terms. They are employed in several SR measures such as *Explicit Semantic Analysis* (ESA) (Gabrilovich and Markovitch, 2007) that allow the cross part of speech computation of SR and are not restricted to standard lexical semantic relations.

The goal of this paper is to shed light on the role of lexical semantics in IR and the way it can improve the performance of retrieval systems. There exist different kinds of resources for lexical semantic knowledge and different ways to embed this knowledge into IR. Wikipedia and Wiktionary, which have been applied in computational methods only recently, offer new possibilities to enhance IR. They have already shown an excellent performance in computing the SR of word pairs (Strube and Ponzetto, 2006; Gabrilovich and

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1338–1347,
Singapore, 6-7 August 2009.

Markovitch, 2007; Zesch et al., 2008). However, it is not yet clearly understood, what the most beneficial method is to employ SR using these resources in IR. We therefore perform a comparative study on an IR benchmark. We particularly analyze the contribution of SR of query and document terms to this task. To motivate those experiments we first prove that there exists a vocabulary gap in the test collection between queries and documents and show that the gap can be reduced by using lexical semantic knowledge. As the vocabulary coverage of knowledge bases is a crucial factor for being effective in IR, we compare the coverage of Wikipedia, Wiktionary and WordNet. We then analyze the lexical semantic relations that hold among query and document terms and how they are represented by the values of a SR measure. Finally, we explore the potential of different SR-based indicators of document relevance.

The remainder of this paper is structured as follows: In Section 2 we give a short overview of the LKBs and CKBs and the measure of SR we employ in this paper. The test collection we use in our experiments is described in Section 3. In Section 4 we analyze the vocabulary of the test collection and determine the coverage of the knowledge bases. This is followed by the examination of lexical semantic relations and the analysis of the SR of query terms in relevant and non-relevant documents in Section 5.

2 Knowledge Sources and Semantic Relatedness Measure

2.1 Linguistic Knowledge Bases

LKBs are mainly created by trained linguists following clearly defined guidelines. Therefore, their content is typically of high quality. This labor and cost intensive approach, however, yields a number of disadvantages for LKBs:

- their coverage and size are limited;
- they lack domain-specific vocabulary;
- continuous maintenance is often not feasible;
- the content can quickly be out-dated;
- only major languages are typically supported.

The most common types of LKBs are (i) dictionaries, which alphabetically list words and their senses of a certain language along with their definitions and possibly some additional information and (ii) thesauri, which group words with similar meaning together and define further semantic relations between the words, e.g., antonymy. The most widely used LKB is WordNet, which is a combination of dictionary and thesaurus. Since the hypernym and hyponym relations between noun groups form an *is-a* hierarchy, WordNet can also be seen as an ontology. The current version 3.0 of WordNet, which we use in our experiments, contains over 155,000 English words organized into almost 118,000 so called synsets, i.e., groups of synonymous words. WordNet covers mainly general vocabulary terms and its strongest part is the noun hierarchy.

2.2 Collaborative Knowledge Bases

Enabled by the development of Web 2.0 technology and created by communities of volunteers, CKBs have emerged as a new source of lexical semantic knowledge in recent years. In contrast to LKBs, they are created by persons with diverse personal backgrounds and fields of expertise. CKBs have the advantage of being freely available unlike many LKBs. However, the content of CKBs is mainly semi- or unstructured text which initially requires the extraction of explicit knowledge that can then be used in computational methods.

One of the CKBs we use in this paper is Wikipedia, a freely available encyclopedia. It currently contains more than 12 million articles in 265 languages. Besides articles, Wikipedia also offers other forms of knowledge that can be used in computational methods. This includes the hierarchy of article categories (Strube and Ponzetto, 2006; Zesch et al., 2007) and links between articles in the same language (Milne and Witten, 2008) and across languages (Schönhofen et al., 2007; Potthast et al., 2008; Sorg and Cimiano, 2008; Müller and Gurevych, 2008). Due to its encyclopedic character, Wikipedia contains many named entities and domain-specific terms which are not found in WordNet. In our experiments we used the Wikipedia dump of February 6th, 2007.

The second CKB we use is Wiktionary which is a multilingual dictionary and an affiliated project of Wikipedia. It resembles WordNet by containing synonym and hyponym information. It also contains information usually not found in LKBs like abbreviations, compounds, contractions, and the etymology of words. The 171 language-specific

editions of Wiktionary contain more than 5 million entries. Note that each language-specific edition contains not only entries for words of that particular language, but also for words of foreign languages. Wiktionary has been used in IR (Müller and Gurevych, 2008; Bernhard and Gurevych, 2009) and other tasks like sentiment analysis (Chesley et al., 2006) or ontology learning (Weber and Buitelaar, 2006). In our experiments we used the Wiktionary dump of Oct 16, 2007.

2.3 Semantic Relatedness Measure

A wide range of methods for measuring the SR of term pairs are discussed in the literature. In our experiments, we employ ESA as it can be used with all three knowledge bases in our experiments and has shown an excellent performance in related work. ESA was introduced by Gabrilovich and Markovitch (2007) employing Wikipedia as a knowledge base. Zesch et al. (2008) explored its performance using Wiktionary and WordNet as knowledge bases.

The idea of ESA is to express a term's meaning by computing its relation to Wikipedia articles. Each article title in Wikipedia is referred to as a concept and the article's text as the textual representation of this concept. A term is represented as a high dimensional concept vector where each value corresponds to the term's frequency in the respective Wikipedia article. The SR of two terms is then measured by computing the cosine between the respective concept vectors. When applying ESA to Wiktionary and WordNet, each word and synset entry, respectively, is referred to as a distinct concept, and the entry's information[1] is used as the textual representation of the concept.

In our experiments, we apply pruning methods as proposed by Gabrilovich and Markovitch (2007) with the goal of reducing noise and computational costs. Wikipedia concepts are not taken into account where the respective Wikipedia articles have less than 100 words or fewer than 5 in- or outlinks. For all three knowledge bases, concepts are removed from a term's concept vector if their normalized values are below a predefined threshold (empirically set to *0.01*).

[1]For WordNet, the glosses and example sentences of the synsets are used. Wiktionary does not contain glosses for all entries due to instance incompleteness. Therefore, a concatenation of selected information from each entry is used. See Zesch et al. (2008) for details.

Documents

Number of unique terms	400194
Ave. document length	256.23
Queries	
Number of queries	50
Number of unique terms	117
Ave. query length	2.44

Table 1: Statistics of the test data (after preprocessing).

3 Data

For our study we use parts of the data from the HARD track at the TREC 2003 conference[2]. The document collection consists of newswire text data in English from the year 1999, drawn from the Xinhua News Service (People's Republic of China), the New York Times News Service, and the Associated Press Worldstream News Service.[3] As we did not have access to the other document collections in the track, we restrict our experiments to the newswire text data.

From the 50 available topics of that track, we use only the title field, which consists of a few keywords describing the information need of a user. Table 1 shows some descriptive statistics of the documents and topics. The topics cover general themes like *animal protection*, *Y2K crisis* or *Academy Awards ceremony*. For the preprocessing of topics and documents we use tokenization, stopword removal and lemmatization employing the TreeTagger (Schmid, 1994). In our study, we rely on the relevance assessments performed at TREC to distinguish between relevant and non-relevant documents for each topic.

4 Vocabulary Mismatch

To confirm the intuition that there exists a vocabulary mismatch between queries and relevant documents, we computed the overlap of the terms in queries and relevant documents. The results are shown in the column *String-based* in Table 2. Averaged over all 50 topics, 35.5% of the relevant documents do contain all terms of the query, and 86.5% contain at least one of the query terms. However, this means that 13.5% of the relevant documents do not contain any query term and

Ave. number of documents where at least one query term is matched (in %)	86.5	100.0	99.1	97.7	97.2	94.9	92.9
Ave. number of query terms matched per document (in%)	55.8	95.6	84.0	87.0	76.8	79.2	65.7

Table 2: Statistics about the matching of the terms of queries and relevant documents.

cannot be retrieved by simple string-matching retrieval methods. In average, each relevant document matches 55.8% of the query terms. With an average query length of 2.44 (see Table 1), this means that in general, only one of two query terms occurs in the relevant documents which significantly lowers the probability of these documents to have a high ranking in the retrieval result.

In a second experiment, we proved the effectiveness of the SR measure and knowledge bases in reducing the vocabulary gap by counting the number of query terms that match the terms in the relevant documents as string or are semantically related to them. The results are shown in Table 2 for the different knowledge bases in the columns *SR-Wikipedia*, *SR-Wiktionary* and *SR-WordNet*. In order to analyse the performance of the SR measure when excluding very low SR values that might be caused by noise, we additionally applied a threshold of 0.05, i.e. only values above this threshold were taken into account. The SR values range between 0 and 1. However, the majority of SR values lie between 0 and 0.1.

Without threshold, using Wikipedia as knowledge base, in 91.2% of the relevant documents all query terms were matched. For Wiktionary with 82.6% and WordNet with 74.8% the number is lower, but still more than twice as high as for the string-based matching. Wikipedia matches in all relevant documents at least one query term. The average number of query terms matched per document is also increased for all three knowledge bases. Applying a threshold of 0.05, the values decrease, but are still above the ones for string-based matching.

The sufficient coverage of query and document terms is crucial for the effectiveness of knowledge bases in IR. It was found that LKBs do not necessarily provide a sufficient coverage (Mandala et al., 1998). Table 3 shows the amount of terms in queries and documents that are contained in Wikipedia, Wiktionary and WordNet. Wikipedia contains almost all query terms and also shows the best coverage for the document terms, followed by Wiktionary and WordNet. The values for all three knowledge bases are all higher than 80% except for the percentage of queries or documents where all terms are covered and the number of covered unique terms. The low percentage of covered unique document terms for even Wikipedia is mostly due to named entities, misspellings, identification codes and compounds.

	SR-Wikipedia	*SR-Wiktionary*	*SR-WordNet*
Queries			
Percentage of queries where all terms are covered	98.0	78.0	62.0
Percentage of covered terms	99.2	89.3	80.3
Percentage of covered unique terms	99.1	88.9	80.3
Ave. percentage of covered terms per query	99.6	89.2	80.1
Ave. percentage of covered unique terms per query	99.6	89.2	80.1
Documents			
Percentage of documents where all terms are covered	7.9	0.3	0.2
Percentage of covered terms	96.5	88.5	84.3
Percentage of covered unique terms	34.5	12.9	10.0
Ave. Percentage of terms covered per document	97.4	91.8	88.8
Ave. percentage of covered unique terms per document	96.3	88.0	83.6

Table 3: Statistics about the coverage of the knowledge bases.

Judging from the number of covered query and document terms alone, one would expect Wikipedia to yield a better performance when applied in IR than Wiktionary and especially WordNet. The higher coverage of Wikipedia is due to its nature of being an encyclopedia featuring arbitrarily long articles whereas entries in WordNet, and also Wiktionary, have a rather short length following specific guidelines. The high coverage alone is however not the only important factor for the effectiveness of a resource. It was shown by Zesch et al. (2008) that Wiktionary outperforms Wikipedia

in the task of ranking word pairs by their semantic relatedness when taking into account only word pairs that are covered by both resources.

5 Comparison of Semantic Relatedness in Relevant and Non-Relevant Documents

We have shown in Section 4 that a mismatch between the vocabulary of queries and relevant documents exists and that the SR measure and knowledge bases can be used to address this gap. In order to further study the SR of query and document terms with the goal to find SR-based indicators for document relevance, we created sets of relevant and non-relevant documents and compared their characteristic values concerning SR.

5.1 Document Selection

For analysing the impact of SR in the retrieval process, we compare relevant and non-relevant documents that were assigned similar relevance scores by a standard IR system. For the document selection we followed a method employed by Vechtomova et al. (2005). We created two sets of documents for each topic: one for relevant and one for non-relevant documents. We first retrieved up to 1000 documents for the topic using the BM25 IR model[4] (Spärck Jones et al., 2000) as implemented by Terrier[5]. The relevant retrieved documents constituted the first set. For the second set we selected for each relevant retrieved document a non-relevant document which had the closest score to the relevant document. After selecting an equal number of relevant and non-relevant documents, we computed the mean average and the standard deviation for the scores of each set. If there was a substantial difference between the values of more than 20%, the sets were rearranged by exchanging non-relevant documents or excluding pairs of relevant and non-relevant documents. If this was not possible, we excluded the corresponding topic from the experiments.

Table 4 shows the statistics for the final sets. From the original 50 topics, 13 were excluded for the above stated reasons or because no relevant documents were retrieved. The average length of about 345 terms for relevant documents is almost 40% larger than the length of non-relevant documents. Also the average number of query term instances is 6.93 in cotrast to 4.64 for non-relevant documents. The large difference of average document length and query term instances suggests a larger difference of the average relevance scores than 20%. However, in the BM25 model the relevance score is decreased with increasing document length and additional occurrences of a query term have little impact after three or four occurrences.

	Rel.	Nonrel.	Diff. (%)
Number of queries	37	37	0
Number of documents	1771	1771	0
Mean BM25 document score	6.388	6.239	2.39
Stdev BM25 document score	1.442	1.288	12.00
Ave. query length	2.32	2.32	0
Ave. document length	345.22	248.89	38.70
Ave. query term instances in documents	6.93	4.64	49.35

Table 4: Data characteristics that are independent of the chosen knowledge base and threshold.

5.2 Types of Lexical Semantic Relations

The most common classical lexical semantic relations between words are synonymy, hyponymy and a couple of others. In order to analyze the importance of these relations in the retrieval process, we automatically annotated the relations that hold between query and document terms using WordNet. Table 5 shows the percentage of lexical semantic relations between query and document terms (normalized by the number of query and document terms). The table also shows the coverage of the relations by the SR measure, i.e. the percentage of annotated relations for which the SR measure computed a value above 0 or the threshold 0.05, respectively. The percentage of relation types in general is higher for relevant documents. Cohyponymy and synonymy are by far the most frequently occurring relation types with up to almost 6%. Hypernyms and hyponyms have both a percentage of less than 1%. Holonymy and meronymy do almost not occur.

When applying no threshold, the SR measure covers up to 21% of the synonyms and cohyponyms and up to 12% of the hyper- and hyponyms in relevant documents. Using Wiktionary as knowledge base, the SR measure shows a better coverage than with Wikipedia. This is consistent with the findings in Zesch et al. (2008).

[4] We used the default values for the constants of the model ($k_1 = 1.2, b = 0.75$).

[5] http://ir.dcs.gla.ac.uk/terrier/

Relation Type	Percentage	SR-Wikipedia 0.0	SR-Wikipedia 0.05	SR-Wiktionary 0.0	SR-Wiktionary 0.05	SR-WordNet 0.0	SR-WordNet 0.05
Relevant Documents							
synonymy	3.61	17.81	13.13	18.33	13.78	15.28	12.18
hypernymy	0.86	8.57	2.30	12.18	3.02	11.69	2.26
hyponymy	0.88	5.72	1.28	6.33	1.67	6.54	1.02
cohyponymy	5.64	19.49	10.49	21.04	10.05	16.85	8.14
holonymy	0.02	0.61	0.17	0.74	0.17	0.53	0.00
meronymy	0.07	1.94	0.78	2.23	0.74	1.88	0.76
non-classical	—	58.80	6.62	23.22	3.13	12.77	2.56
Non-Relevant Documents							
synonymy	3.41	15.84	12.41	16.46	12.90	14.19	11.44
hypernymy	0.56	6.10	1.95	9.43	2.10	8.93	1.57
hyponymy	0.74	4.77	1.00	6.35	1.40	5.90	0.78
cohyponymy	5.42	17.42	9.91	19.23	9.71	15.38	7.66
holonymy	0.02	0.39	0.09	0.49	0.09	0.32	0.00
meronymy	0.10	1.88	0.55	1.84	0.65	1.57	0.57
non-classical	—	57.33	5.54	21.92	2.59	11.77	2.15

Table 5: Percentage of lexical semantic relations between query and document terms and their coverage by SR scores above threshold 0.00 and 0.05 in percent.

The reason for this is the method for constructing the textual representation of the concepts in the SR measure, where synonyms and other related words are concatenated. Also SR-WordNet outperforms Wikipedia for hypernymy and hyponymy. In contrast to Wiktionary, no direct information about related words is used to construct the textual representation of concepts. However, the very short and specific representations are built from glosses and examples which often contain hypernym-hyponym pairs. As WordNet is used for both, the automatic annotation of lexical semantic relations and the computation of SR values, its lower term coverage in general has not much impact on this experiment, as only the relations between terms contained in WordNet are annotated.

More than half of the SR values using Wikipedia are computed for term pairs which were not annotated with a classical relation. This is depicted in Table 5 as non-classical relation. These non-classical relations can be for example functional relations (*pencil* and *paper*) (Budanitsky and Hirst, 2006). However, as WordNet covers only a small part of the terms in the test collection, some of the SR values refered to as non-classical relations might actually be classical relations. For Wiktionary and WordNet, the number of non-classical relations is much lower, due to their smaller size and the way the textual representations of concepts are constructed. In general, the average number of SR scores for classical and non-classical relations are almost consistently higher for relevant documents which suggests that the comparison of SR scores could be beneficial in the IR process.

Relation Type	SR-Wikipedia 0.0	SR-Wikipedia 0.05	SR-Wiktionary 0.0	SR-Wiktionary 0.05	SR-WordNet 0.0	SR-WordNet 0.05
Relevant Documents						
synonymy	0.362	0.371	0.372	0.374	0.366	0.368
hypernymy	0.021	0.021	0.021	0.019	0.016	0.019
hyponymy	0.017	0.021	0.008	0.012	0.007	0.015
cohyponymy	0.270	0.334	0.315	0.353	0.312	0.363
holonymy	0.001	0.000	0.001	0.000	0.000	0.000
meronymy	0.004	0.003	0.003	0.002	0.003	0.002
non-classical	0.045	0.356	0.098	0.491	0.205	0.599
Non-Relevant Documents						
synonymy	0.344	0.348	0.349	0.350	0.343	0.344
hypernymy	0.027	0.030	0.025	0.029	0.022	0.028
hyponymy	0.019	0.029	0.012	0.023	0.009	0.025
cohyponymy	0.250	0.295	0.277	0.312	0.295	0.334
holonymy	0.001	0.000	0.000	0.000	0.000	0.000
meronymy	0.003	0.002	0.002	0.002	0.003	0.002
non-classical	0.041	0.374	0.103	0.538	0.222	0.643

Table 6: Average values of SR scores corresponding to lexical semantic relations between query and document terms above threshold 0.00 and 0.05 in percent.

When applying a threshold of 0.05, the most visible effect is that the percentage of non-classical relations is decreasing much stronger than the percentage of classical relations. The comparison of the average SR values for each relation type in Table 6 confirms that this is due to the fact that the SR measure assigns on average higher values to the classical relations than to the non-classical relations. After applying a threshold of 0.05 the average SR values corresponding to non-classical relations increase and are equal to or higher than the values for classical relations. The values for classical relations are in general higher for relevant documents, whereas the values for non-classical relations are lower.

5.3 SR-based Indicators for Document Relevance

For each topic and document in one of the sets we computed the SR between the query and document terms. We then computed the arithmetic mean of the following characteristic values for each set: the sum of SR scores, the number of SR scores, the number of terms which are semantically related to a query term and the average SR score. In order to eliminate the difference in document length and average number of query term instances between the relevant and non-relevant sets, we normalized all values, except for the average SR score, by the document length and excluded the SR scores of query term instances.

Figure 1 shows the average difference of these values between relevant and non-relevant document sets for SR-thresholds from 0 to 0.6 (step-size=0.01). As the majority of the SR scores have a low value, there is not much change for thresholds above 0.5.

Except for the average SR score, the differences have a peak at thresholds between 0.01 and 0.09 and decrease afterwards to a constant value. The SR scores computed using Wikipedia show the highest differences. Wiktionary and WordNet perform almost equally, but show lower differences than Wikipedia, especially for the sum of scores. All three knowledge bases show higher differences for the number of scores and number of related terms than for the sum of scores. The differences at the peaks are statistically significant[6], except for the differences of the sum of scores for Wiktionary and WordNet.

For the average SR score, the differences are mostly negative at low thresholds and increase to a low positive value for higher thresholds. A higher number of very low SR values is computed for the relevant documents, which causes the average SR score to be lower than for the non-relevant documents at low thresholds.

Additionally, Figure 2 shows the percentage of topics where the mean value of the relevant document set is higher than the one of the non-relevant document set. Wikipedia shows the highest percentage with about 86% for the number of scores and the number of related terms. Wiktionary and WordNet have a low percentage for the sum of scores, but reach up to 75% for the number of scores and the number of related terms.

[6]We used the Wilcoxon test at a significance level of 0.05.

The analysis of the SR of query and document terms shows that there are significant differences for relevant and non-relevant documents that can be measured by computing SR scores with any of the three knowledge bases. Especially when using Wiktionary and WordNet, the number of SR scores and the number of related terms might be better indicators for the document relevance than the sum of SR scores.

6 Conclusions

The vocabulary mismatch of queries and documents is a common problem in IR, which becomes even more serious the larger the document collection grows. CKBs like Wikipedia and Wiktionary, which have been applied in computational methods only recently, offer new possibilities to tackle this problem. In order to find the most beneficial way to employ these resources, we studied the semantic relatedness of query and document terms of an IR benchmark and compared the characteristics and performance of the CKBs Wikipedia and Wiktionary to the LKB WordNet.

We first proved that there exists a vocabulary gap in the test collection between queries and documents and that it can be reduced by employing a concept vector based measure for SR with any of the three knowledge bases. Using WordNet to automatically annotate the lexical semantic relations of query and document terms, we found that cohyponymy and synonymy are the most frequent classical relation types. Although the percentage of annotated relations for which also the SR measure computed values above a predefined threshold was at best 21%, the average number of SR scores for classical and non-classical relations were almost consistently higher for relevant documents.

Comparing the number and the value of SR scores of query and document terms, a significant difference between relevant and non-relevant documents was observed by using any of the three knowledge bases. Although Wikipedia had the best coverage of collection terms and showed the best perfomance in our experiments, Wiktionary and Wikipedia also seem to have a sufficient size for being beneficial in IR. In comparison to our previous work where the sum of SR scores was used as an indicator for document relevance (Müller and Gurevych, 2008), the results suggest that the number of SR scores and the number of related terms might show a better performance, es-

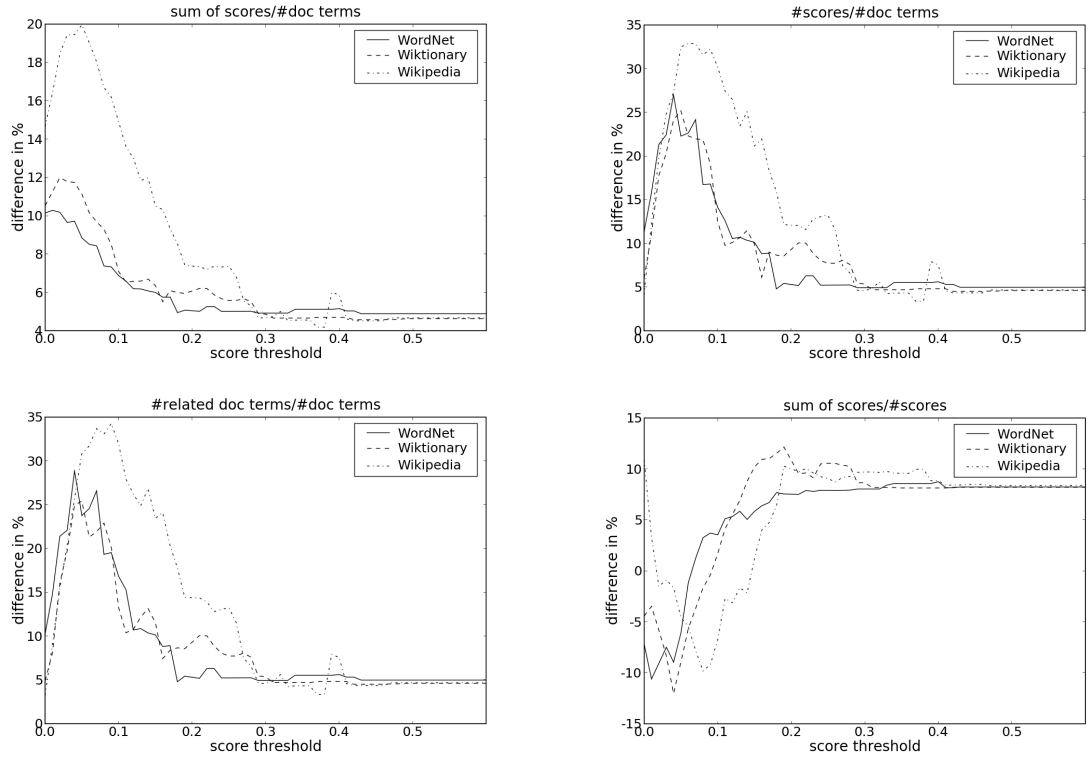

Figure 1: Differences between mean values of relevant and non-relevant document sets.

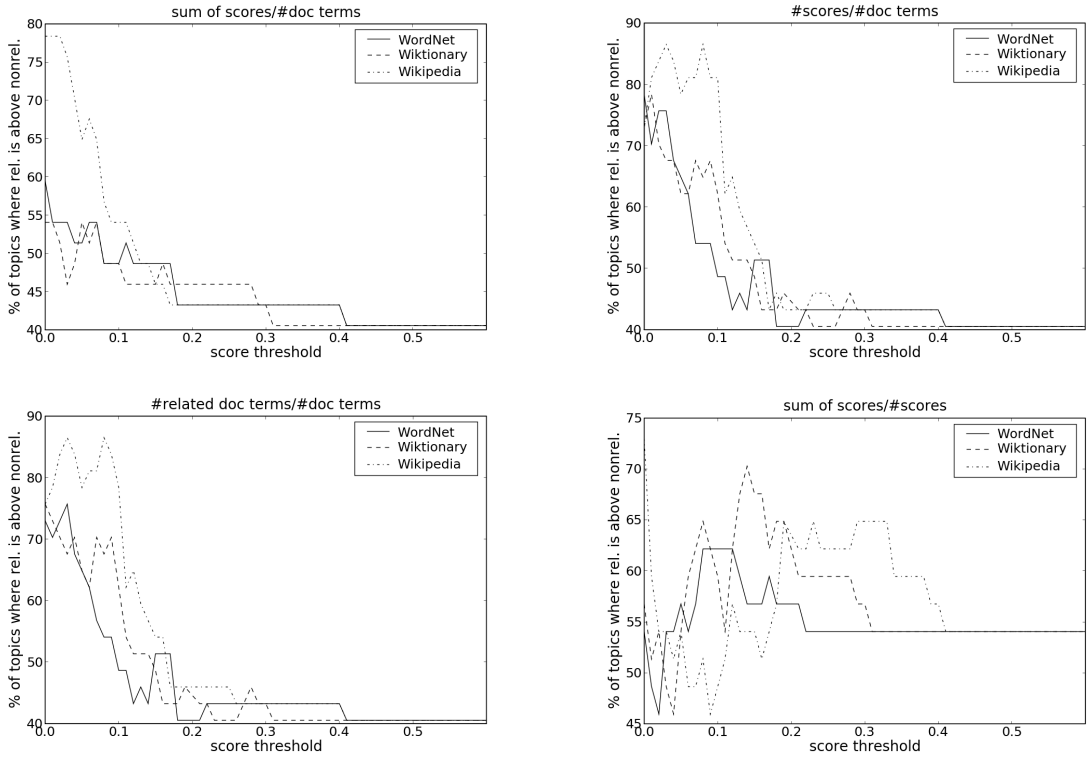

Figure 2: Percentage of topics where the mean value of the relevant document sets is higher than the one of the non-relevant document sets.

pecially for Wiktionary and WordNet.

In our future work, we plan to extend our analysis to other test collections and to query expansion methods in order to generalize our conclusions. As the problem of language ambiguity has a high impact on the use of SR measures, we will also consider word sense disambiguation in our future experiments.

Predicting Subjectivity in Multimodal Conversations

Gabriel Murray and **Giuseppe Carenini**

Abstract

In this research we aim to detect subjective sentences in multimodal conversations. We introduce a novel technique wherein subjective patterns are learned from both labeled and unlabeled data, using n-gram word sequences with varying levels of lexical instantiation. Applying this technique to meeting speech and email conversations, we gain significant improvement over state-of-the-art approaches. Furthermore, we show that coupling the pattern-based approach with features that capture characteristics of general conversation structure yields additional improvement.

1 Introduction

Conversations are rich in subjectivity. Conversation participants agree and disagree with one other, argue for and against various proposals, and generally take turns expressing their private states. Being able to separate these subjective utterances from more objective utterances would greatly facilitate the analysis, mining and summarization of a large number of conversations.

Two of the most prevalent conversational media are meetings and emails. Face-to-face meetings enable numerous people to exchange a large amount of information and opinions in a short period of time, while emails allow for concise exchanges between potentially far-flung participants. Meetings and emails can also feed into one another, with face-to-face meetings occurring at regular intervals and emails continuing the conversations in the interim. This poses several interesting questions, such as whether subjective utterances are more or less likely to be found in email exchanges compared with meetings, and whether the ratios of positive and negative subjective utterances differ between the two modalities.

In this paper we describe a novel approach for predicting subjectivity, and test it in two sets of experiments on meetings and emails. Our approach combines a new general purpose method for learning subjective patterns, with features that capture basic characteristics of conversation structure across modalities. The subjective patterns are essentially n-gram sequences with varying levels of lexical instantiation, and we demonstrate how they can be learned from both labeled and unlabeled data. The conversation features capture structural characteristics of multimodal conversations as well as participant information.

We test our approach in two sets of experiments. The goal of the first set of experiments is to discriminate subjective from non-subjective utterances, comparing the novel approach to existing state-of-the-art techniques. In the second set of experiments, the goal is to discriminate positive-subjective and negative-subjective utterances, establishing their polarity. In both sets of experiments, we assess the impact of features relating to conversation structure.

2 Related Research

Raaijmakers et al. (2008) have approached the problem of detecting subjectivity in meeting speech by using a variety of multimodal features such as prosodic features, word n-grams, character n-grams and phoneme n-grams. For subjectivity detection, they found that a combination of all features was best, while prosodic features were less useful for discriminating between positive and negative utterances. They found character n-grams to be particularly useful.

Riloff and Wiebe (2004) presented a method for learning subjective extraction patterns from a large amount of data, which takes subjective and non-subjective text as input, and outputs significant lexico-syntactic patterns. These patterns are based on syntactic structure output by the Sundance shal-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1348–1357,
Singapore, 6-7 August 2009.

low dependency parser (Riloff and Phillips, 2004). They are extracted by exhaustively applying syntactic templates such as $< subj >$ *passive-verb* and *active-verb* $< dobj >$ to a training corpus, with an extracted pattern for every instantiation of the syntactic template. These patterns are scored according to probability of relevance given the pattern and frequency of the pattern. Because these patterns are based on syntactic structure, they can represent subjective expressions that are not fixed word sequences and would therefore be missed by a simple n-gram approach.

Riloff et al. (2006) explore feature subsumption for opinion detection, where a given feature may subsume another feature representationally if the strings matched by the first feature include all of the strings matched by the second feature. To give their own example, the unigram *happy* subsumes the bigram *very happy*. The first feature will *behaviorally* subsume the second if it representationally subsumes the second and has roughly the same information gain, within an acceptable margin. They show that they can improve opinion analysis results by modeling these relations and reducing the feature set.

Our approach for learning subjective patterns like Raaijmakers et al. relies on n-grams, but like Riloff et al. moves beyond fixed sequences of words by varying levels of lexical instantiation.

Yu and Hatzivassiloglou (2003) addressed three challenges in the news article domain: discriminating between objective documents and subjective documents such as editorials, detecting subjectivity at the sentence level, and determining polarity at the sentence level. They found that the latter two tasks were substantially more difficult than classification at the document level. Of particular relevance here is that they found that part-of-speech (POS) features were especially useful for assigning polarity scores, with adjectives, adverbs and verbs comprising the best set of POS tags. This work inspired us to look at generalization of n-grams based on POS.

On the slightly different task of classifying the intensity of opinions, Wilson et al. (2006) employed several types of features including dependency structures in which words can be backed off to POS tags. They found that this feature class improved the overall accuracy of their system.

Somasundaran et al. (2007) investigated subjectivity classification in meetings. Their findings indicate that both lexical features (list of words and expressions) and discourse features (dialogue acts and adjacency pairs) can be beneficial. In the same spirit, we effectively combine lexical patterns and conversational features.

The approach to predicting subjectivity we present in this paper is a novel contribution to the field of opinion and sentiment analysis. Pang and Lee (2008) give an overview of the state of the art, discussing motivation, features, approaches and available resources.

3 Subjectivity Detection

In this section we describe our approach to subjectivity detection. We begin by describing how to learn subjective n-gram patterns with varying levels of lexical instantiation. We then describe a set of features characterizing multimodal conversation structure which can be used to supplement the n-gram approach. Finally, we describe the baseline subjectivity detection approaches used for comparison.

3.1 Partially Instantiated N-Grams

Our approach to subjectivity detection and polarity detection is to learn significant patterns that correlate with the subjective and polar utterances. These patterns are word trigrams, but with varying levels of lexical instantiation, so that each unit of the n-gram can be either a word or the word's part-of-speech (POS) tag. This contrasts, then, with work such as that of Raaijmakers et al. (2008) who include trigram features in their experiments, but where their learned trigrams are fully instantiated. As an example, while they may learn that a trigram *really great idea* is positive, we may additionally find that *really great NN* and *RB great NN* are informative patterns, and these patterns may sometimes be better cues than the fully instantiated trigrams. To differentiate this approach from the typical use of trigrams, we will refer to it as the VIN (*varying instantiation n-grams*) method.

In some respects, our approach to subjectivity detection is similar to Riloff and Wiebe's work cited above, in the sense that their extraction patterns are partly instantiated. However, the AutoSlog-TS approach relies on deriving syntactic structure with the Sundance shallow parser (Riloff and Phillips, 2004). We hypothesize that our trigram approach may be more robust to disfluent and fragmented meeting speech and emails

1	2	3
really	great	idea
really	great	NN
really	JJ	idea
RB	great	idea
really	JJ	NN
RB	great	NN
RB	JJ	idea
RB	JJ	NN

Table 1: Sample Instantiation Set

on which syntactic parsers may perform poorly. Also, our learned trigram patterns range from fully instantiated to completely uninstantiated. For example, we might find that the pattern *RB JJ NN* is a very good indicator of subjective utterances because it matches a variety of scenarios where people are ascribing qualities to things, e.g. *really bad movie*, *horribly overcooked steak*. Notice that we do not see our approach and AutoSlog-TS as mutually exclusive, and indeed we demonstrate through these experiments that they can be effectively combined.

Our approach begins by running the Brill POS tagger (Brill, 1992) over all sentences in a document. We then extract all of the word trigrams from the document, and represent each trigram using every possible instantiation. Because we are working at the trigram level, and each unit of the trigram can be a word or its POS tag there are $2^3 = 8$ representations in each trigram's instantiation set. To continue the example from above, the instantiation set for the trigram *really great idea* is given in Table 1. As we scan down the instantiation set, we can see that the level of abstraction increases until it is completely uninstantiated. It is this multilevel abstraction that we are hypothesizing will be useful for learning new subjective and polar cues.

All trigrams are then scored according to their prevalence in relevant versus irrelevant documents (e.g. subjective vs. non-subjective sentences), following the scoring methodology of Riloff and Wiebe (2003). We calculate the conditional probability $p(relevance|trigram)$ using the actual trigram counts in relevant and irrelevant text. For learning negative-subjective patterns, we treat all negative sentences as the relevant text and the remainder of the sentences as irrelevant text, and conduct the same process for learning positive-subjective patterns. We consider significant patterns to be those where the conditional probability is greater than 0.65 and the pattern occurs more than five times in the entire document set (slightly higher than $probability >= 0.60$ and $frequency >= 2$ used by Riloff and Wiebe (2003)).

We possess a fairly small amount of conversational data annotated for subjectivity and polarity. The AMI meeting corpus and BC3 email corpus are described in more detail in Section 4.1. To address this shortfall in annotated data, we take two approaches to learning patterns. In the first, we learn a set of patterns from the annotated conversation data. In the second approach, we complement those patterns by learning additional patterns from unannotated data that are typically overwhelmingly subjective or objective in nature. We describe these two approaches here in turn.

3.1.1 Supervised Learning of Patterns from Conversation Data

The first learning strategy is to apply the above-described methods to the annotated conversation data, learning the positive patterns by comparing *positive-subjective* utterances to all other utterances, and learning the negative patterns by comparing the *negative-subjective* utterances to all other utterances, using the described methods. This results in 759 significant positive patterns and 67 significant negative patterns. This difference in pattern numbers can be explained by negative utterances being less common in the AMI meetings, as noted by Wilson (2008). It may be that people are less comfortable in expressing negative sentiments in face-to-face conversations, particularly when the meeting participants do not know each other well (in the AMI scenario meetings, many participants were meeting each other for the first time). But there may be a further explanation for why we learn many more positive than negative patterns. When conversation participants *do* express negative sentiments, they may couch those sentiments in more euphemistic or guarded terms compared with positive sentiments. Table 2 gives examples of significant positive and negative patterns learned from the labeled meeting data. The last two rows in Table 2 show how two patterns in the same instantiation set can have substantially different probabilities.

POS	$p(r\|t)$	NEG	$p(r\|t)$

RB think that	0.95
RB agree with	0.95
IN PRP opinion	0.95

Table 3: Example Subjective Patterns (BLOG06)

3.1.2 Unsupervised Learning of Patterns from Blog Data

The second pattern learning strategy we take to learning subjective patterns is to use a relevant, but unannotated corpus. We focus on weblog (blog) data for several reasons. First, blog posts share many characteristics with both meetings and emails: they are conversational, informal and the language can be very ungrammatical. Second, blog posts are known for being subjective; bloggers post on issues that are passionate to them, offering arguments, opinions and invective. Third, there is a huge amount of available blog data. But because we do not possess blog data annotated for subjectivity, we take the following approach to learning subjective patterns from this data. We work on the assumption that a great many blog posts are inherently subjective, and that comparing this data to inherently *objective* text such as newswire articles, treating the latter as our irrelevant text, should lead to the detection of many new subjective patterns and greatly increase our coverage. While the patterns learned will be noisy, we hypothesize that the increased coverage will improve our subjectivity detection overall.

For our blog data, we use the BLOG06 Corpus[1] that was featured as training and testing data for the Text Analysis Conference (TAC) 2008 track on summarizing blog opinions. The portion used totals approximately 4,000 documents on all manner of topics. Treating that dataset as our relevant, subjective data, we then learn the subjective trigrams by comparing with the *irrelevant* TAC/DUC newswire data from the 2007 and 2008 update summarization tasks. To try to reduce the amount of noise in our learned patterns, we set the conditional probability threshold at 0.75 (vs. 0.65 for annotated data), and stipulate that all significant patterns must occur at least once in the irrelevant text. This last rule is meant to prevent us from learning completely blog-specific patterns such as *posted by NN* or *linked to DT*. In the end, more than 20,000 patterns were learned from the blog data. While manual inspection does show that many undesirable patterns were extracted, among the highest-scoring patterns are many sensible subjective trigrams such as those indicated in Table 3.

This approach is similar in spirit to the work of Biadsy et al. (2008) on unsupervised biography production. Without access to labeled biographical data, the authors chose to use sentences from Wikipedia biographies as their positive set and sentences from newswire articles as their negative set, on the assumption that most of the Wikipedia sentences would be relevant to biographies and most of the newswire sentences would not.

3.2 Deriving VIN Features

For our machine learning experiments, we derive, for each sentence, features indicating the presence of the significant VIN patterns. Patterns are binned according to their conditional probability range (i.e., $0.65 <= p < 0.75$, $0.75 <= p < 0.85$, $0.85 <= p < 0.95$, and $0.95 <= p$). There are three bins for the blog patterns, since the probability cutoff is 0.75 For each bin, there is a feature indicating the count of its patterns in the given sentence. When attempting to match these trigram patterns to sentences, we allow up to two wildcard lexical items between the trigram units. In this way a sentence can match a learned pattern even if the units of the n-gram are not contiguous (Raaijmakers et al. (2008) similarly include an n-gram feature allowing such intervening material).

A key reason for counting the number of matched patterns for each probability range as just described, rather than including a feature for each individual pattern, is to maintain the same level of dimensionality in our machine learning experiments when comparing the VIN approach to the baseline approaches described in Section 3.4.

[1] http://ir.dcs.gla.ac.uk/test_collections/blog06info.html

3.3 Conversational Features

While we hypothesize that the general purpose pattern-based approach described above will greatly aid subjectivity and polarity detection, we also recognize that there are many additional features specific for characterizing multimodal conversations that may correlate well with subjectivity and polarity. Such features include structural characteristics like the position of a sentence in a turn and the position of a turn in the conversation, and participant features relating to dominance or leadership. For example, it may be that subjective sentences are more likely to come at the end of a conversation, or that a person who dominates the conversation may utter more negative sentences.

We use the feature set provided by Murray and Carenini (2008), which they used for automatic summarization of conversations and which are shown in Table 4. Many of the features are based on so-called $Sprob$ and $Tprob$ term-weights, the former of which weights words based on their distributions across conversation participants and the latter of which similarly weights words based on their distributions across conversation turns. Other features include word entropy of the candidate sentence, lexical cohesion of the sentence with the greater conversation, and structural features indicating position of the candidate sentence in the turn and in the conversation, such as the elapsed time since the beginning of the conversation.

Feature ID	Description
MXS	max *Sprob* score
MNS	mean *Sprob* score
SMS	sum of *Sprob* scores
MXT	max *Tprob* score
MNT	mean *Tprob* score
SMT	sum of *Tprob* scores
TLOC	position in turn
CLOC	position in conv.
SLEN	word count, globally normalized
SLEN2	word count, locally normalized
TPOS1	time from beg. of conv. to turn
TPOS2	time from turn to end of conv.
DOM	participant dominance in words
COS1	cosine of conv. splits, w/ *Sprob*
COS2	cosine of conv. splits, w/ *Tprob*
PENT	entropy of conv. up to sentence
SENT	entropy of conv. after the sentence
THISENT	entropy of current sentence
PPAU	time btwn. current and prior turn
SPAU	time btwn. current and next turn
BEGAUTH	is first participant (0/1)
CWS	rough ClueWordScore (cohesion)
CENT1	cos. of sentence & conv., w/ *Sprob*
CENT2	cos. of sentence & conv., w/ *Tprob*

Table 4: Features Key

3.4 Baseline Approaches

There are two baselines in particular to which we are interested in comparing the VIN approach. As stated earlier, we are hypothesizing that the increasing levels of abstraction found with partially instantiated trigrams will lead to improved classification compared with using only fully instantiated trigrams. To test this, we also run the subjective/non-subjective and positive/negative experiments using *only* fully instantiated trigrams. There are 71 such positive trigrams and 5 such negative trigrams learned from the AMI data. There are just over 1200 fully instantiated trigrams learned from the unannotated BLOG06 data.

Believing that the current approach may offer benefits over state-of-the-art pattern-based subjectivity detection, we also implement the AutoSlog-TS method of Riloff and Wiebe (2003) for extracting subjective extraction patterns. In AutoSlog-TS, once all of the patterns are extracted using the Sundance parser, the scoring methodology is much the same as desribed in Section 3.1. Conditional probabilities are calculated by comparing pattern occurrences in the relevant text with occurrences in all text, and we again use a threshold of $p >= 0.65$ and $frequency >= 5$ for significant patterns. For the BLOG06 data, we use a probability cutoff of 0.75 as before. For deriving the features used in our machine learning experiments, the patterns are similarly grouped according to conditional probability. From the annotated data, 48 patterns are learned in total, 46 positive and only 2 negative. From the BLOG06 data, more than 3000 significant patterns are learned. Among significant patterns learned from the AMI corpus are $< subj >$ *BE good*, *change* $< dobj >$, $< subj >$ *agree* and *problem with* $< NP >$.

To gauge the effectiveness of the various feature types, for both sets of experiments we build multiple models on a variety of feature combinations: fully instantiated trigrams (TRIG), varying instantiation n-grams (VIN), AutoSlog-TS (SLOG), conversational structure features (CONV), and the set of all features.

4 Experimental Setup

In this section we describe the corpora used, the relevant subjectivity annotation, and the statistical

classifiers employed.

4.1 Corpora

We use two annotated corpora for these experiments. The AMI corpus (Carletta et al., 2005) consists of meetings in which participants take part in role-playing exercises concerning the design and development of a remote control. Participants are grouped in fours, and each group takes part in a sequence of four meetings, bringing the remote control from design to market. The four members of the group are assigned roles of project manager, industrial designer, user interface designer, and marketing expert. In total there are 140 such scenario meetings, with individual meetings ranging from approximately 15 to 45 minutes.

The BC3 corpus (Ulrich et al., 2008) contains email threads from the World Wide Web Consortium (W3C) mailing list. The threads feature a variety of topics such as web accessibility and planning face-to-face meetings. The annotated portion of the mailing list consists of 40 threads.

4.2 Subjectivity Annotation

Wilson (2008) has annotated 20 AMI meetings for a variety of subjective phenomena which fall into the broad classes of *subjective utterances*, *objective polar utterances* and *subjective questions*. It is this first class in which we are primarily interested here. Two subclasses of subjective utterances are *positive subjective* and *negative subjective* utterances. Such subjective utterances involve the expression of a private state, such as a positive/negative opinion, positive/negative argument, and agreement/disagreement. The 20 meetings were labeled by a single annotator, though Wilson (2008) did conduct a study of annotator agreement on two meetings, reporting a κ of 0.56 for detecting subjective utterances. Of the roughly 20,000 dialogue acts total in the 20 AMI meetings, nearly 4000 are labeled as *positive-subjective* and nearly 1300 as *negative-subjective*. For the first experimental task, we consider the subjective class to be the union of positive-subjective and negative-subjective dialogue acts. For the second experimental task, the goal is to discriminate positive-subjective from negative-subjective.

For the BC3 emails, annotators were initially asked to create extractive and abstractive summaries of each thread, in addition to labeling a variety of sentence-level phenomena, including whether each sentence was subjective. In a second round of annotations, three different annotators were asked to go through all of the sentences previously labeled as subjective and indicate whether each sentence was *positive*, *negative*, *positive-negative*, or *other*. The definitions for positive and negative subjectivity mirrored those given by Wilson (2008). For the purpose of these experiments, we consider a sentence to be subjective if at least two of the annotators labeled it as subjective, and similarly consider a subjective sentence to be positive or negative if at least two annotators label it as such. Using this majority vote labeling, 172 of 1800 sentences are considered subjective, with 44% of those labeled as *positive-subjective* and 37% as *negative-subjective*, showing that there is much more of a balance between positive and negative sentiment in these email threads compared with meeting speech (note that some subjective sentences are not positive or negative). The κ for labeling subjective sentences in the email corpus is 0.32. The lower annotator agreement on emails compared with meetings suggests that subjectivity in email text may be manifested more subtly or conveyed somewhat amibiguously.

4.3 Classifier and Experimental Setup

For these experiments we use a maximum entropy classifier using the *liblinear* toolkit[2] (Fan et al., 2008). Feature subset selection is carried out by calculating the F-statistic for each feature, ranking the features according to the statistic, and training on increasingly smaller subsets of feature in a cross-validation procedure, ultimately choosing the feature set with the highest balanced accuracy during cross-validation.

Because the annotated portions of our corpora are fairly small (20 meetings, 40 email threads), we employ a leave-one-out method for training and testing rather than using dedicated training and test sets. For the polarity labeling task applied to the BC3 corpus, we pool all of the sentences and perform 10-fold cross-validation at the sentence level.

4.4 Evaluation Metrics

We employ two sets of metrics for evaluating all classifiers: precision/recall/f-measure and the receiver operator characteristic (ROC) curve. The ROC curve plots the true-positive/false-positive ratio while the posterior threshold is varied, and

[2] http://www.csie.ntu.edu.tw/ cjlin/liblinear/

we report the area under the curve (AUROC) as the measure of interest. Random performance would feature an AUROC of approximately 0.5, while perfect classification would yield an AUROC of 1. The advantage of the AUROC score compared with precision/recall/f-measure is that it evaluates a given classifier across all thresholds, indicating the classifier's overall discriminating power. This metric is also known to be appropriate when class distributions are skewed (Fawcett, 2003), as is our case. For completeness we report both AUROC and p/r/f, but our discussions focus primarily on the AUROC comparisons.

5 Results

In this section we describe the experimental results, first for the subjective/non-subjective classification task, and subsequently for the positive-negative classification task.

5.1 Subjective / Non-Subjective Classification

For the subjectivity detection task, the results on the AMI and BC3 data closely mirrored each other, with the VIN approach constituting a very effective feature set, outperforming both baselines. We report the results on meeting and emails in turn.

5.1.1 AMI corpus

For the subjectivity task with the AMI corpus, we first report the precision, recall and f-measure results in Table 5 where the various classifiers are compared with a lower bound (LB) in which the positive class is always predicted, leading to perfect recall. It can be seen that the novel systems exhibit substantial improvement in precision and f-measure over this lower-bound. While the VIN approach yields the best precision scores, the full feature set achieves the highest f-measure.

As shown in Figure 1, the average AUROC with the VIN approach is 0.69, compared with 0.61 for AutoSlog-TS, a significant difference according to paired t-test ($p<0.01$). The VIN approach is also significantly better than the standard fully instantiated trigram pattern approach ($p<0.01$). This latter result suggests that the increased level of abstraction found in the varying instantiation n-grams does improve performance.

The conversational features alone give comparable performance to the VIN method (no significant difference), and the best results are found using the full feature set, which gives an average AUROC of 0.71, a significant improvement over VIN only ($p<0.05$).

Sys	Precision	Recall	F-Measure
AMI Corpus			
LB	26	100	41

All Feas	33	34	33

Table 5: P/R/F Results, Subjectivity Task

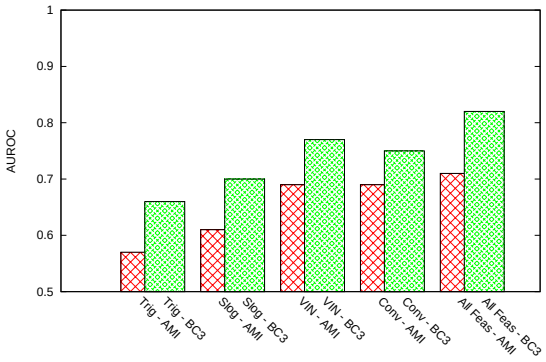

Figure 1: AUROCs on Subjectivity Task for AMI and BC3 corpora

5.1.2 BC3 corpus

For the subjectivity task with the BC3 corpus, the best precision and f-measure scores are found by combining all features, as displayed in Table 5. The f-measure for the VIN approach is ten points higher than for the standard trigram approach.

The average AUROC with the VIN approach is 0.77, compared with 0.70 for AutoSlog-TS (significant at $p<0.05$). The varying instantiation approach is significantly better than the standard trigram pattern approach ($p<0.01$), where the average AUROC is 0.66. We again find that conversational features are very useful for this task, and that the best overall results utilize the entire feature set. These results are displayed in Figure 1.

5.1.3 Impact of Blog Data

An interesting question is whether our use of the BLOG06 data was worthwhile. We can measure this by comparing the VIN AUROC results re-

Table 6: P/R/F Results, Polarity Task

ported above with the VIN AUROC scores using only the annotated data for learning the significant patterns. The finding is that the blog data was very helpful, as the VIN approach averages only 0.66 on the BC3 data and 0.63 on the AMI data when the blog patterns are *not* used, both significantly lower ($p<0.01$). Figure 2 shows the ROC curves for the VIN approach with and without blog patterns applied to the AMI subjectivity detection task, illustrating the impact of the unsupervised pattern-learning strategy.

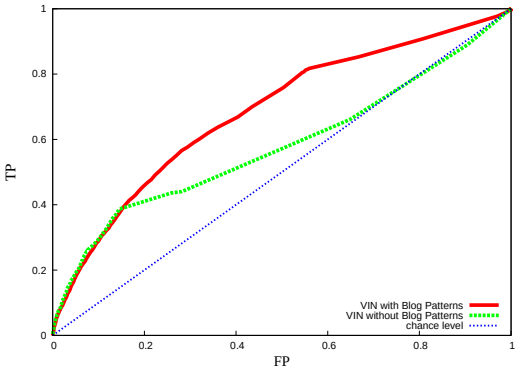

Figure 2: Effect of Blog Patterns on AMI Subjectivity Task

5.2 Positive / Negative Classification

For the polarity classification task, the results differ between the two corpora. We describe the results on meetings and emails in turn.

5.2.1 AMI corpus

The p/r/f results for the AMI polarity task are presented in Table 6, with the scores pertaining to the positive-subjective class. The VIN classifier and full features classifier achieve the highest precision, but the f-measures are below the lower-bound.

Comparing AUROC results, the VIN approach is again significantly better than AutoSlog-TS, averaging 0.65 compared with 0.56, and significantly better than the standard trigram approach ($p<0.01$ in both cases). The results are displayed in Figure 3. The conversational features are significantly less effective than the VIN features ($p<0.05$), and the best overall results are found by utilizing all features, with significant improvement over VIN only at $p<0.05$ and significant improvement over AutoSlog-TS only at $p<0.01$.

5.2.2 BC3 corpus

The results of the polarity task on the BC3 corpus are markedly different from the other experimental results. In this case, neither VIN nor AutoSlog-TS are particularly good for discriminating between positive and negative sentences, and the best strategy is to use features relating to conversational structure. According to p/r/f (Table 6), the only method outperforming the lower-bound in terms of f-measure is the conversational features classifier. According to AUROC scores shown in Figure 3, the conversational features by themselves are significantly better than the VIN approach ($p<0.01$ for non-paired t-test). So for emails, we are more likely to correctly classify positive and negative sentence by looking at features such as position in the turn and participant dominance than by matching our learned patterns. While we showed previously that pattern-based approaches perform well for the subjectivity task on this dataset, there was less success in using the patterns to discern the polarity of email sentences.

We are again interested in whether the use of the BLOG06 data was beneficial. For the BC3 data, there is very little difference between the VIN approach with and without the blog patterns, as they both perform poorly, but with the AMI corpus, the blog patterns yield significant improvement in polarity classification, increasing from an average of 0.56 without the blog patterns to 0.65 with them ($p<0.01$).

6 Discussion and Future Work

A key difference between the AMI and BC3 data with regards to subjectivity is that negative utterances are much more common in the BC3 email threads. Additionally, the pattern-based approaches fared worst in discriminating between

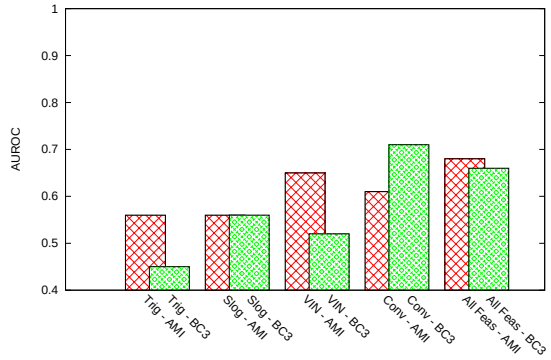

Figure 3: AUROCs on Polarity Task for AMI and BC3 corpora

negative and positive utterances in that corpus. Positive and negative email sentences are more easily recognized via features relating to conversation structure and participant status than through the learned lexical patterns.

The use of patterns learned from unlabeled blog data significantly improved performance. We are currently developing further techniques for learning subjective and polar patterns from such raw, natural text.

A potential area of improvement is to reduce the feature set by eliminating some of the subjective patterns. In Section 2, we briefly described the work of Riloff et al. (2006) on feature subsumption relationships. In our case, in a VIN instantiation set a given trigram instantiation subsumes the less abstract instantiations in the set, so the most abstract instantiation (i.e. completely uninstantiated trigram) representationally subsumes the rest. Eliminating some of the representationally subsumed instantiations when they are also behaviorally subsumed may improve our results.

It is difficult to compare our results directly with those of Raaijmakers et al. (2008) as they used a smaller set of AMI meetings for their experiments, and because for the first experiment we consider the subjective class to be the union of positive-subjective and negative-subjective dialogue acts whereas they additionally include subjective questions and dialogue acts expressing uncertainty. These differences are reflected by the substantially differing scores reported for majority-vote baselines on each task. However, their success with character n-gram features suggests that we could improve our system by incorporating a variety of character features. Character n-grams were the best single feature class in their experiments.

The VIN representation is a general one and may hold promise for learning patterns relevant to other interesting conversation phenomena such as decision-making and action items. We plan to apply the methods described here to these other applications in the near future.

7 Conclusion

In this work we have shown that learning subjective trigrams with varying instantiation levels from both annotated and raw data can improve subjectivity detection and polarity labeling for meeting speech and email threads. The novel pattern-based approach was significantly better than standard trigrams for three of the four tasks, and was significantly better than a state-of-the-art syntactic approach for those same tasks. We also found that features relating to conversational structure were beneficial for all tasks, and particularly for polarity labeling in email data. Interestingly, in three out of four cases combining all the features produced the best performance.

Abstract

We propose a novel language-independent approach for improving statistical machine translation for resource-poor languages by exploiting their similarity to resource-rich ones. More precisely, we improve the translation from a resource-poor source language X_1 into a resource-rich language Y given a bi-text containing a limited number of parallel sentences for X_1-Y and a larger bi-text for X_2-Y for some resource-rich language X_2 that is closely related to X_1. The evaluation for Indonesian→English (using Malay) and Spanish→English (using Portuguese and pretending Spanish is resource-poor) shows an absolute gain of up to 1.35 and 3.37 Bleu points, respectively, which is an improvement over the rivaling approaches, while using much less additional data.

1 Introduction

Recent developments in statistical machine translation (SMT), *e.g.*, the availability of efficient implementations of integrated open-source toolkits like Moses (Koehn et al., 2007), have made it possible to build a prototype system with decent translation quality for any language pair in a few days or even hours. In theory. In practice, doing so requires having a large set of parallel sentence-aligned bi-lingual texts (a *bi-text*) for that language pair, which is often unavailable. Large high-quality bi-texts are rare; except for Arabic, Chinese, and some official languages of the European Union (EU), most of the 6,500+ world languages remain resource-poor from an SMT viewpoint.

While manually creating a small bi-text could be relatively easy, building a *large* one is hard, *e.g.*, because of copyright. Most bi-texts for SMT come from parliament debates and legislation of multi-lingual countries (*e.g.*, French-English from Canada, and Chinese-English from Hong Kong), or from international organizations like the United Nations and the European Union. For example, the *Europarl* corpus of parliament proceedings consists of about 1.3M parallel sentences (up to 44M words) per language for 11 languages (Koehn, 2005), and the *JRC-Acquis* corpus provides a comparable amount of European legislation in 22 languages (Steinberger et al., 2006).

The official languages of the EU are especially lucky in that respect; while this includes such "classic SMT languages" like English and French, and some important international ones like Spanish and Portuguese, most of the rest have a limited number of speakers and were resource-poor until recently; this is changing quickly because of the increasing volume of EU parliament debates and the ever-growing European legislation. Thus, becoming an official language of the EU has turned out to be an easy recipe for getting resource-rich in bi-texts quickly. Of course, not all languages are that 'lucky', but many can still benefit.

In this paper, we propose using bi-texts for resource-rich language pairs to build better SMT systems for resource-poor ones by exploiting the similarity between a resource-poor language and a resource-rich one.

The proposed method allows non-EU languages to benefit from being closely related to one or more official languages of the EU, the most obvious candidates being Norwegian (related to Swedish), Moldavian[1] (related to Romanian), and Macedonian[2] (related to Bulgarian). After Croatia joins the EU, Serbian, Bosnian and Montenegrin will be able to benefit from Croatian gradually turning resource-rich (all four split from Serbo-Croatian after the breakup of Yugoslavia). The newly-made EU-official (and thus not as resource-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1358–1367,
Singapore, 6-7 August 2009.

rich) Czech and Slovak are another possible pair of candidates. As we will see below, even such resource-rich languages like Spanish and Portuguese can benefit from the proposed method. Of course, many pairs of closely related languages can be also found outside of Europe, Malay and Indonesian being just one such example we will experiment with.

The remainder of the present paper is organized as follows: Section 2 presents our method, Section 3 describes the experiments, and Section 4 discusses the results and the general applicability of the approach. Section 5 provides an overview of the related work. Finally, Section 6 concludes and suggests possible directions for future work.

2 Method

We propose a novel language-independent approach for improving statistical machine translation for resource-poor languages by exploiting their similarity to resource-rich ones. More precisely, we improve the translation from a resource-poor source language X_1 into a resource-rich target language Y given a bi-text containing a limited number of parallel sentences for X_1-Y and a much larger bi-text for X_2-Y for some resource-rich language X_2 that is closely related to X_1.

Our method exploits the similarity between related languages with respect to word order, syntax, and, most importantly, vocabulary overlap – related languages share a large number of cognates.

Before we present the method, we will describe two simple strategies for integrating the bi-text for X_2-Y into a phrase-based SMT system for X_1-Y.

2.1 Merging Bi-texts

We can simply concatenate the bi-texts for X_1-Y and X_2-Y into one large bi-text and use it to train an SMT system.

This offers several advantages. First, it can yield improved word alignments for the sentences that came from the X_1-Y bi-text, *e.g.*, since the additional sentences can provide new contexts for the rare words in that bi-text; rare words are hard to align, which could have a disastrous effect on the subsequent phrase extraction stage. Second, it can provide new source-language side translation options, thus increasing the lexical coverage and reducing the number of unknown words at translation time; it can also provide new useful non-compositional phrases on the source-language side, thus yielding more fluent translation output. Third, it can offer new target-language side phrases for known source phrases, which could improve fluency by providing more translation options for the language model (LM) to choose from. Fourth, bad phrases including words from X_2 that do not exist in X_1 will be effectively ignored at translation time since they could never possibly match the input, while bad new target-language translations still have the chance to be filtered out by the language model.

However, simple concatenation can be problematic. First, when concatenating the small bi-text for X_1-Y with the much larger one for X_2-Y, the latter will dominate during word alignment and phrase extraction, thus hugely influencing both lexical and phrase translation probabilities, which can yield poor performance. This can be counteracted by repeating the small bi-text several times so that the large one does not dominate. Second, since the bi-texts are merged mechanically, there is no way to distinguish between phrases extracted from the bi-text for X_1-Y (which should be good), from those coming from the bi-text for X_2-Y (whose quality might be questionable).

2.2 Combining Phrase Tables

An alternative way of making use of the additional bi-text for X_2-Y to train an improved SMT system for $X_1 \rightarrow Y$ is to build separate phrase tables from X_1-Y and X_2-Y, which can then be (a) used together, *e.g.*, as alternative decoding paths, (b) merged, *e.g.*, using one or more extra features to indicate the bi-text each phrase came from, or (c) interpolated, *e.g.*, using simple linear interpolation.

Building two separate phrase tables offers several advantages. First, the good phrases from the bi-text for X_1-Y are clearly distinguished from (or given a higher weight in the linear interpolation compared to) the potentially bad ones from the X_2-Y bi-text. Second, the lexical and the phrase translation probabilities are combined in a principled manner. Third, using an X_2-Y bi-text that is much larger than that for X_1-Y is not problematic any more. Fourth, as with bi-text merging, there are many additional source- and target-language phrases, which offer new translation options.

On the negative side, the opportunity is lost to obtain improved word alignments for the sentences in the X_1-Y bi-text.

2.3 Proposed Method

Taking into account the potential advantages and disadvantages of the above strategies, we propose a method that tries to get the best of both: (i) increased lexical coverage by using additional phrase pairs independently extracted from X_2-Y, and (ii) improved word alignments for X_1-Y by biasing the word alignment process with additional sentence pairs from X_2-Y (possibly also repeating X_1-Y several times). A detailed description of the method follows:

1. Build a bi-text B_{cat} that is a concatenation of the bi-texts for X_1-Y and X_2-Y. Generate word alignments for B_{cat}, extract phrases, and build a phrase table T_{cat}.

2. Build a bi-text B_{rep} from the X_1-Y bi-text repeated k times followed by one copy of the X_2-Y bi-text. Generate word alignments for B_{rep}, then truncate them, only keeping word alignments for one copy of the X_1-Y bi-text. Use these word alignments to extract phrases, and build a phrase table T_{rep_trunc}.

3. Produce a phrase table T_{merged} by combining T_{cat} and T_{rep_trunc}, giving priority to the latter, and use it in an $X_1 \rightarrow Y$ SMT system.

2.4 Transliteration

As we mentioned above, our method relies on the existence of a large number of *cognates* between related languages. While linguists define cognates as words derived from a common root[3] (Bickford and Tuggy, 2002), *computational* linguists typically ignore origin, defining them as words in different languages that are mutual translations and have a similar orthography (Bergsma and Kondrak, 2007; Mann and Yarowsky, 2001; Melamed, 1999). In this paper, we adopt the latter definition.

Cognates between related languages often exhibit minor spelling variations, which can be simply due to different rules of orthography, (*e.g.*, *senhor vs. señor* in Portuguese and Spanish), but often stem from real phonological differences. For example, the Portuguese suffix *-ção* corresponds to the Spanish suffix *-ción*, *e.g.*, *evolução* vs. *evolución*. Such correspondences can be quite frequent and thus easy to learn automatically[4]. Even more frequent can be the inflectional variations. For example, in Portuguese and Spanish respectively, verb endings like *-ou* vs. *-ó* (for 3rd person singular, simple past tense), *e.g.*, *visitou* vs. *visitó*, or *-ei* vs. *-é* (for 1st person singular, simple past tense), *e.g.*, *visitei* vs. *visité*.

If such systematic differences exist between the languages X_1 and X_2, it might be useful to learn and to use them as a pre-processing step in order to transliterate the X_2 side of the X_2-Y bi-text and thus increase its vocabulary overlap with the source language X_1.

We will describe our approach to automatic transliteration in more detail in Section 3.4 below.

3 Experiments

3.1 Language Pairs

We experimented with two language pairs: the closely related Malay and Indonesian and the more dissimilar Spanish and Portuguese.

Malay and Indonesian are mutually intelligible, but differ in pronunciation and vocabulary. An example follows[5]:

- **Malay:** *Semua manusia dilahirkan bebas dan samarata dari segi kemuliaan dan hak-hak.*

- **Indonesian:** *Semua orang dilahirkan merdeka dan mempunyai martabat dan hak-hak yang sama.*

Spanish and Portuguese also exhibit a noticeable degree of mutual intelligibility, but differ in pronunciation, spelling, and vocabulary. Unlike Malay and Indonesian, however, they also differ syntactically and have a high degree of spelling differences as demonstrated by the following examples[6]:

- **Spanish:** *Señora Presidenta, estimados colegas, lo que está sucediendo en Oriente Medio es una tragedia.*

- **Portuguese:** *Senhora Presidente, caros colegas, o que está a acontecer no Medio Oriente é uma tragédia.*

[3] E.g., Latin *tu*, Old English *thou*, Spanish *tú*, Greek *sú* and German *du* are all cognates meaning '2^{nd} person singular'.

[4] Not all such differences are systematic; many apply to a particular word only, *e.g.*, *kerana vs. kareña* in Malay and Indonesian, or *dizer vs. decir* in Portuguese and Spanish.

[5] In English: *All human beings are born free and equal in dignity and rights.* (from Article 1 of the Universal Declaration of Human Rights)

[6] In English: *Madam President, ladies and gentlemen, the events in the Middle East are a real tragedy.*

3.2 Datasets

In our experiments, we used the following number of training sentence pairs (number of words shown in parentheses) for English (en), Indonesian (in), Malay (ml), Portuguese(pt), and Spanish (es):

- **Indonesian-English (*in-en*):**
  - 28,383 pairs (0.8M, 0.9M words);
  - monolingual English en_{in}: 5.1M words.
- **Malay-English (*ml-en*):**
  - 190,503 pairs (5.4M, 5.8M words);
  - monoling. English en_{ml}: 27.9M words.
- **Spanish-English (*es-en*):**
  - 1,240,518 pairs (35.7M, 34.6M words);
  - monolingual English $en_{es:pt}$: 45.3M words (the same as for *pt-en*).
- **Portuguese-English (*pt-en*):**
  - 1,230,038 pairs (35.9M, 34.6M words).
  - monolingual English $en_{es:pt}$: 45.3M words (the same as for *es-en*).

All of the above datasets contain sentences with up to 100 tokens. In addition, for each of the four language pairs, we have a development and a testing bi-text, each with 2,000 parallel sentence pairs. We made sure the development and the testing bi-texts shared no sentences with the training bi-texts; we further excluded from the monolingual English data all sentences from the English sides of the training and the development bi-texts.

The training bi-text datasets for *es-en* and *pt-en* were built from release v.3 of the *Europarl* corpus, excluding the Q4/2000 portion out of which we created our testing and development datasets.

We built the *in-en* bi-texts from texts that we downloaded from the Web. We translated the Indonesian texts to English using *Google Translate*, and we matched[7] them against the English texts using a cosine similarity measure and heuristic constraints based on document length in words and in sentences, overlap of numbers, words in uppercase, and words in the title. Next, we extracted pairs of sentences from the matched document pairs using *competitive linking* (Melamed, 2000), and we retained the ones whose similarity was above a pre-specified threshold. The *ml-en* was built in a similar manner.

[7]Note that the automatic translations were used for matching only; the final bi-text contained no automatic translations.

3.3 Baseline SMT System

In the baseline, we used the following setup: We first tokenized and lowercased both sides of the training bi-text. We then built separate directed word alignments for English$\rightarrow X$ and $X\rightarrow$English ($X\in\{$Indonesian, Spanish$\}$) using IBM model 4 (Brown et al., 1993), combined them using the *intersect+grow heuristic* (Och and Ney, 2003), and extracted phrase-level translation pairs of maximum length seven using the *alignment template approach* (Och and Ney, 2004). We thus obtained a phrase table where each pair is associated with five parameters: forward and reverse phrase translation probabilities, forward and reverse lexical translation probabilities, and phrase penalty.

We then trained a log-linear model using standard SMT feature functions: trigram language model probability, word penalty, distance-based[8] distortion cost, and the parameters from the phrase table. We set all weights by optimizing Bleu (Papineni et al., 2002) using minimum error rate training (MERT) (Och, 2003) on a separate development set of 2,000 sentences (Indonesian or Spanish), and we used them in a beam search decoder (Koehn et al., 2007) to translate 2,000 test sentences (Indonesian or Spanish) into English. Finally, we detokenized the output, and we evaluated it against a lowercased gold standard using Bleu[9].

3.4 Transliteration

As was mentioned in Section 2, transliteration can be helpful for languages with regular spelling differences. Thus, we built a system for transliteration from Portuguese into Spanish that was trained on a list of automatically extracted likely cognates. The system was applied on the Portuguese side of the *pt-en* training bi-text.

Classic approaches to automatic cognate extraction look for non-stopwords with similar spelling that appear in parallel sentences in a bi-text (Kondrak et al., 2003). In our case, however, we need to extract cognates between Spanish and Portuguese given *pt-en* and *es-en* bi-texts only, *i.e.*, without having a *pt-es* bi-text. Although it is easy to construct a *pt-es* bi-text from the Europarl corpus, we chose not to do so since, in general, synthe-

[8]We also tried lexicalized reordering (Koehn et al., 2005). While it yielded higher absolute Bleu scores, the relative improvement for a sample of our experiments was very similar to that achieved with distance-based re-ordering.

[9]We used version 11b of the NIST scoring tool: `http://www.nist.gov/speech/tools/`

sizing a bi-text for X_1-X_2 would be impossible: *e.g.*, it cannot be done for *ml-in* given our training datasets for *in-en* and *ml-en* since the English sides of these bi-texts have no sentences in common.

Thus, we extracted the list of likely cognates between Portuguese and Spanish from the training *pt-en* and *es-en* bi-texts using English as a pivot as follows: We started with IBM model 4 word alignments, from which we extracted four conditional lexical translation probabilities: $\Pr(p_j|e_i)$ and $\Pr(e_i|p_j)$ for Portuguese-English, and $\Pr(s_k|e_i)$ and $\Pr(e_i|s_k)$ for Spanish-English, where p_j, e_i and s_k stand for a Portuguese, an English and a Spanish word respectively. Following Wu and Wang (2007), we then induced conditional lexical translation probabilities $\Pr(p_j|s_k)$ and $\Pr(s_k|p_j)$ for Portuguese-Spanish as follows:

$$\Pr(p_j|s_k) = \sum_i \Pr(p_j|e_i, s_k)\Pr(e_i|s_k)$$

Assuming p_j is conditionally independent of s_k given e_i, we can simplify the above expression:

$$\Pr(p_j|s_k) = \sum_i \Pr(p_j|e_i)\Pr(e_i|s_k)$$

Similarly, for $\Pr(s_k|p_j)$, we obtain

$$\Pr(s_k|p_j) = \sum_i \Pr(s_k|e_i)\Pr(e_i|p_j)$$

We excluded all stopwords, words of length less than three, and those containing digits. We further calculated $\mathrm{Prod}(p_j, s_k) = \Pr(p_j|s_k)\Pr(s_k|p_j)$, and we excluded all Portuguese-Spanish word pairs (p_j, s_k) for which $\mathrm{Prod}(p_j, s_k) < 0.01$. From the remaining pairs, we extracted likely cognates based on $\mathrm{Prod}(p_j, s_k)$ and on the orthographic similarity between p_j and s_k.

Following Melamed (1995), we measured the orthographic similarity using the *longest common subsequence ratio* (LCSR), defined as follows:

$$\mathrm{LCSR}(s_1, s_2) = \frac{|\mathrm{LCS}(s_1,s_2)|}{\max(|s_1|,|s_2|)}$$

where $\mathrm{LCS}(s_1, s_2)$ is the *longest common subsequence* of s_1 and s_2, and $|s|$ is the length of s.

We retained as likely cognates all pairs for which LCSR was 0.58 or higher; that value was found by Kondrak et al. (2003) to be optimal for a number of language pairs in the *Europarl* corpus.

Finally, we performed *competitive linking* (Melamed, 2000), assuming that each Portuguese wordform had at most one Spanish best cognate match. Thus, using the values of $\mathrm{Prod}(p_j, s_k)$, we induced a fully-connected weighted bipartite graph. Then, we performed a greedy approximation to the maximum weighted bipartite matching in that graph (*i.e.*, competitive linking) as follows: First, we accepted as cognates the cross-lingual pair (p_j, s_k) with the highest $\mathrm{Prod}(p_j, s_k)$ in the graph, and we discarded p_j and s_k from further consideration. Then, we accepted the next highest-scored pair, and we discarded the involved wordforms and so forth. The process was repeated until there were no matchable pairs left.

As a result of the above procedure, we ended up with 28,725 Portuguese-Spanish cognate pairs, 9,201 (or 32%) of which had spelling differences. For each pair in the list of cognate pairs, we added spaces between any two adjacent letters for both wordforms, and we further appended the start and the end characters ^ and $. For example, the cognate pair *evolução – evolución* became

^ e v o l u ç ã o $ — ^ e v o l u c i ó n $

We randomly split the resulting list into a training (26,725 pairs) and a development dataset (2,000 pairs), and trained and tuned a character-level phrase-based monotone SMT system similar to (Finch and Sumita, 2008) to transliterate a Portuguese wordform into a Spanish wordform. We used a Spanish language model trained on 14M word tokens (obtained from the above-mentioned 45.3M-token monolingual English corpus after excluding punctuation, stopwords, words of length less than three, and those containing digits): one per line and character-separated with added start and end characters as in the above example. We set both the maximum phrase length and the language model order to ten; this value was found by tuning on the development dataset. The system was tuned using MERT, and the feature weights were saved. The tuning Bleu was 95.22%, while the baseline Bleu, for leaving the Portuguese words intact, was 87.63%. Finally, the training and the tuning datasets were merged, and a new training round was performed. The resulting system was used with the saved feature weights to transliterate the Portuguese side of the training *pt-en* bi-text, which yielded a new pt_{es}-*en* training bi-text.

We did the same for Malay into Indonesian. We extracted 5,847 cognate pairs, 844 (or 14.4%) of which had spelling differences, and we trained a transliteration system. The highest tuning Bleu was 95.18% (for maximum phrase size and LM order of 10), but the baseline was 93.15%. We then re-trained the system on the combination of the training and the development datasets, and we transliterated the Malay side of the training *ml-en* bi-text, obtaining a new ml_{in}-*en* training bi-text.

Table 1: **Cross-lingual SMT experiments (shown in bold).** Columns 2-5 present the bi-texts used for training, development and testing, and the monolingual data used to train the English language model. The following columns show the resulting Bleu (in %s) for different numbers of training sentence pairs.

3.5 Cross-lingual Translation

In this subsection, we study the similarity between the original and the additional source languages.

First, we measured the vocabulary overlap between Spanish and Portuguese, which was feasible since our training *pt-en* and *es-en* bi-texts are from the same time span in the *Europarl* corpus and their English sides largely overlap. We found 110,053 Portuguese and 121,444 Spanish word types, and 44,461 (or 36.6%) of them were identical. Unfortunately, we could not do the same for Malay and Indonesian since the English sides of the *in-en* and *ml-en* bi-texts do not overlap.

Second, following the setup of the baseline system, we performed cross-lingual experiments. The results are shown in Table 1. As we can see, this yielded a huge decrease in Bleu compared to the baseline – three to five times – even for very large training datasets, and even when a proper English LM and development dataset were used: compare line 1 to lines 3-6, and line 7 to lines 9-11.

Third, we tried transliteration. Bleu doubled for Spanish (see lines 10-11), but improved far less for Indonesian (lines 5-6). Training on the transliterated data and testing on Malay and Portuguese yielded about 10-12% relative decrease for Malay (lines 1-2) but 50% for Portuguese (lines 7-8).[10] Thus, unlike Spanish and Portuguese, there were far less systematic spelling variations between Malay and Indonesian. A closer inspection confirmed this: many extracted likely Malay-Indonesian cognate pairs with spelling differences were in fact forms of a word existing in both languages, *e.g.*, *kata* and *berkata* ('*to say*').

[10]However, as lines 8 and 11 show, a system trained on 1.23M pt_{es}*-en* sentence pairs, performs equally well when translating Portuguese and Spanish text: 13.71% *vs.* 13.79%.

3.6 Using an Additional Language

We performed various experiments combining the original and an additional training bi-text:

Two-tables: We built two separate phrase tables for the two bi-texts, and we used them in the alternative decoding path model of Birch et al. (2007).

Interpolation: We built two separate phrase tables for the original and for the additional bi-text, and we used linear interpolation to combine the corresponding conditional probabilities: $\Pr(e|s) = \alpha \Pr_{orig}(e|s) + (1-\alpha)\Pr_{extra}(e|s)$. We optimized the value of α on the development dataset, trying .5, .6, .7, .8 and .9; we used the same α for all four conditional probabilities.

Merge: We built separate phrase tables, T_{orig} and T_{extra}, for the original and for the additional training bi-text. We then concatenated them giving priority to T_{orig}: We kept all phrase pairs from T_{orig}, adding to them those ones from T_{extra} that were not present in T_{orig}. For each phrase pair added, we retained its associated conditional probabilities and the phrase penalty. We further added three additional features to each entry in the new table: F_1, F_2 and F_3. The value of F_1 was 1 if the phrase pair came from T_{orig}, and 0.5 otherwise. Similarly, F_2=1 if the phrase pair came from T_{extra}, and F_2=0.5 otherwise. The value of F_3 was 1 if the pair came from both T_{orig} and T_{extra}, and 0.5 otherwise. We experimented using (1) F_1 only, (2) F_1 and F_2, (3) F_1, F_2, and F_3. We set all feature weights using MERT, and we optimized the number of features on the development set.[11]

[11]In theory, we should have also re-normalized the probabilities since they may not sum to one. In practice, this was not that important since the log-linear SMT model does not require that the features be probabilities at all (*e.g.*, the phrase penalty), and we had extra features whose impact was bigger.

Concat$\times k$: We concatenated k copies of the original and one copy of the additional training bi-text; we then trained and tuned an SMT system as for the baseline. The value for k was optimized on the development dataset.

Concat$\times k$**:align**: We concatenated k copies of the original and one copy of the additional training bi-text. We then generated IBM model 4 word alignments, and we truncated them, only keeping them for one copy of the original training bi-text. Next, we extracted phrase pairs, thus buildng a phrase table, and we tuned an SMT system as for the baseline.

Our Method: Our method was described in Section 2. We used **merge** to combine the phrase tables for **concat**$\times k$**:align** and **concat**$\times$**1**, considering the former as T_{orig} and the latter as T_{extra}. We had two parameters to tune: k and the number of extra features in the merged phrase table.

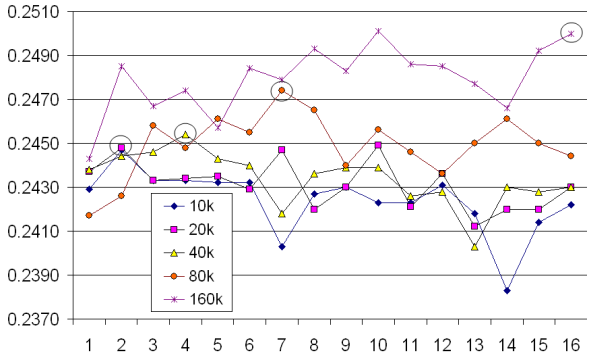

Figure 1: **Impact of k on Bleu for *concat*$\times k$ for different number of extra *ml-en* sentence pairs in Indonesian→English SMT.**

4 Results and Discussion

First, we studied the impact of k on **concat**$\times k$ for Indonesian→English SMT using Malay as an additional language. We tried all values of k such that $1 \leq k \leq 16$ with $10000n$ extra *ml-en* sentence pairs, $n \in \{1,2,4,8,16\}$. As we can see in Figure 1, the highest Bleu scores are achieved for $(n;k) \in \{(1;2),(2;2),(4;4),(8;7),(16;16)\}$, *i.e.*, when $k \approx n$. In order to limit the search space, we used this relationship between k and n in our experiments (also for Portuguese and Spanish).

Table 2 shows the results for experiments on improving Indonesian→English SMT using 10K, 20K, ..., 160K additional *ml-en* pairs of parallel sentences. Several observations can be made. First, using more additional sentences yields better results. Second, with one exception, all experiments yield improvements over the baseline. Third, the improvements are always statistically significant for **our method**, according to (Collins et al., 2005)'s sign test. Overall, among the different bi-text combination strategies, **our method** performs best, followed by **concat**$\times k$, **merge**, and **interpolate**, which are very close in performance; these three strategies are the only ones to consistently yield higher Bleu as the number of additional *ml-en* sentence pairs grows. Methods like **concat**$\times$1, **concat**$\times k$**:align** and **two-tables** are somewhat inconsistent in that respect. The latter method performs worst and is the only one to go below the baseline (for 10K *ml-en* pairs).

Table 3 shows the results when using *pt-en* data to improve Spanish→English SMT. Overall, the results and the conclusions that can be made are consistent with those for Table 2. We can further observe that, as the size of the original bi-text increases, the gain in Bleu decreases, which is to be expected. Note also that here transliteration is very important: it doubles the absolute gain in Bleu.

Finally, Table 4 shows a comparison to the pivoting technique of Callison-Burch et al. (2006). for English→Spanish SMT. Despite using just Portuguese, we achieve an improvement that is, in five out of six cases, much better than what they achieve with *eight* pivot languages (which include not only Portuguese, but also two other Romance languages, French and Italian, which are closely related to Spanish). Moreover, our method yields improvements for very large original datasets – 1.2M pairs, while theirs stops improving at 160K. However, our improvements are only statistically significant for 160K original pairs or less. Finally, note that our translation direction is reversed.

Based on the experimental results, we can make several conclusions. First, we have shown that using bi-text data from related languages improves SMT: we achieved up to 1.35 and 3.37 improvement in Bleu for *in-en* (+*ml-en*) and *es-en* (+*pt-en*) respectively. Second, while simple concatenation can help, it is problematic when the additional sentences out-number the ones from the original bi-text. Third, concatenation can work very well if the original bi-text is repeated enough times so that the additional bi-text does not dominate. Fourth, merging phrase tables giving priority to the original bi-text and using additional fea-

Table 3: **Improving Spanish→English SMT using 160K additional *pt-en* sentence pairs.** Column three shows whether transliteration was used; the following columns list the Bleu scores (in %s) for different methods. A small subscript shows the best parameter value(s) found on the development set and used on the test set to produce the given result. Bleu scores that are statistically significantly better than the baseline/our method are marked on the left/right side by $^{<}$ (for $p < 0.01$) or $^{\leq}$ (for $p < 0.05$).

tures is a good strategy. Fifth, part of the improvement when combining bi-texts is due to increased vocabulary coverage because of cognates, but another part comes from improved word alignments. Sixth, the best results are achieved when the latter two sources are first isolated and then combined (our method). Finally, transliteration can help a lot in case of systematic spelling variations between the original and the additional source languages.

5 Related Work

In this section, we describe two general lines of related previous research: using cognates between the source and the target language, and source-language side paraphrasing with a pivot language.

5.1 Cognates

Many researchers have used likely cognates to obtain improved word alignments and thus build better SMT systems. Al-Onaizan et al. (1999) extracted such likely cognates for Czech-English using one of the variations of LCSR (Melamed, 1995) described in (Tiedemann, 1999) as a similarity measure. They used these cognates to improve word alignments with IBM models 1-4 in three different ways: (1) by seeding the parameters of IBM model 1, (2) by constraining the word co-occurrences when training IBM models 1-4, and (3) by adding the cognate pairs to the bi-text as additional "sentence pairs". The last approach performed best and was later used by Kondrak et al. (2003) who demonstrated improved SMT for nine European languages.

Unlike these approaches, which extract cognates between the source and the target language, we use cognates between the source and some other related language that is different from the target. Moreover, we only implicitly rely on the existence of such cognates; we do not try to extract them at all, and we leave them in their original sentence contexts.[12]

[12]However, in some of our experiments, we extract cognates for training a transliteration system from the resource-rich source language X_2 into the resource-poor one X_1.

Table 4: **Comparison to the pivoting technique of Callison-Burch et al. (2006) for English→Spanish.** Shown are Bleu scores (in %s) and absolute improvement over the baseline for training bi-texts with different numbers of parallel sentences (10K, 20K, . . ., 1230K) and fixed amount of additional data: (1) about 1.3M sentence pairs for each of eight additional languages in Callison-Burch et al. (2006)'s pivoting, and (2) 160K and 1,230K pairs for one language (Portuguese) for our method. Statistically significant improvements over the baseline are marked with a * (for $p < 0.01$) and with a $^\diamond$ (for $p < 0.05$).

5.2 Paraphrasing with a Pivot-Language

Another relevant line of research is on using multilingual parallel corpora to improve SMT using additional languages as pivots.

Callison-Burch et al. (2006) improved English→Spanish and English→French SMT using source-language paraphrases extracted with the pivoting technique of Bannard and Callison-Burch (2005) and eight additional languages from the *Europarl corpus* (Koehn, 2005). For example, using German as a pivot, they extracted English paraphrases from a parallel English-German corpus by looking for English phrases that were aligned to the same German phrase: *e.g.*, if *under control* and *in check* were aligned to *unter controlle*, they were hypothesized to be paraphrases with some probability. Such (English) paraphrases were added as additional entries in the phrase table of an English→Spanish/English→French phrase-based SMT system and paired with the foreign (Spanish/French) translation of the original (English) phrase. The system was then tuned with MERT using an extra feature penalizing low-probability paraphrases; this yielded up to 1.8% absolute improvement in Bleu.

Other important publications about pivoting approaches for machine translation include (Wu and Wang, 2007), (Utiyama and Isahara, 2007), (Hajič et al., 2000) and (Habash and Hu, 2009).

Unlike pivoting, which can only improve source-language lexical coverage, we augment both the source- and the target-language sides. Second, while pivoting ignores context when extracting paraphrases, we take it into account. Third, by using as an additional language one that is related to the source, we are able to get increase in Bleu that is comparable and even better than what pivoting achieves with eight pivot languages. On the negative side, our approach is limited in that it requires that X_2 be related to X_1, while the pivoting language Z does not need to be related to X_1 nor to Y. However, we only need one additional parallel corpus (for X_2-Y), while pivoting needs two: one for X_1-Z and one for Z-Y. Finally, note that our approach is orthogonal to pivoting, and thus the two can be combined.

6 Conclusion and Future Work

We have proposed a novel method for improving SMT for resource-poor languages by exploiting their similarity to resource-rich ones.

In future work, we would like to extend that approach in several interesting directions. First, we want to make better use of multi-lingual parallel corpora, *e.g.*, while we had access to a Spanish-Portuguese-English corpus, we used it as two separate bi-texts Spanish-English and Portuguese-English. Second, we would like to exploit multiple auxiliary resource-rich languages the resource-poor source language is related to. Third, we could also experiment with using auxiliary languages that are related to the *target* language.

What's in a name? In some languages, grammatical gender

Abstract

This paper presents an investigation of the relation between words and their gender in two gendered languages: German and Romanian. Gender is an issue that has long preoccupied linguists and baffled language learners. We verify the hypothesis that gender is dictated by the general sound patterns of a language, and that it goes beyond suffixes or word endings. Experimental results on German and Romanian nouns show strong support for this hypothesis, as gender prediction can be done with high accuracy based on the form of the words.

1 Introduction

For speakers of a language whose nouns have no gender (such as modern English), making the leap to a language that does (such as German), does not come easy. With no or few rules or heuristics to guide him, the language learner will try to draw on the "obvious" parallel between grammatical and natural gender, and will be immediately baffled to learn that *girl – Mädchen* – is neuter in German. Furthermore, one may refer to the same object using words with different gender: *car* can be called *(das) Auto* (neuter) or *(der) Wagen* (masculine). Imagine that after hard work, the speaker has mastered gender in German, and now wishes to proceed with a Romance language, for example Italian or Spanish. He is now confronted with the task of relearning to assign gender in these new languages, made more complex by the fact that gender does not match across languages: e.g. *sun* – feminine in German (*die Sonne*), but masculine in Spanish (*el sol*), Italian (*il sole*) and French (*le soleil*); *moon* – masculine in German (*der Mond*), but feminine in Spanish (*la luna*), Italian (*la luna*) and French (*la lune*). Gender doesn't even match within a single language family: *travel* – masculine in Spanish (*el viage*) and Italian (*il viaggio*), but feminine in Portuguese (*a viagem*).

Grammatical gender groups nouns in a language into distinct classes. There are languages whose nouns are grouped into more or less than three classes. English for example has none, and makes no distinction based on gender, although Old English did have three genders and some traces remain (e.g. *blonde, blond*).

Linguists assume several sources for gender: (i) a first set of nouns which have natural gender and which have associated matching grammatical gender; (ii) nouns that resemble (somehow) the nouns in the first set, and acquire their grammatical gender through this resemblance. Italian and Romanian, for example, have strong and reliable phonological correlates (Vigliocco et al., 2004b, for Italian). (Doca, 2000, for Romanian). In Romanian the majority of feminine nouns end in *ă* or *e*. Some rules exists for German as well (Schumann, 2006), for example nouns ending in *-tät, -ung, -e, -enz, -ur, -keit, -in* tend to be feminine. Also, when specific morphological processes apply, there are rules that dictate the gender of the newly formed word. This process explains why *Frau* (woman) is feminine in German, while *Fräulein* (little woman, miss) is neuter – *Fräulein = Frau + lein*. The existing rules have exceptions, and there are numerous nouns in the language which are not derived, and such suffixes do not apply.

Words are names used to refer to concepts. The fact that the same concept can be referred to using names that have different gender – as is the case for *car* in German – indicates that at least in some cases, grammatical gender is in the name and not the concept. We test this hypothesis – that the gender of a noun is in its word form, and that this goes beyond word endings – using noun gender data for German and Romanian. Both Romanian and German have 3 genders: masculine, feminine and

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1368–1377,
Singapore, 6-7 August 2009.

neuter. The models built using machine learning algorithms classify test nouns into gender classes based on their form with high accuracy. These results support the hypothesis that in gendered languages, the word form is a strong clue for gender. This supplements the situation when some concepts have natural gender that matches their grammatical gender: it allows for an explanation where there is no such match, either directly perceived, or induced through literary devices.

The present research has both theoretical and practical benefits. From a theoretical point of view, it contributes to research on phonology and gender, in particular in going a step further in understating the link between the two. From a practical perspective, such a connection between gender and sounds could be exploited in advertising, in particular in product naming, to build names that fit a product, and which are appealing to the desired customers. Studies have shown that especially in the absence of meaning, the form of a word can be used to generate specific associations and stimulate the imagination of prospective customers (Sells and Gonzales, 2003; Bedgley, 2002; Botton et al., 2002).

2 Gender

What is the origin of grammatical gender and how does it relate to natural gender? Opinions are split. Historically, there were two main, opposite, views: (i) there is a semantic explanation, and natural gender motivated the category (ii) the relationship between natural and grammatical gender is arbitrary.

Grimm (1890) considered that grammatical gender is an extension of natural gender brought on by imagination. Each gender is associated with particular adjectives or other attributes, and in some cases (such as for *sun* and *moon*) the assignment of gender is based on personification. Brugmann (1889) and Bloomfield (1933) took the position that the mapping of nouns into genders is arbitrary, and other phenomena – such as derivations, personification – are secondary to the established agreement. Support for this second view comes also from language acquisition: children who learn a gendered language do not have a natural gender attribute that they try to match onto the newly acquired words, but learn these in a separate process. Any match or mapping between natural and grammatical gender is done after the natural gender "feature" is acquired itself. Kilarski (2007) presents a more detailed overview of currents and ideas about the origin of gender. Unterbeck (1999) contains a collection of papers that investigate grammatical gender in several languages, aspects of gender acquisition and its relation with grammatical number and agreement.

There may be several reasons for the polemic between these two sides. One may come from the categorization process, the other from the relation between word form and its meaning. Let us take them each in turn, and see how they influenced gender.

Grammatical gender separates the nouns in a language into disjoint classes. As such, it is a categorization process. The traditional – classical – theory of categorization and concepts viewed categories and concepts as defined in terms of a set of common properties that all its members should share. Recent theories of concepts have changed, and view concepts (and categories) not necessarily as "monolithic" and defined through rules, but rather as clusters of members that may resemble each other along different dimensions (Margolis and Laurence, 1999).

In most linguistic circles, the principle of arbitrariness of the association between form and meaning, formalized by de Saussure (1916) has been largely taken for granted. It seems however, that it is hard to accept such an arbitrary relation, as there have always been contestants of this principle, some more categorical than others (Jakobson, 1937; Jespersen, 1922; Firth, 1951). It is possible that the correlation we perceive between the word form and the meaning is something that has arisen after the word was coined in a language, being the result of what Firth called "phonetic habit" through "an attunement of the nervous system", and that we have come to prefer, or select, certain word forms as more appropriate to the concept they name – "There is no denying that there are words which we feel instinctively to be adequate to express the ideas they stand for. ... Sound symbolism, we may say, makes some words more fit to survive" (Jespersen, 1922).

These two principles relate to the discussion on gender in the following manner: First of all, the categories determined by grammatical gender need not be homogeneous, and their members need not all respect the same membership criterion. This frees us from imposing a matching between natural and grammatical gender where no such relation is obvious or pos-

sible through literary devices (personification, metaphor, metonymy). Nouns belonging to the same gender category may resemble each other because of semantic considerations, lexical derivations, internal structure, perceived associations and so on. Second, the fact that we allow for the possibility that the surface form of a word may encode certain word characteristics or attributes, allows us to hypothesize that there is a surface, phonological, similarity between words grouped within the same gender category, that can supplement other resemblance criteria in the gender category (Zubin and Köpcke, 1986).

Zubin and Köpcke (1981), Zubin and Köpcke (1986) have studied the relation between semantic characteristics and word form with respect to gender for German nouns. Their study was motivated by two observations: Zipf (1935) showed that word length is inversely correlated with frequency of usage, and Brown (1958) proposed that in choosing a name for a given object we are more likely to use a term corresponding to a "basic" level concept. For example, *chair, dog, apple* would correspond to the basic level, while *furniture, animal, fruit* and *recliner, collie, braeburn apple* correspond to a more general or a more specific level, respectively. Their study of gender relative to these levels have shown that basic level terms have masculine, feminine, and rarely neuter genders, while the more undifferentiated categories at the superordinate level are almost exclusively neuter.

In psycholinguistic research, Friederici and Jacobsen (1999) adopt the position that a lexical entry consists of two levels: form and semantic and grammatical properties to study the influence of gender priming – both from a form and semantic perspective – on language comprehension. Vigliocco et al. (2004a) study gender priming for German word production. While this research studies the influence of the word form on the production of nouns with the same or different grammatical gender, there is no study of the relation between word forms and their corresponding gender.

In recent studies we have found on the relation between word form and its associated gender, the only phonological component of a word that is considered indicative is the ending. Spalek et al. (2008) experiment on French nouns, and test whether a noun's ending is a strong clue for gender for native speakers of French. Vigliocco et al. (2004b) test cognitive aspects of grammatical gender of Italian nouns referring to animals.

Cucerzan and Yarowsky (2003) present a bootstrapping process to predict gender for nouns in context. They show that context gives accurate clues to gender (in particular through determiners, quantifiers, adjectives), but when the context is not useful, the algorithm can fall back successfully on the word form. Cucerzan and Yarowsky model the word form for predicting gender using suffix trie models. When a new word is encountered, the word is mapped onto the trie starting from the last letter, and it is assigned the gender that has the highest probability based on the path it matches in the trie. In context nouns appear with various inflections – for number and case in particular. Such morphological derivations are gender specific, and as such are strong indicators for gender.

The hypothesis tested here is that gender comes from the general sound of the language, and is distributed throughout the word. For this, the data used should not contain nouns with "tell tale" inflections. The data will therefore consist of nouns in the singular form, nominative case. Some nouns are derived from verbs, adverbs or adjectives, or other nouns through morphological derivations. These derivations are regular and are identifiable through a rather small number of regular suffixes. These suffixes (when they are indicative of gender) and word endings will be used as baselines to compare the accuracy of prediction on the full word with the ending fragment.

3 Data

We test our gender-language sounds connection through two languages from different language families. German will be the representative of the Germanic languages, and Romanian for the Romance ones. We first collect data in the two languages, and then represent them through various features – letters, pronunciation, phonetic features.

3.1 Noun collections

German data For German we collect nouns and their grammatical gender from a German-English dictionary, part of the BEOLINGUS multi-lingual dictionary[1]. In the first step we collected the German nouns and their gender from this dictionary. In step 2, we filter out compounds. The reason for this step is that a German noun compound will

[1] `http://dict.tu-chemnitz.de/`

have the gender of its head, regardless of its nominal modifiers. For the lack of a freely available tool to detect and split noun compounds, we resort to the following algorithm:

1. initialize the list of nouns L_N to the empty list;
2. take each noun n in the dictionary D, and
   (a) if $\exists n_i \in L_N$ such that n is an end substring of n_i, then add n to L_N and remove n_i from L_N;
   (b) if $\exists n_i \in L_N$ such that n_i is a end substring of n, skip n;

Essentially, we remove from the data all nouns that include another noun as the end part (which is the head position in German noun compounds). This does not filter examples that have suffixes added to form the feminine version of a masculine noun, for example: *(der) Lehrer – (die) Lehrerin* (teacher). The suffixes are used in one of the baselines for comparison with our learning method.

We obtain noun pronunciation information from the Bavarian Archive for Speech Signals[2]. We filter again our list L_N to keep nouns for which we have pronunciation information. This allows us to compare the learning results when letter or pronunciation information is used.

After collecting the nouns and their pronunciation, we map the pronunciation onto lower level phonetic features, following the IPA encoding of sounds for the German language. The mapping between sounds and IPA features was manually encoded following IPA tables.

Romanian data We extract singular nominative forms of nouns from the Romanian lexical database (Barbu, 2008). The resource contains the proper word spelling, including diacritics and special characters. Because of this and the fact that there is a straightforward mapping between spelling and pronunciation in Romanian, we can use the entire data extracted from the dictionary in our experiments, without special pronunciation dictionaries. Following the example for the German language, we encode each sound through lower level phonological features using IPA guidelines.

As in Italian, in Romanian there are strong phonological cues for nouns, especially those having the feminine gender: they end in *ă* and *e*. To determine whether the connection between a word form and gender goes beyond this superficial rule, we generate a dataset in which the nouns are stripped of their final letter, and their representation is built based on this reduced form.

Table 1 shows the data collected and the distribution in the three classes.

	German		Romanian	
masc.	565	32.64%	7338	15.14%
fem.	665	38.42%	27187	56.08%
neut.	501	28.94%	13952	28.78%
total	1731		48477	

Table 1: Data statistics

Because for Romanian the dataset is rather large, we can afford to perform undersampling to balance our classes, and have a more straightforward evaluation. We generate a perfectly balanced dataset by undersampling the feminine and the neuter classes down to the level of the masculine class. We work then with a dataset of 22014 instances, equally distributed among the three genders.

3.2 Data representation

For each word in our collections we produce three types of representation: letters, phonemes and phonological features. Table 2 shows examples for each of these representations. The letter and phoneme representations are self-explanatory. We obtain the pronunciation corresponding to each word from a pronunciation dictionary, as mentioned in Section 3.1, which maps a word onto a sequence of phonemes (phones). For Romanian we have no such resource, but me make without since in most part the pronunciation matches the letter representation[3].

German		
letter	abend (m)	a b e n d
phoneme		a: b @ n d
Romanian		
letter	seară (f)	s e a r ă

Table 2: Data representation in terms of letters and phonemes for the German and Romanian forms of the word *evening*. For Romanian, the letter and phoneme representation is the same.

[2] http://www.phonetik.uni-muenchen.de/Bas/

[3] The exceptions are the diphthongs and a few groups of letters: ce, ci, che, chi, oa, and the letter x.

Phonemes, the building blocks of the phonetic representation, can be further described in terms of phonological features – "configurations" of the vocal tract (e.g tongue and lips position), and acoustic characteristics (e.g. manner of air flow). We use IPA standards for mapping phones in German and Romanian onto these phonological features. We manually construct a map between phones and features, and then automatically binarize this representation and use it to generate a representation for each phone in each word in the data. For the word *abend (de) / seara (ro) (evening)* in Figure 2, the phonological feature representation for German is:

0000100000001000010000000001
0001000100000000000010000000
0000100000000100000000010001
1000000100000010000000000000
1000000100000000000010000000,

with the feature base:

< alveolar, approximant, back, bilabial, central, close, closemid, consonant, fricative, front, glottal, labiodental, long, mid, nasal, nearclose, nearopen, open, openmid, palatal, plosive, postalveolar, rounded, short, unrounded, uvular, velar, vowel >.

For Romanian, the phonological feature base is:

< accented, affricate, approximant, back, bilabial, central, close, consonant, dental, fricative, front, glottal, labiodental, mid, nasal, open, plosive, postalveolar, rounded, trill, unrounded, velar, voiced, voiceless, vowel >,

and the phonological feature representation of the word changes accordingly.

4 Kernel Methods and String Kernels

Our hypothesis that the gender is in the name is equivalent to proposing that there are sequences of letters/sounds/phonological features that are more common among nouns that share the same gender or that can distinguish between nouns under different genders. To determine whether that is the case, we use a string kernel, which for a given string (sequence) generates a representation that consists of all its substrings of length less than a parameter l. The words are represented as strings with boundaries marked with a special character ('#'). The high dimensional representation generated by the string kernel is used to find a hyperplane that separates instances of different classes. In this section we present in detail the kernel we use.

Kernel-based learning algorithms work by embedding the data into a feature space (a Hilbert space), and searching for linear relations in that space. The embedding is performed implicitly, that is by specifying the inner product between each pair of points rather than by giving their coordinates explicitly.

Given an input set $\mathcal{X}$ (the space of examples), and an embedding vector space $\mathcal{F}$ (feature space), let $\phi : \mathcal{X} \rightarrow \mathcal{F}$ be an embedding map called feature map.

A *kernel* is a function k, such that for all $x, z \in \mathcal{X}$, $k(x, z) =< \phi(x), \phi(z) >$, where $< ., . >$ denotes the inner product in $\mathcal{F}$.

In the case of binary classification problems, kernel-based learning algorithms look for a discriminant function, a function that assigns $+1$ to examples belonging to one class and -1 to examples belonging to the other class. This function will be a linear function in the space $\mathcal{F}$, that means it will have the form:

$$f(x) = \text{sign}(< w, \phi(x) > +b),$$

for some weight vector w. The kernel can be exploited whenever the weight vector can be expressed as a linear combination of the training points, $\sum_{i=1}^{n} \alpha_i \phi(x_i)$, implying that f can be expressed as follows:

$$f(x) = \text{sign}(\sum_{i=1}^{n} \alpha_i k(x_i, x) + b)$$

.

Various kernel methods differ in the way in which they find the vector w (or equivalently the vector α). Support Vector Machines (SVM) try to find the vector w that define the hyperplane that maximum separate the images in $\mathcal{F}$ of the training examples belonging to the two classes. Mathematically SVMs choose the w and b that satisfy the following optimization criterion:

$$\min_{w,b} \frac{1}{n} \sum_{i=1}^{n} [1 - y_i(< w, \phi(x_i) > +b)]_+ + \nu ||w||^2$$

where y_i is the label ($+1/-1$) of the training example x_i, ν a regularization parameter and $[x]_+ = \max(x, 0)$.

Kernel Ridge Regression (KRR) selects the vector w that simultaneously has small empirical error and small norm in Reproducing Kernel Hilbert Space generated by kernel k. The resulting minimization problem is:

$$\min_w \frac{1}{n}\sum_{i=1}^{n}(y_i - < w, \phi(x_i) >)^2 + \lambda||w||^2$$

where again y_i is the label ($+1/-1$) of the training example x_i, and λ a regularization parameter. Details about SVM and KRR can be found in (Taylor and Cristianini, 2004). What is important is that above optimization problems are solved in such a way that the coordinates of the embedded points are not needed, only their pairwise inner products which in turn are given by the kernel function k.

SVM and KRR produce binary classifiers and gender classification is a multi-class classification problem. There are a lot of approaches for combining binary classifiers to solve multi-class problems. We used *one-vs-all* scheme. For arguments in favor of one-vs-all see (Rifkin and Klautau, 2004).

The kernel function offers to the kernel methods the power to naturally handle input data that are not in the form of numerical vectors, for example strings. The kernel function captures the intuitive notion of similarity between objects in a specific domain and can be any function defined on the respective domain that is symmetric and positive definite. For strings, a lot of such kernel functions exist with many applications in computational biology and computational linguistics (Taylor and Cristianini, 2004).

Perhaps one of the most natural ways to measure the similarity of two strings is to count how many substrings of length p the two strings have in common. This give rise to the p-spectrum kernel. Formally, for two strings over an alphabet Σ, $s, t \in \Sigma^*$, the p-spectrum kernel is defined as:

$$k_p(s,t) = \sum_{v \in \Sigma^p} \text{num}_v(s)\text{num}_v(t)$$

where $\text{num}_v(s)$ is the number of occurrences of string v as a substring in s [4] The feature map defined by this kernel associate to each string a vector of dimension $|\Sigma|^p$ containing the histogram of frequencies of all its substrings of length p. Taking into account all substrings of length less than p it will be obtained a kernel that is called the *blended spectrum kernel*:

$$k_1^p(s,t) = \sum_{q=1}^{p} k_q(s,t)$$

The blended spectrum kernel will be the kernel that we will use in conjunction with SVM and KRR. More precisely we will use a normalized version of the kernel to allow a fair comparison of strings of different length:

$$\hat{k}_1^p(s,t) = \frac{k_1^p(s,t)}{\sqrt{k_1^p(s,s)k_1^p(t,t)}}$$

5 Experiments and Results

We performed 10-fold cross-validation learning experiments with kernel ridge regression and the string kernel (KRR-SK) presented in Section 4. We used several baselines to compare the results of the experiments against:

BL-R Gender is assigned following the distribution of genders in the data.

BL-M Gender is assigned following the majority class (only for German, for Romanian we use balanced data).

BL-S Gender is assigned based on suffix-gender relation found in the literature. We use the following mappings:

- German (Schumann, 2006):
  feminine *-ade, -age, -anz, -e, -ei, -enz, -ette, -heit, -keit, -ik, -in, -ine, -ion, -itis, -ive, -schaft, -tät, -tur, -ung, -ur*;
  masculine *-ant, -er, -ich, -ismus, -ling*;
  neuter *-chen, -ist, -lein, -ment, -nis, -o, -tel, -um*.
  In our data set the most dominant gender is feminine, therefore we assign this gender to all nouns that do not match any of the previous suffixes. Table 4 shows a few suffixes for each gender, and an example noun.
- Romanian: in Romanian the word ending is a strong clue for gender, especially for feminine nouns: the vast majority end in either *-e* or *-ă* (Doca, 2000). We design a heuristic that assigns the gender "preferred" by the last letter – the

[4] Note that the notion of substring requires contiguity. See (Taylor and Cristianini, 2004) for discussion about the ambiguity between the terms "substring" and "subsequence" across different traditions: biology, computer science.

Method	Accuracy	masc. F-score	fem. F-score	neut. F-score

Table 5: Word-ending precision on classifying gender and examples for Romanian

majority gender of all nouns ending in the respective letter – based on analysis of our data. In Table 5 we include some of the letter endings with an example noun, and a percentage that shows the precision of the ending in classifying the noun in the gender indicated in the table.

The results of our experiments are presented in Table 3, in terms of overall accuracy, and f-score for each gender. The performance presented corresponds to the letter-based representation of words. It is interesting to note that this representation performed overall better than the phoneme or phonological feature-based ones. An explanation may be that in both the languages we considered, there is an (almost) one-to-one mapping between letters and their pronunciation, making thus the pronunciation-based representation unnecessary. As such, the letter level captures the interesting commonalities, without the need to go down to the phoneme-level.

We performed experiments for Romanian when the last letter of the word is removed. The reason for this batch of experiments is to further test the hypothesis that gender is more deeply encoded in a word form than just the word ending. For both languages we observe statistically significant higher performance than all baselines. For Romanian, the last letter heuristic gives a very high baseline, confirming that Romanian has strong phonological cues for gender in the ending. Had the word ending been the only clue to the word's gender,

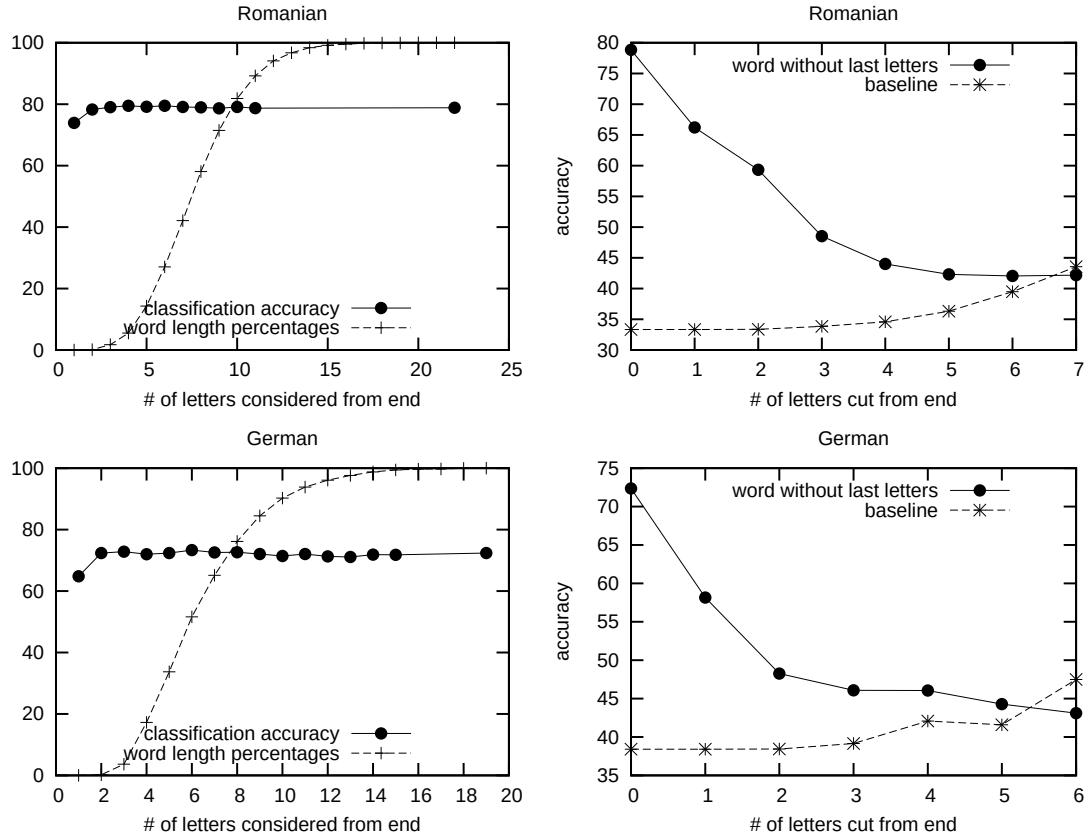

Figure 1: Gender prediction based on the last N letters, and based on the word minus the last N letters

once it is removed the performance on recognizing gender should be close to the random assignment. This is not the case, and the improvement over the random baseline is 32% points. It is interesting to notice that when cutting off the last letter the class for which the gender assignment heuristic was clearest – the feminine class with -ă and -e endings – the performance remains very high – 85% F-score.

To further test where the gender indicators are located, we performed two more sets of experiments: (i) classify words in their corresponding gender class using the word minus the last N letters; (ii) classify words based on the last N letters. The results of these experiments in terms of accuracy are presented in Figure 1. When considering only the last N letters the performance is high for both German and Romanian, as expected if the gender indicators are concentrated at the end of the word. It is interesting though to notice the results of classification based on the word without the last N letters. The prediction accuracy monotonically decreases, but remains above the baseline until more than 6 letters are cut. Because as letters are cut some words completely disappear, the baseline changes accordingly. 94.07% of the words have a length of at most 12 letters in the Romanian dataset, and 96.07% in the German one. Because gender prediction can be done with accuracy higher than the random baseline even after 6 letters are cut from the ending of the word indicate that for more than 94% of the words considered, gender clues are spread over more than the second half of the word. Again, we remind the reader that the word forms are in nominative case, with no case or number inflections (which are strong indicators of gender in both Romanian and German).

Except for lines $KRR - SK_{noWB}$, the results in Table 3 are obtained through experiments conducted on words containing word boundary markers, as indicated in Section 4. Because of these markers, word starting or word ending substrings are distinct from all the others, and information about their position in the original word is thus preserved. To further explore the idea that gender indicators are not located only in word endings, we ran classification experiments for German and Romanian when the word representation does not contain word boundary markers. This means that the substrings generated by the string kernel have

no position information. The results of these experiments are presented in rows $KRR-SK_{noWB}$ in Table 3. The accuracy is slightly lower than the best results obtained when word boundaries are marked and the entire word form is used. However, they are well above all the baselines considered, without no information about word endings.

For both German and Romanian, the gender that was learned best was feminine. For German part of this effect is due to the fact that the feminine class is more numerous in the data. For Romanian the data was perfectly balanced, so there is no such bias. Neuter and masculine nouns have lower learning performance. For Romanian, a contribution to this effect is the fact that neuter nouns behave as masculine nouns in their singular form (take the same articles, inflections, derivations), but as feminine in the plural, and our data consists of nouns in singular form. It would seem that from an orthographic point of view, neuter and masculine nouns are closer to each other than to feminine nouns.

From the reviewed related work, the one that uses the word form to determine gender is Cucerzan and Yarowsky (2003) for Romanian. There are two important differences with respect to the approach presented here. First, they consider words in context, which are inflected for number and case. Number and case inflections are reflected in suffixes that are gender specific. The words considered here are in singular form, nominative case – as such, with no inflections. Second, Cucerzan and Yarowsky consider two classes: feminine vs. masculine and neuter. Masculine and neuter nouns are harder to distinguish, as in singular form neuter nouns behave like masculine nouns in Romanian. While the datasets and word forms used by Cucerzan and Yarowsky are different than the one used here, the reader may be curious how well the word form distinguishes between feminine and the other two classes in the experimental set-up used here. On the full[5] Romanian dataset described in Section 3, a two class classification gives 99.17% accuracy. When predicting gender for all words in their dataset, Cucerzan and Yarowsky obtain 98.25% accuracy.

6 Conclusion

When a speaker of a genderless language tries to learn a language with grammatical gender, it is very tempting to try to assign grammatical gender based on perceived or guessed natural gender types. This does not work out well, and it only serves to confuse the learner even more, when he finds out that nouns expressing concepts with clear feminine or masculine natural gender will have the opposite or a neutral grammatical gender, or that one concept can be referred to through names that have different grammatical genders. Going with the flow of the language seems to be a better idea, and allow the sound of a word to dictate the gender.

In this paper we have investigated the hypothesis that gender is encoded in the word form, and this encoding is more than just the word endings as it is commonly believed. The results obtained show that gender assignment based on word form analysis can be done with high accuracy – 72.36% for German, and 78.83% for Romanian. Existing gender assignment rules based on word endings have lower accuracy. We have further strengthened the point by conducting experiments on Romanian nouns without tell-tale word endings. The accuracy remains high, with remarkably high performance in terms of F-score for the feminine class (85%). This leads us to believe that gender information is somehow redundantly coded in a word. We plan to look closer at cases where we obtain different predictions based on the word ending and the full form of the word, and use boosting to learn weights for classifiers based on different parts of the word to see whether we can further improve the results.

As we have underlined before, word form similarity between words under the same gender is one criterion for gender assignment. It would be interesting to verify whether gender recognition can be boosted by using lexical resources that capture the semantics of the words, such as WordNets or knowledge extracted from Wikipedia, and verify whether similarities from a semantic point of view are also responsible for gender assignments in various languages.

[5] By "full" we mean the dataset before balancing the classes 48,477 instances (see Table 1).

Abstract

This paper explores the use of innovative kernels based on syntactic and semantic structures for a target relation extraction task. Syntax is derived from constituent and dependency parse trees whereas semantics concerns to entity types and lexical sequences. We investigate the effectiveness of such representations in the automated relation extraction from texts. We process the above data by means of Support Vector Machines along with the syntactic tree, the partial tree and the word sequence kernels. Our study on the ACE 2004 corpus illustrates that the combination of the above kernels achieves high effectiveness and significantly improves the current state-of-the-art.

1 Introduction

Relation Extraction (RE) is defined in ACE as the task of finding relevant semantic relations between pairs of entities in texts. Figure 1 shows part of a document from ACE 2004 corpus, a collection of news articles. In the text, the relation between *president* and *NBC's entertainment division* describes the relationship between the first entity (person) and the second (organization) where the person holds a managerial position.

Several approaches have been proposed for automatically learning semantic relations from texts. Among others, there has been increased interest in the application of kernel methods (Zelenko et al., 2002; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005a; Bunescu and Mooney, 2005b; Zhang et al., 2005; Wang, 2008). Their main property is the ability of exploiting a huge amount of features without an explicit feature representation. This can be done by computing a kernel function between a pair of linguistic objects, where such function is a kind of similarity measure satisfying certain properties. An example is the sequence kernel (Lodhi et al., 2002), where the objects are strings of characters and the kernel function computes the number of common subsequences of characters in the two strings. Such substrings are then weighted according to a decaying factor penalizing longer ones. In the same line, Tree Kernels count the number of *subtree* shared by two input trees. An example is that of syntactic (or subset) tree kernel (SST) (Collins and Duffy, 2001), where trees encode grammatical derivations.

> Jeff Zucker, the longtime executive producer of NBC's "Today" program, will be named Friday as the new **president** of **NBC's entertainment division**, replacing Garth Ancier, NBC executives said.

Figure 1: A document from ACE 2004 with all entity mentions in bold.

Previous work on the use of kernels for RE has exploited some similarity measures over diverse features (Zelenko et al., 2002; Culotta and Sorensen, 2004; Zhang et al., 2005) or subsequence kernels over dependency graphs (Bunescu and Mooney, 2005a; Wang, 2008). More specifically, (Bunescu and Mooney, 2005a; Culotta and Sorensen, 2004) use kernels over dependency trees, which showed much lower accuracy than feature-based methods (Zhao and Grishman, 2005). One problem of the dependency kernels above is that they do not exploit the overall structural aspects of dependency trees. A more effective solution is the application of convolution kernels to constituent parse trees (Zhang et al., 2006) but this is not satisfactory from a general per-

This work has been partially funded by the LiveMemories project (http://www.livememories.org/) and Expert System (http://www.expertsystem.net/) research grant.

Singapore, 6-7 August 2009.

spective since dependency structures offer some unique advantages, which should be exploited by an appropriate kernel.

Therefore, studying convolution tree kernels for dependency trees is worthwhile also considering that, to the best of our knowledge, these models have not been previously used for relation extraction[1] task. Additionally, sequence kernels should be included in such global study since some of their forms have not been applied to RE.

In this paper, we study and evaluate diverse convolution and sequence kernels for the RE problem by providing several kernel combinations on constituent and dependency trees and sequential structures. To fully exploit the potential of dependency trees, in addition to the SST kernel, we applied the partial tree (PT) kernel proposed in (Moschitti, 2006), which is a general convolution tree kernel adaptable for dependency structures. We also investigate various sequence kernels (e.g. the word sequence kernel (WSK) (Cancedda et al., 2003)) by incorporating dependency structures into word sequences. These are also enriched by including information from constituent parse trees.

We conduct experiments on the standard ACE 2004 newswire and broadcast news domain. The results show that although some kernels are less effective than others, they exhibit properties that are complementary to each other. In particular, we found that relation extraction can benefit from increasing the feature space by combining kernels (with a simple summation) exploiting the two different parsing paradigms. Our experiments on RE show that the current composite kernel, which is constituent-based is more effective than those based on dependency trees and individual sequence kernel but at the same time their combinations, i.e. dependency plus constituent trees, improve the state-of-the-art in RE. More interestingly, also the combinations of various sequence kernels gain significant better performance than the current state-of-the-art (Zhang et al., 2005).

Overall, these results are interesting for the computational linguistics research since they show that the above two parsing paradigms provide different and important information for a semantic task such as RE. Regarding sequence-based kernels, the WSK gains better performance than previous sequence and dependency models for RE.

[1]The function defined on (Culotta and Sorensen, 2004), although on dependency trees, is not a convolution tree kernel.

A review of previous work on RE is described in Section 2. Section 3 introduces support vector machines and kernel methods whereas our specific kernels for RE are described is Section 4. The experiments and conclusions are presented in sections 5 and 6, respectively.

2 Related Work

To identify semantic relations using machine learning, three learning settings have mainly been applied, namely supervised methods (Miller et al., 2000; Zelenko et al., 2002; Culotta and Sorensen, 2004; Kambhatla, 2004; Zhou et al., 2005), semi supervised methods (Brin, 1998; Agichtein and Gravano, 2000), and unsupervised method (Hasegawa et al., 2004). In a supervised learning setting, representative related work can be classified into generative models (Miller et al., 2000), feature-based (Roth and tau Yih, 2002; Kambhatla, 2004; Zhao and Grishman, 2005; Zhou et al., 2005) or kernel-based methods (Zelenko et al., 2002; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005a; Zhang et al., 2005; Wang, 2008; Zhang et al., 2006).

The learning model employed in (Miller et al., 2000) used statistical parsing techniques to learn syntactic parse trees. It demonstrated that a lexicalized, probabilistic context-free parser with head rules can be used effectively for information extraction. Meanwhile, feature-based approaches often employ various kinds of linguistic, syntactic or contextual information and integrate into the feature space. (Roth and tau Yih, 2002) applied a probabilistic approach to solve the problems of named entity and relation extraction with the incorporation of various features such as word, part-of-speech, and semantic information from WordNet. (Kambhatla, 2004) employed maximum entropy models with diverse features including words, entity and mention types and the number of words (if any) separating the two entities.

Recent work on Relation Extraction has mostly employed kernel-based approaches over syntactic parse trees. Kernels on parse trees were pioneered by (Collins and Duffy, 2001). This kernel function counts the number of common subtrees, weighted appropriately, as the measure of similarity between two parse trees. (Culotta and Sorensen, 2004) extended this work to calculate kernels between augmented dependency trees. (Zelenko et al., 2002) proposed extracting

relations by computing kernel functions between parse trees. (Bunescu and Mooney, 2005a) proposed a shortest path dependency kernel by stipulating that the information to model a relationship between two entities can be captured by the shortest path between them in the dependency graph.

Although approaches in RE have been dominated by kernel-based methods, until now, most of research in this line has used the kernel as some similarity measures over diverse features (Zelenko et al., 2002; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005a; Zhang et al., 2005; Wang, 2008). These are not convolution kernels and produce a much lower number of substructures than the PT kernel. A recent approach successfully employs a convolution tree kernel (of type SST) over constituent syntactic parse tree (Zhang et al., 2006; Zhou et al., 2007), but it does not capture grammatical relations in dependency structure. We believe that an efficient and appropriate kernel can be used to solve the RE problem, exploiting the advantages of dependency structures, convolution tree kernels and sequence kernels.

3 Support Vector Machines and Kernel Methods

In this section we give a brief introduction to support vector machines, kernel methods, diverse tree and sequence kernel spaces, which can be applied to the RE task.

3.1 Support Vector Machines (SVMs)

Support Vector Machines refer to a supervised machine learning technique based on the latest results of the statistical learning theory (Vapnik, 1998). Given a vector space and a set of training points, i.e. positive and negative examples, SVMs find a separating hyperplane $H(\vec{x}) = \vec{\omega} \times \vec{x} + b = 0$ where $\omega \in R^n$ and $b \in R$ are learned by applying the Structural Risk Minimization principle (Vapnik, 1995). SVMs is a binary classifier, but it can be easily extended to multi-class classifier, e.g. by means of the *one-vs-all* method (Rifkin and Poggio, 2002).

One strong point of SVMs is the possibility to apply kernel methods (robert Mller et al., 2001) to implicitly map data in a new space where the examples are *more easily* separable as described in the next section.

3.2 Kernel Methods

Kernel methods (Schlkopf and Smola, 2001) are an attractive alternative to feature-based methods since the applied learning algorithm only needs to compute a product between a pair of objects (by means of kernel functions), avoiding the explicit feature representation. A kernel function is a scalar product in a possibly unknown feature space. More precisely, The object o is mapped in $\vec{x}$ with a feature function $\phi : \mathcal{O} \rightarrow \Re^n$, where $\mathcal{O}$ is the set of the objects.

The kernel trick allows us to rewrite the decision hyperplane as:

$$H(\vec{x}) = \Big(\sum_{i=1..l} y_i \alpha_i \vec{x}_i \Big) \cdot \vec{x} + b =$$

$$\sum_{i=1..l} y_i \alpha_i \vec{x}_i \cdot \vec{x} + b = \sum_{i=1..l} y_i \alpha_i \phi(o_i) \cdot \phi(o) + b,$$

where y_i is equal to 1 for positive and -1 for negative examples, $\alpha_i \in \Re$ with $\alpha_i \geq 0$, $o_i \; \forall i \in \{1, .., l\}$ are the training instances and the product $K(o_i, o) = \langle \phi(o_i) \cdot \phi(o) \rangle$ is the kernel function associated with the mapping ϕ.

Kernel engineering can be carried out by combining basic kernels with additive or multiplicative operators or by designing specific data objects (vectors, sequences and tree structures) for the target tasks.

Regarding NLP applications, kernel methods have attracted much interest due to their ability of implicitly exploring huge amounts of structural features automatically extracted from the original object representation. The kernels for structured natural language data, such as parse tree kernel (Collins and Duffy, 2001) and string kernel (Lodhi et al., 2002) are examples of the well-known convolution kernels used in many NLP applications.

Tree kernels represent trees in terms of their substructures (called tree fragments). Such fragments form a feature space which, in turn, is mapped into a vector space. Tree kernels measure the similarity between pair of trees by counting the number of fragments in common. There are three important characterizations of fragment type (Moschitti, 2006): the SubTrees (ST), the SubSet Trees (SST) and the Partial Trees (PT). For sake of space, we do not report the mathematical description of them, which is available in (Vishwanathan and Smola, 2002), (Collins and Duffy,

2001) and (Moschitti, 2006), respectively. In contrast, we report some descriptions in terms of feature space that may be useful to understand the new engineered kernels.

In principle, a SubTree (ST) is defined by taking any node along with its descendants. A Sub-Set Tree (SST) is a more general structure which does not necessarily include all the descendants. It must be generated by applying the same grammatical rule set, which generated the original tree. A Partial Tree (PT) is a more general form of substructures obtained by relaxing constraints over the SST.

4 Kernels for Relation Extraction

In this section we describe the previous kernels based on constituent trees as well as new kernels based on diverse types of trees and sequences for relation extraction. As mentioned in the previous section, we can engineer kernels by combining tree and sequence kernels. Thus we focus on the problem to define structure embedding the desired syntactic relational information between two named entities (NEs).

4.1 Constituent and Dependency Structures

Syntactic parsing (or syntactic analysis) aims at identifying grammatical structures in a text. A parser thus captures the hidden hierarchy of the input text and processes it into a form suitable for further processing. There are two main paradigms for representing syntactic information: constituent and dependency parsing, which produces two different tree structures.

Constituent tree encodes structural properties of a sentence. The parse tree contains constituents, such as noun phrases (NP) and verb phrases (VP), as well as terminals/part-of-speech tags, such as determiners (DT) or nouns (NN). Figure 2.a shows the constituent tree of the sentence: *In Washington, U.S. officials are working overtime*.

Dependency tree encodes grammatical relations between words in a sentence with the words as nodes and dependency types as edges. An edge from a word to another represents a grammatical relation between these two. Every word in a dependency tree has exactly one parent except the root. Figure 2.b shows and example of the dependency tree of the previous sentence.

Given two NEs, such as *Washington* and *officials*, both the above trees can encode the syntactic dependencies between them. However, since each parse tree corresponds to a sentence, there may be more than two NEs and many relations expressed in a sentence. Thus, the use of the entire parse tree of the whole sentence holds two major drawbacks: first, it may be too computationally expensive for kernel calculation since the size of a complete parse tree may be very large (up to 300 nodes in the Penn Treebank (Marcus et al., 1993)); second, there is ambiguity on the target pairs of NEs, i.e. different NEs associated with different relations are described by the same parse tree. Therefore, it is necessary to identify the portion of the parse tree that best represent the useful syntactic information.

Let e_1 and e_2 be two entity mentions in the same sentence such that they are in a relationship R. For the constituent parse tree, we used the path-enclosed tree (PET), which was firstly proposed in (Moschitti, 2004) for Semantic Role Labeling and then adapted by (Zhang et al., 2005) for relation extraction. It is the smallest common subtree including the two entities of a relation. The dashed frame in Figure 2.a surrounds PET associated with the two mentions, *officials* and *Washington*. Moreover, to improve the representation, two extra nodes T1-PER, denoting the type PERSON, and T2-LOC, denoting the type LOCATION, are added to the parse tree, above the two target NEs, respectively. In this example, the above PET is designed to capture the relation *Located-in* between the entities "officials" and "Washington" from the ACE corpus. Note that, a third NE, *U.S.*, is characterized by the node GPE (GeoPolitical Entity), where the absence of the prefix T1 or T2 before the NE type (i.e. GPE), denotes that the NE does not take part in the target relation.

In previous work, some dependency trees have been used (Bunescu and Mooney, 2005a; Wang, 2008) but the employed kernel just exploited the syntactic information concentrated in the path between e_1 and e_2. In contrast, we defined and studied three different dependency structures whose potential can be fully exploited by our convolution partial tree kernel:

- Dependency Words (DW) tree is similar to PET adapted for dependency tree constituted by simple words. We select the minimal subtree which includes e_1 and e_2, and we insert an extra node as father of the NEs, labeled with the NE category. For example, given

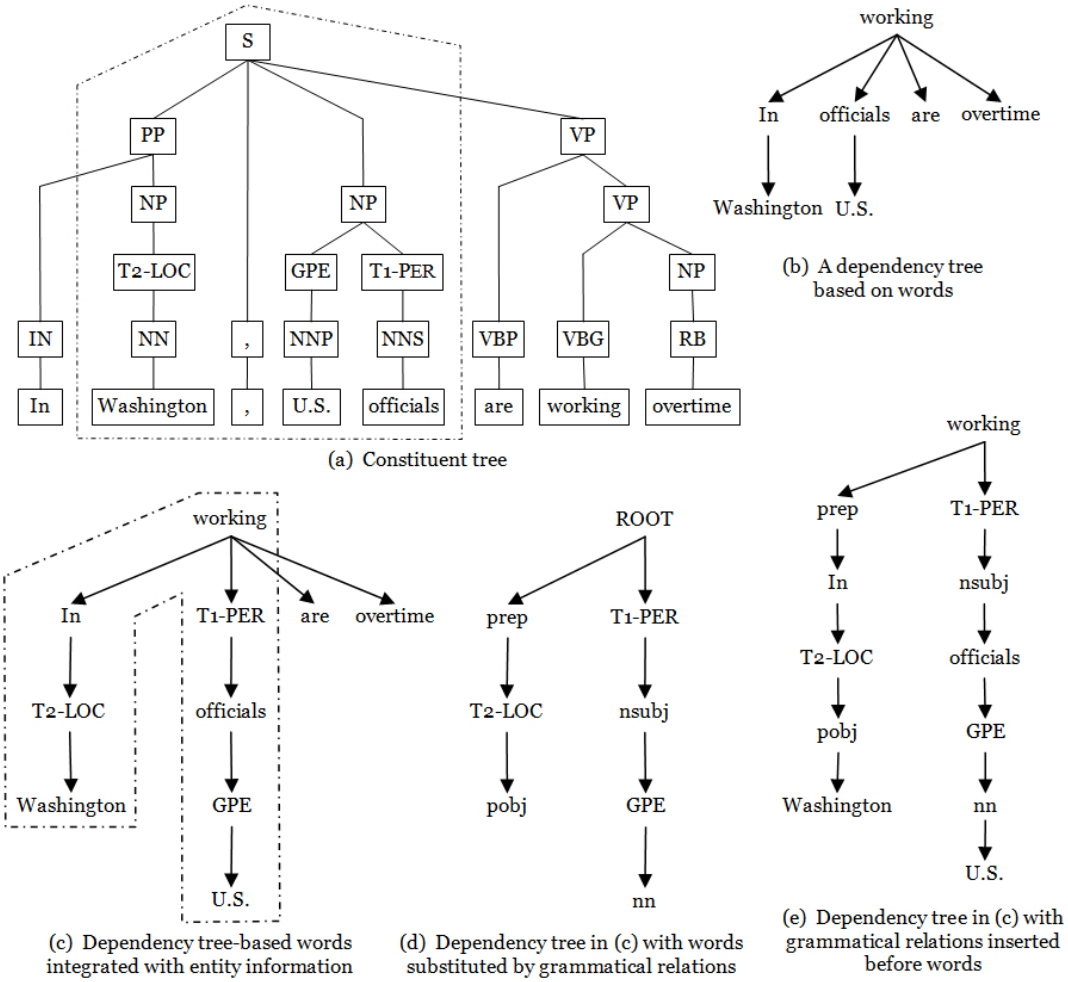

Figure 2: The constituent and dependency parse trees integrated with entity information

the tree in Figure 2.b, we design the tree in Figure 2.c surrounded by the dashed frames, where T1-PER, T2-LOC and GPE are the extra nodes inserted as fathers of *Washington*, *soldier* and *U.S.*.

- Grammatical Relation (GR) tree, i.e. the DW tree in which words are replaced by their grammatical functions, e.g. *prep*, *pobj* and *nsubj*. For example, Figure 2.d, shows the GR tree for the previous relation: *In* is replaced by *prep* , *U.S.* by *nsubj* and so on.

- Grammatical Relation and Words (GRW) tree, words and grammatical functions are both used in the tree, where the latter are inserted as a father node of the former. For example, Figure 2.e, shows such tree for the previous relation.

4.2 Sequential Structures

Some sequence kernels have been used on dependency structures (Bunescu and Mooney, 2005b; Wang, 2008). These kernels just used lexical words with some syntactic information. To fully exploit syntactic and semantic information, we defined and studied six different sequences (in a style similar to what proposed in (Moschitti, 2008)), which include features from constituent and dependency parse trees and NEs:

1. Sequence of terminals (lexical words) in the PET (SK_1), e.g.:
   T2-LOC Washington , U.S. T1-PER officials.

2. Sequence of part-of-speech (POS) tags in the PET (SK_2), i.e. the SK_1 in which words are replaced by their POS tags, e.g.:
   T2-LOC NN , NNP T1-PER NNS.

3. Sequence of grammatical relations in the

PET (SK_3), i.e. the SK_1 in which words are replaced by their grammatical functions, e.g.: *T2-LOC pobj , nn T1-PER nsubj*.

4. Sequence of words in the DW (SK_4), e.g.: *Washington T2-LOC In working T1-PER officials GPE U.S.*.

5. Sequence of grammatical relations in the GR (SK_5), i.e. the SK_4 in which words are replaced by their grammatical functions, e.g.: *pobj T2-LOC prep ROOT T1-PER nsubj GPE nn*.

6. Sequence of POS tags in the DW (SK_6), i.e. the SK_4 in which words are replaced by their POS tags, e.g.: *NN T2-LOC IN VBP T1-PER NNS GPE NNP*.

It is worth noting that the potential information contained in such sequences can be fully exploited by the word sequence kernel.

4.3 Combining Kernels

Given that syntactic information from different parse trees may have different impact on relation extraction (RE), the viable approach to study the role of dependency and constituent parsing is to experiment with different syntactic models and measuring the impact in terms of RE accuracy. For this purpose we compared the composite kernel described in (Zhang et al., 2006) with the partial tree kernels applied to DW, GR, and GRW and sequence kernels based on six sequences described above. The composite kernels include polynomial kernel applied to entity-related feature vector. The word sequence kernel (WSK) is always applied to sequential structures. The used kernels are described in more detail below.

4.3.1 Polynomial Kernel

The basic kernel between two named entities of the ACE documents is defined as:

$$K_P(R_1, R_2) = \sum_{i=1,2} K_E(R_1.E_i, R_2.E_i),$$

where R_1 and R_2 are two relation instances, E_i is the i^{th} entity of a relation instance. $K_E(\cdot, \cdot)$ is a kernel over entity features, i.e.:

$$K_E(E_1, E_2) = (1 + \vec{x}_1 \cdot \vec{x}_2)^2,$$

where $\vec{x}_1$ and $\vec{x}_2$ are two feature vectors extracted from the two NEs.

For the ACE 2004, the features used include: entity headword, entity type, entity subtype, mention type, and LDC[2] mention type. The last four attributes are taken from the ACE corpus 2004. In ACE, each mention has a head annotation and an extent annotation.

4.3.2 Kernel Combinations

1. Polynomial kernel plus a tree kernel:

$$CK_1 = \alpha \cdot K_P + (1 - \alpha) \cdot K_x,$$

where α is a coefficient to give more impact to K_P and K_x is either the partial tree kernel applied to one the possible dependency structures, DW, GR or GRW or the SST kernel applied to PET, described in the previous section.

2. Polynomial kernel plus constituent plus dependency tree kernels:

$$CK_2 = \alpha \cdot K_P + (1 - \alpha) \cdot (K_{SST} + K_{PT})$$

where K_{SST} is the SST kernel and K_{PT} is the partial tree kernel (applied to the related structures as in point 1).

3. Constituent tree plus square of polynomial kernel and dependency tree kernel:

$$CK_3 = \alpha \cdot K_{SST} + (1 - \alpha) \cdot (K_P + K_{PT})^2$$

4. Dependency word tree plus grammatical relation tree kernels:

$$CK_4 = K_{PT-DW} + K_{PT-GR}$$

where K_{PT-DW} and K_{PT-GR} are the partial tree kernels applied to dependency structures DW and GR.

5. Polynomial kernel plus dependency word plus grammatical relation tree kernels:

$$CK_5 = \alpha \cdot K_P + (1-\alpha) \cdot (K_{PT-DW} + K_{PT-GR})$$

Some preliminary experiments on a validation set showed that the second, the fourth and the fifth combinations yield the best performance with $\alpha = 0.4$ while the first and the third combinations yield the best performance with $\alpha = 0.23$.

Regarding WSK, the following combinations are applied:

[2]Linguistic Data Consortium (LDC): http://www.ldc.upenn.edu/Projects/ACE/

1. $SK_3 + SK_4$
2. $SK_3 + SK_6$
3. $SSK = \sum_{i=1,..,6} SK_i$
4. $K_{SST} + SSK$
5. $CSK = \alpha \cdot K_P + (1 - \alpha) \cdot (K_{SST} + SSK)$

Preliminary experiments showed that the last combination yields the best performance with $\alpha = 0.23$.

We used a polynomial expansion to explore the bi-gram features of i) the first and the second entity participating in the relation, ii) grammatical relations which replace words in the dependency tree. Since the kernel function set is closed under normalization, polynomial expansion and linear combination (Schlkopf and Smola, 2001), all the illustrated composite kernels are also proper kernels.

5 Experiments

Our experiments aim at investigating the effectiveness of convolution kernels adapted to syntactic parse trees and various sequence kernels for the RE task. For this purpose, we use the subset and partial tree kernel over different kinds of trees, namely constituent and dependency syntactic parse trees. Diverse sequences are applied individually and in combination together. We consider our task of relation extraction as a classification problem where categories are relation types. All pairs of entity mentions in the same sentence are taken to generate potential relations, which will be processed as positive and negative examples.

5.1 Experimental setup

We use the newswire and broadcast news domain in the English portion of the ACE 2004 corpus provided by LDC. This data portion includes 348 documents and 4400 relation instances. It defines seven entity types and seven relation types. Every relation is assigned one of the seven types: Physical, Person/Social, Employment/Membership/-Subsidiary, Agent-Artifact, PER/ORG Affiliation, GPE Affiliation, and Discourse. For sake of space, we do not explain these relationships here, nevertheless, they are explicitly described in the ACE document guidelines. There are 4400 positive and 38,696 negative examples when generating pairs of entity mentions as potential relations.

Documents are parsed using Stanford Parser (Klein and Manning, 2003) to produce parse trees. Potential relations are generated by iterating all pairs of entity mentions in the same sentence. Entity information, namely entity type, is integrated into parse trees. To train and test our binary relation classifier, we used SVMs. Here, relation detection is formulated as a multiclass classification problem. The *one vs. rest* strategy is employed by selecting the instance with largest margin as the final answer. For experimentation, we use 5-fold cross-validation with the Tree Kernel Tools (Moschitti, 2004) (available at http://disi.unitn.it/~moschitt/Tree-Kernel.htm).

5.2 Results

In this section, we report the results of different kernels setup over constituent (CT) and dependency (DP) parse trees and sequences taken from these parse trees. The tree kernel (TK), composite kernel (CK_1, CK_2, CK_3, CK_4, and CK_5 corresponding to five combination types in Section 4.3.2) were employed over these two syntactic trees. For the tree kernel, we apply the SST kernel for the path-enclosed tree (PET) of the constituent tree and the PT kernel for three kinds of dependency tree DW, GR, and GRW, described in the previous section. The two composite kernels CK_2 and CK_3 are applied over both two parse trees. The word sequence kernels are applied over six sequences $SK_1, SK_2, SK_3, SK_4, SK_5$, and SK_6 (described in Section 4.3).

The results are shown in Table 1 and Table 2. In the first table, the first column indicates the structure used in the combination shown in the second column, e.g. PET associated with CK_1 means that the SST kernel is applied on PET (a portion of the constituent tree) and combined with the CK_1 schema whereas PET and GR associated with CK_5 means that SST kernel is applied to PET and PT kernel is applied to GR in CK_5. The remaining three columns report Precision, Recall and F1 measure. The interpretation of the second table is more immediate since the only tree kernel involved is the SST kernel applied to PET and combined by means of CK_1.

We note that: first, the dependency kernels, i.e. the results on the rows from 3 to 6 are below the composite kernel CK_1, i.e. 68.9. This is the state-of-the-art in RE, designed by (Zhang et al., 2006), where our implementation provides

Parse Tree	Kernel	P	R	F
PET	$\mathbf{CK_1}$	**69.5**	**68.3**	**68.9**
DW	CK_1	53.2	59.7	56.3
GR	CK_1	58.8	61.7	60.2
GRW	CK_1	56.1	61.2	58.5
DW and GR	CK_5	59.7	64.1	61.8
PET and GR	$\mathbf{CK_2}$	**70.7**	**69.0**	**69.8**
	$\mathbf{CK_3}$	**70.8**	**70.2**	**70.5**

Table 1: Results on the ACE 2004 evaluation test set. Six structures were experimented over the constituent and dependency trees.

Kernel	P	R	F
$\mathbf{CK_1}$	**69.5**	**68.3**	**68.9**
SK_1	72.0	52.8	61.0
SK_2	61.7	60.0	60.8
SK_3	62.6	60.7	61.6
SK_4	73.1	50.3	59.7
SK_5	59.0	60.7	59.8
SK_6	57.7	61.8	59.7
$\mathbf{SK_3 + SK_4}$	**75.0**	**63.4**	**68.8**
$SK_3 + SK_6$	66.8	65.1	65.9
$\mathbf{SSK = \sum_i SK_i}$	**73.8**	**66.2**	**69.8**
CSK	**75.6**	**66.6**	**70.8**
$\mathbf{CK_1 + SSK}$	**76.6**	**67.0**	**71.5**
(Zhou et al., 2007) CK_1 *with Heuristics*	*82.2*	*70.2*	*75.8*

Table 2: Performance comparison on the ACE 2004 data with different kernel setups.

a slightly smaller result than the original version (i.e. an F1 of about 72 using a different syntactic parser).

Second, CK_1 improves to 70.5, when the contribution of PT kernel applied to GR (dependency tree built using grammatical relations) is added. This suggests that dependency structures are effectively exploited by PT kernel and that such information is somewhat complementary to constituent trees.

Third, in the second table, the model $CK_1 + SSK$, which adds to CK_1 the contribution of diverse sequence kernels, outperforms the state-of-the-art by 2.6%. This suggests that the sequential information encoded by several sequence kernels can better represents the dependency information.

Finally, we also report in the last row (in italic) the superior RE result by (Zhou et al., 2007). However, to achieve this outcome the authors used the composite kernel CK_1 with several heuristics to define an effective portion of constituent trees. Such heuristics expand the tree and remove unnecessary information allowing a higher improvement on RE. They are tuned on the target RE task so although the result is impressive, we cannot use it to compare with pure automatic learning approaches, such us our models.

6 Conclusion and Future Work

In this paper, we study the use of several types of syntactic information: constituent and dependency syntactic parse trees. A relation is represented by taking the path-enclosed tree (PET) of the constituent tree or of the path linking two entities of the dependency tree. For the design of automatic relation classifiers, we have investigated the impact of dependency structures to the RE task. Our novel composite kernels, which account for the two syntactic structures, are experimented with the appropriate convolution kernels and show significant improvement with respect to the state-of-the-art in RE.

Regarding future work, there are many research line that may be followed:

i) Capturing more features by employing external knowledge such as ontological, lexical resource or WordNet-based features (Basili et al., 2005a; Basili et al., 2005b; Bloehdorn et al., 2006; Bloehdorn and Moschitti, 2007) or shallow semantic trees, (Giuglea and Moschitti, 2004; Giuglea and Moschitti, 2006; Moschitti and Bejan, 2004; Moschitti et al., 2007; Moschitti, 2008; Moschitti et al., 2008).

ii) Design a new tree-based structures, which combines the information of both constituent and dependency parses. From dependency trees we can extract more precise but also more sparse relationships (which may cause overfit). From constituent trees, we can extract subtrees constituted by non-terminal symbols (grammar symbols), which provide a better generalization (with a risk of underfitting).

iii) Design a new kernel which can integrate the advantages of the constituent and dependency tree. The new tree kernel should inherit the benefits of the three available tree kernels: ST, SST or PT.

Abstract

This paper presents an approach to automatic acquisition of the argument-predicate relations from a semantically annotated corpus. We use SALSA, a German newspaper corpus manually annotated with role-semantic information based on frame semantics. Since the relatively small size of SALSA does not allow to estimate the semantic relatedness in the extracted argument-predicate pairs, we use a larger corpus for ranking. Two experiments have been performed in order to evaluate the proposed approach. In the first experiment we compare automatically extracted argument-predicate relations with the gold standard formed from associations provided by human subjects. In the second experiment we calculate correlation between automatic relatedness measure and human ranking of the extracted relations.

1 Introduction

There are many debates in lexical semantics about what kind of world knowledge actually belongs to the meaning of a lexeme. Nowadays, it is widely accepted that predicates impose selectional restrictions on their arguments. For example, since we know that the predicate *to be hungry* mainly takes expressions describing animate beings as arguments, we can correctly resolve the anaphora in the following sentence: *We gave the bananas to the monkeys because they were hungry*. There exists also multiple linguistic evidence showing that the semantics of arguments can help to predict implicit predicates. For example, the sentence *John finished the cigarette* usually means *John finished smoking the cigarette* because the meaning of the noun *cigarette* is strongly associated with the smoking activity.

It has been claimed that information about predicates associated with nouns can be helpful for a variety of tasks in natural language processing (NLP), see for example (Pustejovsky et al., 1993; Voorhees, 1994). However, at present there exists no corresponding lexical semantic resource. Several approaches have been presented that aim at creating a knowledge base containing noun-verb relations. There are two main research paradigms for developing such knowledge bases. The first paradigm assumes manual development of the resource (Pustejovsky et al., 2006), while the second one relies on automatic acquisition methods, see for example (Cimiano and Wenderoth, 2007). In this paper we propose a procedure for automatic acquisition of argument-predicate relations from a semantically annotated corpus. In line with (Lapata and Lascarides, 2003) our approach is based on the assumption that predicates are omitted in a discourse when they are highly predictable from the semantics of their arguments. We exploit SALSA (Burchardt et al., 2006), a German newspaper corpus manually annotated with FrameNet frames based on frame semantics. Using a manually annotated corpus for relation extraction has one particular advantage compared to extraction from plain text: the type of an argument-predicate relation is already annotated; there is no need to determine it by automatic means which are usually error-prone. However, the relatively small size of SALSA does not allow to make relevant predictions about the degree of semantic relatedness in the extracted argument-predicate pairs, see section 4. We therefore employ a considerably larger unannotated corpus for weighting. The results are evaluated quantitatively against human judgments obtained experimentally. The proposed evaluation procedure is similar to that presented in (Cimiano and Wenderoth, 2007). First, we create a gold standard for 30 words from the argument list and evaluate our approach with respect to this

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1388–1397,
Singapore, 6-7 August 2009.

gold standard. Second, we provide results from an evaluation in which test subjects are asked to rate automatically extracted relations using a four-point scale.

The paper is structured as follows: Section 2 describes some linguistic phenomena requiring inferences of an implicit predicate from the semantics of an explicitly given argument. In section 3 we give a short overview of the related work. Sections 4 discusses the SALSA corpus. Section 5 introduces our approach. Finally, section 6 describes an experimental evaluation of the presented approach and section 7 concludes the paper.

2 Implicit Predicates

In this section we discuss some linguistic phenomena requiring inferences of an implicit predicate from the semantics of an explicitly given argument for their resolution. One of the most studied phenomena that Pustejovsky (1991) has called logical metonymy is illustrated by the examples (1a) and (1b) below. In the case of logical metonymy an implicit predicate is inferable from particular verb-noun and adjective-noun pairs in a systematic way. The verb *anfangen* 'to start' and the adjective *kompliziert* 'complicated' in the mentioned examples semantically select for an event, while the nouns (*Buch* 'book' and *Frage* 'question' respectively) have a different semantic type. However, the set of the most probable implicit predicates is predictable from the semantics of the nouns. Thus, (1a) plausibly means *Als ich angefangen habe, dieses Buch zu lesen/schreiben...* 'When I have started to read/write this book...' and (2a) plausibly means *eine Frage die kompliziert zu beantworten ist* 'a question which is complicated to answer'.

Example 1

(a) *Als ich mit diesem Buch angefangen habe...*
'When I have started this book...'
(b) *eine komplizierte Frage*
'a complicated question'
(c) *Studentenfutter*
'student food'
(d) *Nachrichtenagentur Xinhua über Beziehungen beider Seiten der Taiwan-Strasse*
'News agency Xinhua about relations of both sides of the Taiwan Strait'
(e) *Hans ist beredt*
'Hans is eloquent'

As we can see from Example 1, besides logical metonymy there are other linguistic phenomena requiring knowledge about predicates associated with an argument for their resolution. Example (1c) contains a noun compound which can be interpreted on basis of the meaning of the noun *Futter* 'food'. In general, noun compounds can be interpreted in many different ways depending on the semantics of the constituencies: *morning coffee* is a coffee which is drunk in the morning, *brick house* is a house which is made of bricks etc. In case of (1c) the relation via the predicate *essen* 'to eat' taking *Studenten* 'students' as a subject and *Futter* 'food' as an object seems to be the most plausible one.

The phrase (1d) is a title of a newspaper article. As in the previous examples, a predicate is left out in (1d). The meaning of the preposition *über* 'about' can help to narrow down the set of possible predicates, but still allows an inadequately large range of interpretations. However, the semantics of the noun *Nachrichtenagentur* 'news agency' supports such interpretations as *berichten* 'to report' or *informieren* 'to inform'.

Most of the literature discusses predicates inferable from nouns. However, other parts of speech can support similar inferences. In example (1e) a predicate is predictable on the basis of the meaning of the adjective *beredt* 'eloquent'. The sentence (1e) most plausibly means that Hans speaks eloquently.

Example 1 shows that knowledge about predicates associated with explicitly given arguments can help to deal with several linguistic phenomena. The cases when a predictable predicate is left out are not rare in natural language. For example, for logical metonymy a corpus study has shown that the constructions like *begin V NP* occur rarely if the verb *V* corresponds to a highly plausible interpretation of *begin NP* (Briscoe et al., 1990).

3 Related Work

The most influential account of logical metonymy is provided by Pustejovsky's theory of the Generative Lexicon, GL (Pustejovsky, 1991). According to Pustejovsky the meaning of a noun includes a *qualia structure* representing "the essential attributes of an object as defined by the lexical item". Thus, the lexical meaning of the noun *book* includes *read* and *write* as qualia roles. In the framework of GL, Pustejovsky et al. (2006)

are manually developing the Brandeis Semantic Ontology which is a large generative lexicon ontology and dictionary. There also exist several approaches to automatic acquisition of qualia structures from text corpora which aim at supporting the time-consuming manual work. For example, Pustejovsky et al. (1993) use generalized syntactic patterns for extracting qualia structures from a partially parsed corpus. Cimiano and Wenderoth (2007) suggest a pattern-based method for automatic extraction of qualia structures from the Web. The results of the human judgment experiment reported in (Cimiano and Wenderoth, 2007) suggest that the automatic acquisition of qualia structures is a difficult task. Human test subjects have shown a very low agreement (11,8% average agreement) in providing qualia structures for given nouns.

Another line of research on inferring implicit predicates concerns using information about collocations derived from corpora. For example, Lapata and Lascarides (2003) resolve logical metonymy on the basis of the distribution of paraphrases like *finish the cigarette – finish smoking the cigarette* and *easy problem – problem which is easy to solve* in a corpus. This approach shows promising results, but it is limited to logical metonymy. Similarly, Nastase et al. (2006) use grammatical collocations for defining semantic relations between constituents in noun compounds.

In our study we aim at extracting intuitively plausible argument-predicate relations from a semantically annotated corpus. Using an annotated corpus we avoid problems of defining types of these relations by automatic means which are usually error-prone. We represent argument-predicate relations in terms of FrameNet frames which allow for a fine-grained and grounded representation supporting paraphrasing, see next sections. Our approach is not restricted to nouns. We also concern relations where argument positions are filled by adjectives, adverbs or even verbs.

4 The SALSA Corpus

For relation extraction we have chosen the SALSA corpus (Burchardt et al., 2006) developed at Saarland University. SALSA is a German corpus manually annotated with role-semantic information, based on the syntactically annotated TIGER newspaper corpus (Brants et al., 2002). The 2006 SALSA release which we have used contains about 20 000 annotated predicate instances. The corpus is annotated with the set of FrameNet frames.

The FrameNet, FN (Ruppenhofer et al., 2006), lexical resource is based on frame semantics (Fillmore, 1976), see *http://framenet.icsi.berkeley.edu*. The lexical meaning of predicates in FN is expressed in terms of frames (approx. 800 frames) which are supposed to describe prototypical situations spoken about in natural language. Every frame contains a set of roles (or frame elements, FEs) corresponding to the participants of the described situation. Predicates with similar semantics are assigned to the same frame, e.g. *to give* and *to hand over* refer to the GIVING frame. Consider a FN annotation for the sentence (2a) below. In this annotation DONOR, RECIPIENT and THEME are roles in the frame GIVING and *John*, *Mary* and *a book* are fillers of these roles. The FN annotation generalizes across near meaning-preserving transformations, see (2b).

Example 2

(a) [*John*]$_{\text{DONOR}}$ [*gave*]$_{\text{GIVING}}$ [*Mary*]$_{\text{RECIPIENT}}$ [*a book*]$_{\text{THEME}}$.
(b) [*John*]$_{\text{DONOR}}$ [*gave*]$_{\text{GIVING}}$ [*a book*]$_{\text{THEME}}$ [*to Mary*]$_{\text{RECIPIENT}}$.

In FN information about syntactic realization patterns of frame elements as well as information about frequency of occurrences of these patterns in corpora is provided. For example, the role DONOR in the frame GIVING is most frequently filled by a noun phrase in the subject position or by a prepositional phrase with the preposition *by* as the head in the complement position.

The FN project originally aimed at developing a frame-semantic lexicon for English. Later on FN frames turned out to be to a large extent language independent (Burchardt et al., 2006). In most of the cases German predicates could be successfully described by the FN frames. However, some of the frames required adaptation to the German data, e.g. new FEs were introduced. Since FN does not cover all possible word senses, new frames needed to be added for some of the predicates.

We have chosen the SALSA corpus for our experiments because to our knowledge it is the only freely available corpus which contains both syntactic and role-semantic annotation. However, we are aware that SALSA (approx. 700 000 tokens) is too small to compute a reliable co-occurrence model for measuring plausibility of the extracted argument-predicate relations, though it

is relatively large for a manually annotated corpus. As it was shown in (Bullinaria and Levy, 2007), co-occurrence-based approaches need very large training corpora in order to reliably compute semantic relatedness. The SALSA corpus, comprising less than 1 million tokens, is too small for this purpose. Moreover, a considerable number of predicates in SALSA appeared to be unannotated. Some of the high frequency pairs, as for example *Bombe, explodieren* 'bomb, to explode', occur in SALSA only once, just as occasional pairs like *Deutsche, entdecken* 'German, to discover'. We have tried to overcome the size problems by using a larger unannotated corpus for recomputing the rating of our resulting relations, see next section.

5 Automatic Acquisition of the *Argument-Predicate* Relations

In line with (Lapata and Lascarides, 2003), our approach to extraction of argument-predicate (AP) relations is based on two assumptions:

A1: If predicates are highly predictable from the semantics of their arguments then they can be omitted in a discourse;
A2: If a predicate frequently takes a word as an argument then it is highly predictable from the semantics of this word.

In the proposed experimental setting argument-predicate relations are defined in terms of the FrameNet frames. Thus, we aim at extracting from SALSA tuples of the form ⟨*Argument*, ROLE, FRAME, *Predicate*⟩ such that the *Argument* plausibly fills the ROLE in the FRAME evoked by the *Predicate*. As already mentioned in section 3, our approach is not restricted to nouns. We also treat arguments expressed by other content parts of speech. The proposed relation extraction procedure consists in

- finding for every content word which occurs in the corpus a set of predicates taking this word as an argument with a high probability;
- defining a relation between the word and every predicate from this set by finding which roles the noun fills in frames evoked by the predicate;
- estimating the degree of the semantic relatedness in the extracted argument-predicate pairs.

For example, analyzing the following sentence

[*Fünf Oppositionelle*]$_{\text{SUSPECT}}$ *sind in Ebebiyin* [*von der Polizei*]$_{\text{AUTHORITIES}}$ [*festgenommen*]$_{\text{ARREST}}$ *worden*.

'Five members of the opposition have been arrested by the police in Ebebiyin.'

we aim at extracting the following tuples:

Argument	Role	Frame	Predicate
Oppositionell	SUSPECT	ARREST	*festnehmen*
Polizei	AUTHORITIES	ARREST	*festnehmen*

Relation Extraction

In SALSA, every sentence is annotated with a set of frames in such a way that for every frame its FEs refer to some syntactic constituents in the sentence. In order to extract argument-predicate relations from SALSA we need 1) to find a content head for every constituent corresponding to a FE; 2) to resolve possibly existing anaphora. Since SALSA is syntactically annotated, the first task proved to be relatively easy.[1] On the contrary, anaphora resolution is well-known to be one of most challenging NLP tasks. In our study, we do not focus on it, and we treat only pronominal anaphora using the following straightforward resolution algorithm: given a pronoun the first noun which agrees in number and gender with the pronoun is supposed to be its antecedent. In order to evaluate this resolution procedure we have inspected 100 anaphoric cases. In approximately three fourths of the cases the anaphora were resolved correctly. Therefore, we have assigned a confidence rate of 0,75 to the FE fillers resulting from a resolved anaphora. In non-anaphoric cases a confidence rate of 1 was assigned.

For every extracted tuple of the form ⟨*Argument*, ROLE, FRAME, *Predicate*⟩ we have summed up the corresponding confidence rates. Finally, we have obtained around 30 000 tuples with confidence rates ranging from 0,75 to 88. It is not surprising that most of the arguments appeared to be nouns, while most of the predicates are expressed by verbs. Since SALSA has been annotated manually, there are almost no mistakes in defining types of the semantic

[1] We have excluded from the consideration foreign-language expressions, while proper nouns were treated in the usual way. For verb phrases with auxiliary or modal verbs as heads the main verb was taken as a corresponding role filler.

relations between arguments and predicates.[2] For several pairs, the semantic relation between an argument and a predicate is ambiguous. Consider the tuples extracted for the word pair *Buch, schreiben* 'book, to write' which are given below. While the first tuple corresponds to phrases like *ein Buch schreiben* 'to write a book', the second one abstracts from the expressions like *in einem Buch schreiben* 'to write in a book'.

Argument	Role	Frame	Predicate
Buch	TEXT	TEXT_CREATION	*schreiben*
Buch	MEDIUM	STATEMENT	*schreiben*

Additionally, ambiguity can arise because of the annotation disagreements in SALSA. For example, the pair (*Haft, sitzen*) 'imprisonment', 'to sit' in Table 1 was annotated in SALSA both with the BEING_LOCATED and with the POSTURE frames.

As mentioned in section 4, a considerable number of predicates in SALSA is not annotated semantically. In order to find out how many relevant AP-relations get lost if we consider only semantically annotated predicates, we have additionally extracted AP-pairs on the basis of the syntactic annotation only. The anaphora resolution procedure as described above was again applied to the syntactic argument heads. We have obtained around 56 500 pairs with confidence rates ranging from 0,75 to 71,50.[3]

As one could expect, being a newspaper corpus SALSA appeared to be thematically unbalanced. The most frequent argument-predicate relations occurring in SALSA reflect common topics discussed in newspapers: economics (e.g. (*Prozent, steigen*), 'percent', 'to increase'), criminality (e.g. (*Haft, verurteilen*) 'imprisonment', 'to sentence'), catastrophes (e.g. (*Mensch, töten*) 'human', 'to kill') etc.

Ranking

As mentioned in section 4, the size of SALSA does not allow to make relevant predictions about the distribution of frames and role fillers. Only 2% of the relations occur in SALSA more then 3 times. In order to overcome this problem we have developed a measure of semantic relatedness between the extracted arguments and predicates which takes into account their co-occurrence in a larger and more representative corpus. For computing semantic relatedness we have used a lemmatized newspaper corpus (Süddeutsche Zeitung, SZ) of 145 million words. Given a tuple t with a confidence rate c containing an argument a and a predicate p, the relatedness measure *rm* of t was computed as follows:

$$rm(t) = lsa(a, p) + c/max(c),$$

where the $lsa(a, p)$ is based on Latent Semantic Analysis, LSA (Deerwester et al., 1990). LSA is a vector-based technique that has been shown to give reliable estimates on semantic relatedness. It makes use of distributional similarities of words in text and constructs a semantic space (or word space) in which every word of a given vocabulary is represented as a vector. Such vectors can then be compared to one another by the usual vector similarity measures (e.g. cosine). We calculated the LSA word space using the Infomap toolkit10 v. 0.8.6 (*http://infomap-nlp.sourceforge.net*). The co-occurrence matrix (window size: 5 words) comprised 80 000×3 000 terms and was reduced by SVD to 300 dimensions. For the vector comparisons the cosine measure was applied. To those words which did not occur in the analyzed SZ corpus (approx. 3500 words) a *lsa* measure of 0 was assigned. To provide a comparable contribution to rm, the confidence rates c extracted from SALSA are divided by the maximal confidence rate. The *rm* function is a linear interpolation of the *lsa* and the normalized *c* measure. As mentioned above, the *c* measure is a discriminative factor for only 2% of the relations. For the remaining 98% the normalized *c* values are small (0,003 or 0,002 or 0,001). Therefore, calculating the *rm* measure we mainly rely on *lsa*, while normalized *c* actually plays a role only for the relations frequently occurring in SALSA. Table 1 contains the 5 most semantically related predicates for an example argument.

6 Evaluation

Since the extracted argument-predicate relations are intended to be used for inferring intuitively obvious predicates,we evaluate to which extend they correspond to human intuition.

[2] Mistakes can arise only because of the annotation errors and errors in the anaphora resolution procedure.

[3] The comparison of the results obtained by the extraction procedure based on the semantic annotation with the results of the procedure based on the syntactic annotation only is provided in the next section.

Table 1: Examples of the extracted argument-predicate relations

Argument	Role	Frame	Predicate	*rm*
Haft	FINDING	VERDICT	*verurteilen* 'to sentence'	0,939
'imprisonment'	LOCATION	BEING_LOCATED	*sitzen* 'to sit'	0,237
	LOCATION	POSTURE	*sitzen* 'to sit'	0,226
	MESSAGE	REQUEST	*fordern* 'to demand'	0,153
	BAD_OUTCOME	RUN_RISK-FNSALSA	*drohen* 'to threaten'	0,144

Gold Standard

Similar to (Cimiano and Wenderoth, 2007) we provide a gold standard for 30 test arguments occurring in the SALSA corpus. The test arguments were selected randomly from the set of those arguments that have more than one predicate associated with them such that a value of argument-predicate relatedness exceeds the average one. These words were nearly uniformly distributed among 20 participants of the experiment, who were all non-linguists. We also ensured that each word was treated by three different subjects. For every word we asked our subjects to write between 5 and 10 short phrases that contain a predicate taking the given word as an argument, e.g. *book – to read a book*. The participants were asked to provide phrases instead of single predicates, because we wanted to control the syntactic and semantic position of the arguments. The participants received an instruction informally describing the notion of predicate and what kind of phrases they are supposed to come up with. Besides the task description they were shown examples containing appropriate and inappropriate phrases. Some of the examples are given below.

Example 3

(a) *Aktie* 'stock' : *Kauf der Aktien* 'buying of stocks', *Aktien kaufen* 'to buy stocks', *Aktien an der Börse* 'stocks on the bourse' (is inappropriate because the word "bourse" describes a place and not an event)

(b) *beredt* 'eloquent': *beredt sprechen* 'to speak eloquently', *ein beredter Sprecher* 'an eloquent speaker' (is inappropriate because the word "speaker" describes a person and not an event)

The test was conducted via e-mail. In order to compare the human associations with the extracted AP-relations, we have manually annotated the obtained phrases with SALSA frames. The agreement for the described task for every cue word was calculated as the averaged pairwise agreement between the AP-relations delivered by the three subjects, S_1, S_2 and S_3, as follows:

$$Agr = \frac{\frac{|S_1 \cap S_2|}{|S_1 \cup S_2|} + \frac{|S_2 \cap S_3|}{|S_2 \cup S_3|} + \frac{|S_2 \cap S_3|}{|S_2 \cup S_3|}}{3}.$$

Agreement results for every cue word are reported in table 2. Second column of the table contains gold standard predicates which were provided by all 3 participants treating the same word.[4] Averaging over all words, we got a mean agreement of 13%. Though this value seems to be low, it is consistent with a mean agreement of 11,8% for a similar task reported in (Cimiano and Wenderoth, 2007), see section 3. Cimiano and Wenderoth (2007) show that the lowest agreement is yielded for more abstract words, while the agreement for very concrete words is reasonable. We could not make a similar observation, see table 2.

Comparison with the Gold Standard

In the first experiment we checked whether predicates which people associate with the test arguments can be automatically extracted by our procedure. For this aim we compared the gold standard with all automatically extracted argument-predicate relations[5] containing some of the 30 cue words as follows. These relations were ranked according to the relatedness measure described in previous section. In line with (Cimiano and Wenderoth, 2007) we exploited an approach common in information retrieval for estimating the quality of correspondence of a ranked output to a gold standard, see (Baeza-Yates and Ribeiro-Neto, 1999).

Given some n automatically extracted relations with the highest ranking we calculated a precision-recall curve expressing precision and recall of our procedure compared to the gold standard. The precision characterizes the procedure exactness, i.e. how many redundant relations are retrieved. The

[4]The overall gold standard consists of 33 tuples.

[5]In order to evaluate the procedure extracting AP-relations on the basis of the semantic annotation we compared automatically extracted tuples to the gold standard tuples. For the procedure using the syntactic annotation only the AP-pairs were considered without regarding frames and FEs.

recall measures the completeness, i.e. how many relations of the gold standard are extracted automatically. For each point of the curve (which is a pair (p, r) of values of precision p and recall r) we calculated the F-measure as $F = 2pr/(p + r)$ which is the harmonic mean between recall and precision. The precision-recall curve is a set of precision values for the prespecified recall levels varying from 0 to 1 with a step 0,1. Then, to produce only one value evaluating the quality of the ranked output compared to the gold standard, for each precision-recall curve we calculated F_{max}, the maximal value of the F-measure achieved for the points of this curve. F_{max} expresses the best trade-off between precision and recall for the given ranked output. Finally, among all possible n (numbers of the considered relations with the highest ranking) we selected that one which provides the maximal F_{max} value.

The resulting maximal F_{max} values are 0,47 for the procedure extracting AP-relations on the basis of the semantic annotation and 0,41 for the procedure using the syntactic annotation only. We compared these results with the baseline results of maximal F_{max} values produced for the output with random ranking. The calculation of the baseline was repeated 100 times, each time a new random ranking was generated. The lowest baseline results are 0,08/0,06 (semantic/syntactic annotation), the highest are 0,18/0,14 and the medians are 0,1/0,07. One can see that the results produced using the relatedness measure (0,47/0,41) greatly exceed the baseline. Based on this comparison we conclude that the ranking done using the relatedness measure brings a significant advantage. The values of precision and recall for the reported maximal F_{max} values are 0,5/0,33 (semantic/syntactic annotation) and 0,45/0,54 respectively. This results show that half of the AP-relations from the gold standard appeared to be in the list of the top-ranked tuples extracted by the "semantic" procedure, while the size of this list ($n = 28$) was almost equal to the size of the gold standard (33). The differences in performance between the "semantic" and "syntactic" procedures could be explained by the fact that the "syntactic" procedure finds in the corpus more related predicates for every argument than the "semantic" one. Nevertheless, the "semantic" procedure shows better performance.

Next we investigated the results for each argument used in the gold standard separately in the same way as described above. For each argument the F_{max} measure has been computed. Because of the low agreement between the subjects questioned for the gold standard (see above), in these calculations we considered all predicates reported by our subjects. The calculated F_{max} values are reported in table 2 which shows a correlation between F_{max} values calculated for the "semantic" and "syntactic" procedures. However, there is no correlation with human agreement. This issue needs a further investigation, see section 7.

Human Judgments of the Relatedness

Following (Cimiano and Wenderoth, 2007), in order to check whether the calculated relatedness is reasonable according to human intuition, we have performed another experiment. For each of the 30 words selected for the gold standard we selected the 5 top ranked predicates. Since for some of the cue arguments only 3 predicates were found in the corpus, the final test set contains only 138 argument-predicate tuples. From these tuples we generated short grammatically correct phrases structurally similar to those in example 3. These phrases were uniformly distributed among 10 subjects so that every phrase was evaluated by one subject. The participants were asked to rate the phrases with respect to their naturalness using a scale from 0 to 3, whereby 0 means 'unnatural', 1 'possible', 2 'natural' and 3 'totally natural and self-evident'.

Further on we investigated the relationship between the human estimates and the relatedness values obtained automatically. For this aim we used the Spearman rank correlation coefficient. Because of four-points scale used, the human rankings are equal for many tuples which lead to the so-called effect of ties. For this reason we computed the correlation coefficient with a correction for ties. The coefficient value is 0,30 and this correlation is statistically significant with p-value 0,0006. Based on these results we conclude that our relatedness measure is correlated with human judgments. Taking into account the subjective character of human ranking in terms of naturalness, the achieved correlation values can be considered as high.

Table 2: Evaluation results for 30 gold standard cue words.

Cue word	**Shared predicates**	***Agr***	**Sem.** F_{max}	**Syn.** F_{max}
Name 'name'	*haben* 'to have'	14%	0,2	0,48
Urlaub 'vacation'	*fahren* 'to go'	8%	0,13	0,16
Sprache 'language'	*sprechen* 'to speak', *lernen* 'to learn'	14%	0,4	0,3
Strafe 'fine'	*verurteilen* 'to sentence'	11%	0,21	0,3
Stuhl 'chair'	*sitzen* 'to sit'	14%	0,1	0,2
Bombe 'bomb'	*hochgehen* 'to blow up'	14%	0,11	0,22
Blatt 'gazette', 'page', 'leaf'	–	2%	0	0
Flughafen 'airport'	*ankommen* 'to arrive', *fahren* 'to go'	21%	0,17	0,17
Gesetz 'low'	–	8%	0,17	0,38
Polizei 'police'	*rufen* 'to call'	11%	0,22	0,23
Kompromiss 'compromise'	*schliessen* 'to make'	15%	0,07	0,29
Fluggesellschaft 'airline'	–	3%	0,11	0,38
Antrag 'proposal', 'application'	*stellen* 'to introduce', *ablehnen* 'to decline'	24%	0,43	0,42
Zeitung 'newspaper'	*lesen* 'to read'	13%	0,17	0,09
Brief 'letter'	*verschicken* 'to send', *schreiben* 'to write'	19%	0,23	0,12
Flüchtling 'refugee'	*aufnehmen* 'to accept'	13%	0	0,07
Buch 'book'	*schreiben* 'to write', *lesen* 'to read'	15%	0,44	0,39
Zähler 'counter'	*ablesen* ' to read'	11%	0	0
Anzahl 'number'	–	3%	0,23	0,19
Prozent 'percent'	–	3%	0,48	0,21
Ziel 'goal'	*verfehlen* 'to miss', *erreichen* 'to reach'	20%	0,3	0,48
Schule 'school'	*schwänzen* 'to miss', *gehen* 'to go'	22%	0,13	0,23
Amt 'position', 'department'	*bekleiden, innehaben* 'to hold', *gehen* 'to go'	20%	0	0,17
Frage 'question'	*beantworten* 'to answer', *stellen* 'to ask'	20%	0,15	0,37
Mensch 'human'	*sein* 'to be'	16%	0,09	0,03
Zeuge 'witness'	*aussagen* 'to testify', *sein* 'to be'	22%	0,13	0,19
Thema 'theme'	–	7%	0,14	0,26
Preisträger 'prize winner'	–	5%	0,08	0,08
Initiative 'initiative'	*ergreifen* 'to take'	17%	0,1	0,13
Wohnung 'flat'	–	7%	0,09	0,17

7 Conclusion and Discussion

In this paper we presented an approach to automatic extraction of argument-predicate relations from a frame-annotated corpus.[6] In our approach we aimed to combine the advantages offered by annotated and unannotated lexical resources. Besides extracting AP-pairs the proposed method allows us to define types of semantic relations in terms of FrameNet frames. The proposed procedure is not restricted to arguments expressed by nouns and treats also other content parts of speech.

The main goal of this paper was to show that though manually annotated corpora usually have a relatively small size, they can be successfully exploited for the relation extraction. An obvious limitation of the presented approach is that it is bounded to manual annotations which are hard to obtain. However, since semantic annotations are useful for many different goals in linguistics and NLP, the number of reliable annotated corpora constantly grows.[7] Moreover, recently several tools have been developed which perform role annotation automatically, for example see (Erk and Pado, 2006). Therefore we believe that approaches using semantic annotation are valid and promising. In the future we plan to experiment with large role-annotated corpora for English such as PropBank (approx. 300 000 words, (Palmer et al., 2005)) and the FrameNet-annotated corpus provided by the FN project (more than 135 000 annotated sentences, (Ruppenhofer et al., 2006)). Since these corpora do not contain syntactic annotation, for extracting argument-predicate relations we will need to parse annotated sentences.

There are several ways to improve the proposed procedure. First, an implementation of a more advanced anaphora resolution algorithm treating pronominal as well as nominal anaphora should significantly raise the precision/recall characteristics. Second, splitting German compounds occurring in the corpus should provide additional evidence. We have treated such words as *Kunde* 'client' and *Privatkunde* 'private client' as different lexemes, while they are strongly related se-

[6] The complete list of the extracted AP-relations as well as the results of the experiment will be available online at *http://www.ikw.uni-osnabrueck.de/∼eovchinn/APrels/*.

[7] At present FrameNet annotated corpora are available for English, German and Spanish, see *http://framenet.icsi.berkeley.edu*.

mantically and information about predicates co-occurring with the second word could probably be used for describing the semantics of the first one. Concerning relatedness measure, additional corpus-based measures such as Web-based measures (Cimiano and Wenderoth, 2007) or measures based on syntactic relations (Pustejovsky et al., 1993) could appear to be useful for improving the ranking of the extracted relations.

The presented procedure was evaluated quantitatively against human judgments obtained experimentally. The participants of the experiment were asked to provide short phrases containing given cue words and predicates associated with these words as well as to rate phrases generated from the automatically extracted AP-relations. Concerning the first experiment, the low human agreement has shown that the proposed association task appeared to be difficult for the subjects. Nevertheless, the described learning procedure proved to extract intuitively reasonable relations.

The evaluation strategy presented in this paper on relies on the underlying assumptions (**A1** and **A2** in section 5) and is compatible with the other approaches to relation extraction, cf. (Cimiano and Wenderoth, 2007). However, it is plausible that human responses in the context of providing associated predicates for target words will differ from the responses in the experimental settings where subjects are asked to infer implicit predicates, e.g. to extend phrases containing implicit predicates. In the future we plan to implement a procedure making use of the extracted AP-relations which would automatically extend phrases containing implicit predicates. Then we intend to compare output results of the procedure with the human responses. Additionally, a study of a possible correspondence between human agreement on associated predicates and a semantic type of an argument (e.g. concrete/abstract, natural kind/artifact) should be performed on more test arguments.

Potential Applications

As already mentioned in the literature, see for example (Lapata and Lascarides, 2003), knowledge about implicit predicates could be potentially useful for a variety of NLP tasks such as language generation, information extraction, question answering or machine translation. Many applications of semantic relations in NLP are connected to paraphrasing or query expansion, see for example (Voorhees, 1994). Suppose that a search engine or a question answering system receives the query *schnelle Bombe* 'quick bomb'. Probably, in this case the user is interested in finding information about bombs that explode quickly rather then about bombs in general. Knowledge about predicates associated with the noun *Bombe* 'bomb' could be used for predicting a set of probable implicit predicates. For generation of the semantically and syntactically correct paraphrases it is sometimes not enough to guess the most probable argument-predicate pairs. Information about types of an argument-predicate relation could be helpful, i.e. which semantic and syntactic position does the argument fill in the argument structure of the predicate. For example, compare *eine Bombe explodiert schnell* 'a bomb explodes quickly' for *schnelle Bombe* with *ein Buch schnell lesen/schreiben* 'to read/write a book quickly' for *schnelles Buch* 'quick book'. In the first case the argument *Bombe* fills the subject position, while in the second case *Buch* fills the object position. Since FrameNet contains information about syntactic realization patterns for frame elements, representation of argument-predicate relations in terms of frames directly supports generation of semantically and syntactically correct paraphrases.

The described procedure could also support manual development of a lexical resource, providing evidence from corpora as well as the distributional information.

Abstract

Distinguishing speculative statements from factual ones is important for most biomedical text mining applications. We introduce an approach which is based on solving two sub-problems to identify speculative sentence fragments. The first sub-problem is identifying the speculation keywords in the sentences and the second one is resolving their linguistic scopes. We formulate the first sub-problem as a supervised classification task, where we classify the potential keywords as real speculation keywords or not by using a diverse set of linguistic features that represent the contexts of the keywords. After detecting the actual speculation keywords, we use the syntactic structures of the sentences to determine their scopes.

1 Introduction

Speculation, also known as hedging, is a frequently used language phenomenon in scientific articles, especially in experimental studies, which are common in the biomedical domain. When researchers are not completely certain about the inferred conclusions, they use speculative language to convey this uncertainty. Consider the following example sentences from abstracts of articles in the biomedical domain. The abstracts are available at the U.S. National Library of Medicine PubMed web page[1]. The PubMed Identifier (PMID) of the corresponding article is given in parenthesis.

1. *We showed that the Roaz protein bound specifically to O/E-1 by using the yeast two-hybrid system. (PMID: 9151733)*

2. *These data suggest that p56lck is physically associated with Fc gamma RIIIA (CD16) and functions to mediate signaling events related to the control of NK cellular cytotoxicity. (PMID: 8405050)*

The first sentence is definite, whereas the second one contains speculative information, which is conveyed by the use of the word *"suggest"*. While speculative information might still be useful for biomedical scientists, it is important that it is distinguished from the factual information.

Recognizing speculations in scientific text has gained interest in the recent years. Previous studies focus on identifying speculative sentences (Light et al., 2004; Medlock and Briscoe, 2007; Szarvas, 2008; Kilicoglu and Bergler, 2008). However, in many cases, not the entire sentence, but fragments of a sentence are speculative. Consider the following example sentences.

1. *The mature mitochondrial forms of the erythroid and housekeeping ALAS isozymes are predicted to have molecular weights of 59.5 kd and 64.6 kd, respectively. (PMID: 2050125)*

2. *Like RAD9, RAD9B associates with HUS1, RAD1, and RAD17, suggesting that it is a RAD9 paralog that engages in similar biochemical reactions. (PMID: 14611806)*

Both sentences are speculative, since they contain speculative information, which is signaled by the use of the word *"predicted"* in the first sentence and the word *"suggesting"* in the second sentence. The scope of the speculation keyword *"predicted"* in the first sentence spans the entire sentence. Therefore, classifying the sentence as speculative does not cause information loss. However, the scope of the speculation keyword *"suggesting"* in the second sentence applies only to the second clause of the sentence. In other words, only the statement *"RAD9B is a RAD9 paralog that engages in similar biochemical reactions"* is speculative. The statement *"Like RAD9, RAD9B associates with HUS1, RAD1, and RAD17"* conveys factual information. Therefore, classifying

[1] http://www.ncbi.nlm.nih.gov/pubmed/

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1398–1407,
Singapore, 6-7 August 2009.

the entire sentence as speculative will result in information loss.

In this paper, we aim to go beyond recognizing speculative sentences and tackle the problem of identifying speculative fragments of sentences. We propose an approach which is based on solving two sub-problems: (1) detecting the real speculation keywords, (2) resolving their linguistic scopes in the sentences. As the previous examples demonstrated speculations are signaled with speculation keywords (e.g. *might, suggest, likely, hypothesize, could, predict, and etc.*). However, these keywords are not always used in a speculative context. In other words, they are not always real speculation keywords. Unlike previous approaches which classify sentences as speculative or not, we formulate the problem as classifying the keywords as real speculation keywords or not. We extract a diverse set of features such as linguistic features that represent the context of the keyword and positional features of the sentence in which the keyword occurs. We use these features with Support Vector Machines (SVM) to learn models to classify whether the occurrence of a keyword is in a speculative context or not. After detecting the real speculation keywords, we use the syntactic structures of the sentences to identify their linguistic scopes.

2 Related Work

Although hedging in scientific articles has been studied from a linguistics perspective since the 1990s (e.g. (Hyland, 1998)), it has only gained interest from a natural language processing perspective in the recent years.

The problem of identifying speculative sentences in biomedical articles has been introduced by Light *et al.* (2004). The authors discussed the possible application areas of recognizing speculative language and investigated whether the notion of speculative sentences can be characterized to enable manual annotation. The authors developed two automated systems to classify sentences as speculative or not. The first method is based on substring matching. A sentence is classified as speculative if it contains one of the 14 predefined strings (*suggest, potential, likely, may, at least, in part, possibl, further investigation, unlikely, putative, insights, point toward, promise, propose*). The second method is based on using SVM with bag-of-words features. The substring matching method performed slightly better than the SVM with bag-of-words features approach.

Medlock and Briscoe (2007) extended the work of Light *et al.* (2004) by refining their annotation guidelines and creating a publicly available data set (FlyBase data set) for speculative sentence classification. They proposed a weakly supervised machine learning approach to classify sentences as speculative or not with the aim of minimizing the need for manually labeled training data. Their approach achieved 76% precision/recall break-even point (BEP) performance on the FlyBase data set, compared to the BEP of 60% obtained by Light *et al.*'s (2004) substring matching approach on the same data set. Szarvas (2008) extended the weakly supervised machine learning methodology of Medlock and Briscoe (2007) by applying feature selection to reduce the number of candidate keywords, by using limited manual supervision to filter the features, and by extending the feature representation with bigrams and trigrams. In addition, by following the annotation guidelines of Medlock and Briscoe (2007), Szarvas (2008) made available the BMC Bioinformatics data set, by annotating four full text papers from the open access BMC Bioinformatics website. They achieved a BEP performance of 85.29% and an F-measure of 85.08% on the FlyBase data set. The F-measure performance achieved on the BMC Bioinformatics data set was 74.93% when the FlyBase data set was used for training. Kilicoglu and Bergler (2008) compiled a list of speculation keywords from the examples in (Hyland, 1998) and extended this list by using WordNet (Fellbaum, 1998) and UMLS SPECIALIST Lexicon (McCray et al., 1994). They used manually crafted syntactic patterns to identify speculative sentences and achieved a BEP and an F-measure of 85% on the FlyBase data set and a BEP and an F-measure of 82% on the BMC Bioinformatics data set.

Unlike pervious studies, which treat the problem of identifying speculative language as a sentence classification task, we tackle the more challenging problem of identifying the portions of sentences which are speculative. In other words, we allow a sentence to include both speculative and non-speculative parts. We introduce and evaluate a diverse set of features that represent the context of a keyword and use these features in a supervised machine learning setting to classify

the keywords as real speculation keywords or not. Then, we develop a rule-based method to determine their linguistic scopes by considering the keyword-specific features and the syntactic structures of the sentences. To the best of our knowledge, the BioScope corpus (Vincze et al., 2008) is the only available data set that has been annotated for speculative sentence fragments and we report the first results on this corpus.

3 Corpus

The BioScope corpus[2] has been annotated at the token level for speculation keywords and at the sentence level for their linguistic scopes (Vincze et al., 2008). The corpus consists of three subcorpora: medical free texts (radiology reports), biomedical article abstracts, and biomedical full text articles. In this paper we focus on identifying speculations in scientific text. Therefore, we use the biomedical article abstracts and the biomedical full text articles in our experiments. The statistics (number of documents, number of sentences, and number of occurrences of speculation keywords) for these two sub-corpora are given in Table 1. The scientific abstracts in the BioScope corpus were included from the Genia corpus (Collier et al., 1999). The full text papers consist of five articles from the FlyBase data set and four articles from the open access BMC Bioinformatics website. The sentences in the FlyBase and BMC Bioinformatics data sets were annotated as speculative or not and made available by Medlock and Briscoe (2007) and Szarvas (2008), respectively and have been used by previous studies in identifying speculative sentences (Medlock and Briscoe, 2007; Kilicoglu and Bergler, 2008; Szarvas, 2008). Vincze *et al.* (2008) annotated these full text papers and the Genia abstracts for speculation keywords and their scopes and included them to the BioScope corpus. The keywords were annotated with a minimalist strategy. In other words, the minimal unit that expresses speculation was annotated as a keyword. A keyword can be a single word (e.g. suggest, predict, might) or a phrase (complex keyword), if none of the words constituting the phrase expresses a speculation by itself. For example the phrase *"no evidence of"* in the sentence *"Direct sequencing of the viral genomes and reinfection kinetics showed no evidence of wild-type reversion even after prolonged infection with the Tat- virus."* is an example of a complex keyword, since the words forming the phrase can only express speculation together.

Data Set	Documents	Sentences	Hedge Keywords
Abstracts	1273	11871	2694
Full Papers	9	2670	682

Table 1: Summary of the biomedical scientific articles subcorpora of the BioScope corpus

In contrast to the minimalist strategy followed when annotating the keywords, the annotation of scopes of the keywords was performed by assigning the scope to the largest syntactic unit possible by including all the elements between the keyword and the target word to the scope (in order to avoid scopes without a keyword) and by including the modifiers of the target word to the scope (Vincze et al., 2008). The reader can refer to (Vincze et al., 2008) for the details of the corpus and the annotation guidelines.

The inter-annotator agreement rate was measured as the F-measure of the annotations of the first annotator by considering the annotations of the second one as the gold standard. The agreement rate for speculation keyword annotation is reported as 92.05% for the abstracts and 90.81% for the full text articles and the agreement rate for speculation scope resolution is reported as 94.04% for the abstracts and 89.67% for the full text articles (Vincze et al., 2008). These rates can be considered as the upper bounds for the automated methods proposed in this paper.

4 Identifying Speculation Keywords

Words and phrases such as *"might", "suggest", "likely", "no evidence of", and "remains to be elucidated"* that can render statements speculative are called speculation keywords. Speculation keywords are not always used in speculative context. For instance, consider the following sentences:

1. *Thus, it appears that the T-cell-specific activation of the proenkephalin promoter is mediated by NF-kappa B. (PMID: 91117203)*

2. *Differentiation assays using water soluble phorbol esters reveal that differentiation becomes irreversible soon after AP-1 appears. (PMID: 92088960)*

The keyword *"appears"* in the first sentence renders it speculative. However, in the second sentence, *"appears"* is not used in a speculative context.

[2] Available at: http://www.inf.u-szeged.hu/rgai/bioscope

The first sub-problem that we need to solve in order to identify speculative sentence fragments is identifying the real speculation keywords in a sentence (i.e. the keywords which convey speculative meaning in the sentence). We formulate the problem as a supervised classification task. We extract the list of keywords from the training data which has been labeled for speculation keywords. We match this list of keywords in the unlabeled (test data) and train a model to classify each occurrence of a keyword in the unlabeled test set as a real speculation keyword or not. The challenge of the task can be demonstrated by the following statistics from the Genia Abstracts of the BioScope corpus. There are 1273 abstracts in the corpus. There are 138 unique speculation keywords and the total number of their occurrence in the abstracts is 6125. In only 2694 (less than 50%) of their occurrences they are used in speculative context (i.e., are real speculation keywords).

In this study we focus on identifying the features that represent the context of a speculation keyword and use SVM with linear kernel (we used the SVM^{light} package (Joachims, 1999)) as our classification algorithm. The following subsection describes the set of features that we propose.

4.1 Feature Extraction

We introduce a set of diverse types of features including keyword specific features such as the stem and the part-of-speech (POS) of the keyword, and keyword context features such as the words surrounding the keyword, the dependency relation types originating at the keyword, the other keywords that occur in the same sentence as the keyword, and positional features such as the section of the paper in which the keyword occurs. While designing the features, we were inspired by studies on other natural language processing problems such as Word Sense Disambiguation (WSD) and summarization. For example, machine learning methods with features based on part-of-speech tags, word stems, surrounding and co-occurring words, and dependency relationships have been successfully used in WSD (Montoyo et al., 2005; Ng and Lee, 1996; Dligach and Palmer, 2008) and positional features such as the position of a sentence in the document have been used in text summarization (e.g. (Radev et al., 2004)).

4.1.1 Keyword Features

Statistics from the BioScope corpus suggest that different keywords have different likelihoods of being used in a speculative context (Vincze et al., 2008). For example, the keyword *"suggest"* has been used in a speculative context in all its occurrences in the abstracts and in the full papers. On the other hand, *"appear"* is a real speculation keyword in 86% of its occurrences in the abstracts and in 83% of its occurrences in the full papers, whereas *"can"* is a real speculation keyword in 12% of its occurrences in the abstracts and in 16% of its occurrences in the full papers. POS of a keyword might also play a role in determining whether it is a real speculation keyword or not. For example, consider the keyword *"can"*. It is more likely to have been used in a speculative context when it is a modal verb, than when it is a noun. Based on these observations, we hypothesize that features specific to a keyword such as the keyword itself, the stem of the keyword, and the POS of the keyword might be useful in discriminating the speculative versus non-speculative use of it. We use Porter's Stemming Algorithm (Porter, 1980) to obtain the stems of the keywords and Stanford Parser (de Marneffe et al., 2006) to get the POS of the keywords. If a keywords consists of multiple words, we use the concatenation of the POS of the words constituting the keyword as a feature. For example, the extracted POS feature for the keywords *"no evidence"* and *"no proof"* is *"DT.NN"* .

4.1.2 Dependency Relation Features

Besides the occurrence of a speculation keyword, the syntactic structure of the sentence also plays an important role in characterizing speculations. Kilicoglu and Bergler (2008) showed that manually identified syntactic patterns are effective in classifying sentences as speculative or not. They identified that, while some keywords do not indicate hedging when used alone, they might act as good indicators of hedging when used with a clausal complement or with an infinitival clause. For example, the *"appears"* keyword in the example sentences, which are given in the beginning of Section 4, is not a real speculation keyword in the second example *"...soon after AP-1 appears."* , whereas it is a real speculation keyword in the first example, where it is used with a *that* clausal complement *"...it appears that..."*. Similarly, *"appears"* is used in a speculative context in the fol-

lowing sentence, where it is used with an infinitival clause: *"Synergistic transactivation of the BMRF1 promoter by the Z/c-myb combination appears to involve direct binding by the Z protein."*.

Another observation is that, some keywords act as real speculation keywords only when used with a negation. For example, words such as *"know", "evidence", and "proof"* express certainty when used alone, but express a speculation when used with a negation (e.g., *"not known", "no evidence", "no proof"*).

Auxiliaries in verbal elements might also give clues for the speculative meaning of the main verbs. Consider the example sentence: *"Our findings may indicate the presence of a reactivated virus hosted in these cells."*. The modal auxiliary *"may"* acts as a clue for the speculative context of the main verb *"indicate"*.

We defined boolean features to represent the syntactic structures of the contexts of the keywords. We used the Stanford Dependency Parser (de Marneffe et al., 2006) to parse the sentences that contain a candidate speculation keyword and extracted the following features from the dependency parse trees.

Clausal Complement: A Boolean feature which is set to 1, if the keyword has a child which is connected to it with a clausal complement or infinitival clause dependency type.

Negation: A Boolean feature which is set to 1, if the keyword (1) has a child which is connected to it with a negation dependency type (e.g. "not known": "not" is a child of "known", and the Stanford Dependency Type connecting them is "neg") or (2) the determiner "no" is a child of the keyword (e.g., "no evidence": "no" is a child of "evidence" and the Stanford Dependency Type connecting them is "det").

Auxiliary: A Boolean feature which is set to 1, if the keyword has a child which is connected to it with an auxiliary dependency type (e.g. "may indicate": "may" is a child of "indicate", and the Stanford Dependency Type connecting them is "aux").

If a keyword consists of multiple-words, we examine the children of the word which is the ancestor of the other words constituting the keyword. For example, "no evidence" is a multi-word keyword, where "evidence" is the parent of "no". Therefore, we extract the dependency parse tree features for the word "evidence".

4.1.3 Surrounding Words

Recent studies showed that using machine learning with variants of the "bag-of-words" feature representation is effective in classifying sentences as speculative vs. non-speculative (Light et al., 2004; Medlock and Briscoe, 2007; Szarvas, 2008). Therefore, we also decided to include bag-of-words features that represent the context of the speculation keyword. We extracted the words surrounding the keyword and performed experiments both with and without stemming, and with window sizes of one, two, and three. Consider the sentence: *"Our findings may indicate the presence of a reactivated virus hosted in these cells."*. The bag-of-words features for the keyword "indicate", when a window size of three and no stemming is used are: *"our", "findings", "may", "indicate", "the", "presence", "of"*. In other words, the feature set consists of the keyword, the three words to the left of the keyword, and the three words to the right of the keyword.

4.1.4 Positional Features

Different parts of a scientific article might have different characteristics in terms of the usage of speculative language. For example, Hyland (1998) analyzed a data set of molecular biology articles and reported that the distribution of speculations is similar between abstracts and full text articles, whereas the Results and Discussion sections tend to contain more speculative statements compared to the other sections (e.g. Materials and Methods or Introduction and Background sections). The analysis of Light *et al.* (2004) showed that the last sentence of an abstract is more likely to be speculative than non-speculative.

For the scientific abstracts data set, we defined the following boolean features to represent the position of the sentence the keyword occurs in. Our intuition is that titles and the first sentences in the abstract tend to be non-speculative, whereas the last sentence of the abstract tends to be speculative.

Title: A Boolean feature which is set to 1, if the keyword occurs in the title.

First Sentence: A Boolean feature which is set to 1, if the keyword occurs in the first sentence of the abstract.

Last Sentence: A Boolean feature which is set to 1, if the keyword occurs in the last sentence of the abstract.

For the scientific full text articles data set, we defined the following features that represent the position of the sentence in which the keyword occurs. Our assumption is that the "Results and Discussion" and the "Conclusion" sections tend to

contain more speculative statements than the "Materials and Methods" and "Introduction and Background" sections. We also assume that figure and table legends are not likely to contain speculative statements.

Title: A Boolean feature which is set to 1, if the keyword occurs in the title of the article, or in the title of a section or sub-section.

First Sentence: A Boolean feature which is set to 1, if the keyword occurs in the first sentence of the abstract.

Last Sentence: A Boolean feature which is set to 1, if the keyword occurs in the last sentence of the abstract.

Background: A Boolean feature which is set to 1, if the keyword occurs in the Background or Introduction section.

Results: A Boolean feature which is set to 1, if the keyword occurs in the Results or in the Discussion section.

Methods: A Boolean feature which is set to 1, if the keyword occurs in the Materials and Methods section.

Conclusion: A Boolean feature which is set to 1, if the keyword occurs in the Conclusion section.

Legend: A Boolean feature which is set to 1, if the keyword occurs in a table or figure legend.

4.1.5 Co-occurring Keywords

Speculation keywords usually co-occur in the sentences. Consider the sentence: *"We, therefore, wished to determine whether T3SO4 could mimic the action of thyroid hormone in vitro."*. Here, *"whether"* and *"could"* are speculation keywords and their co-occurence might be a clue for their speculative context. Therefore, we decided to include the co-occurring keywords to the feature set of a keyword.

5 Resolving the Scope of a Speculation

After identifying the real speculation keywords, the next step is determining their scopes in the sentences, so that the speculative sentence fragments can be detected. Manual analysis of sample sentences from the BioScope corpus and their parse trees suggests that the scope of a keyword can be characterized by its part-of-speech and the syntactic structure of the sentence in which it occurs. Consider the example sentence whose parse tree is shown in Figure 1. The sentence contains three speculation keywords, "or" and two occurrences of "might". The scope of the conjunction "or", extends to the "VP" whose children it coordinates. In other words, the scope of "or" is "[might be one of the earliest crucial steps in the lysis of normal and dex-resistant CEM cells, *or* might serve as a marker for the process]". Here, "or" conveys a speculative meaning, since we are not certain which of the two sub-clauses (sub-clause 1: [might be one of the earliest crucial steps in the lysis of normal and dex-resistant CEM cells] *or* sub-clause 2: [might serve as a marker for the process]) is correct. The scope of both occurrences of the modal verb "might" is the parent "VP". In other words, the scope of the first occurrence of "might" is "[*might* be one of the earliest crucial steps in the lysis of normal and dex-resistant CEM cells]" and the scope of the second occurrence of "might" is "[*might* serve as a marker for the process]". By examining the keywords, sample sentences and their syntactic parse trees we developed the following rule-based approach to resolve the scopes of speculation keywords. The examples given in this section are based on the syntactic structure of the Penn Tree Bank. But, the rules are generic (e.g. "the scope of a verb followed by an infinitival clause, extends to the whole sentence").

The scope of a conjunction or a determiner (e.g. or, and/or, vs) is the syntactic phrase to which it is attached. For example, the scope of "or" in Figure 1 is the "VP" immediately dominating the "CC".

The scope of a modal verb (e.g. may, might, could) is the "VP" to which it is attached. For example, the scope of "might" in Figure 1 is the "VP" immediately dominating the "MD".

The scope of an adjective or an adverb starts with the keyword and ends with the last token of the highest level "NP" which dominates the adjective or the adverb. Consider the sentence "The endocrine events that are rapidly expressed (seconds) are due to a [possible interaction with cellular membrane]." The scope of the speculation keyword "possible" is enclosed in rectangular brackets. The sub-tree that this scope maps to is: "(NP (NP (DT a) (JJ possible) (NN interaction)) (PP (IN with) (NP (JJ cellular) (NN membrane))))". If there does not exist a "NP" dominating the adverb or adjective keyword, the scope extends to the whole sentence. For example the scope of the speculation adverb "probably" in the sentence "[The remaining portion of the ZFB motif was probably lost in TPases of insect Transib transposons]" is the whole sentence.

The scope of a verb followed by an infinitival

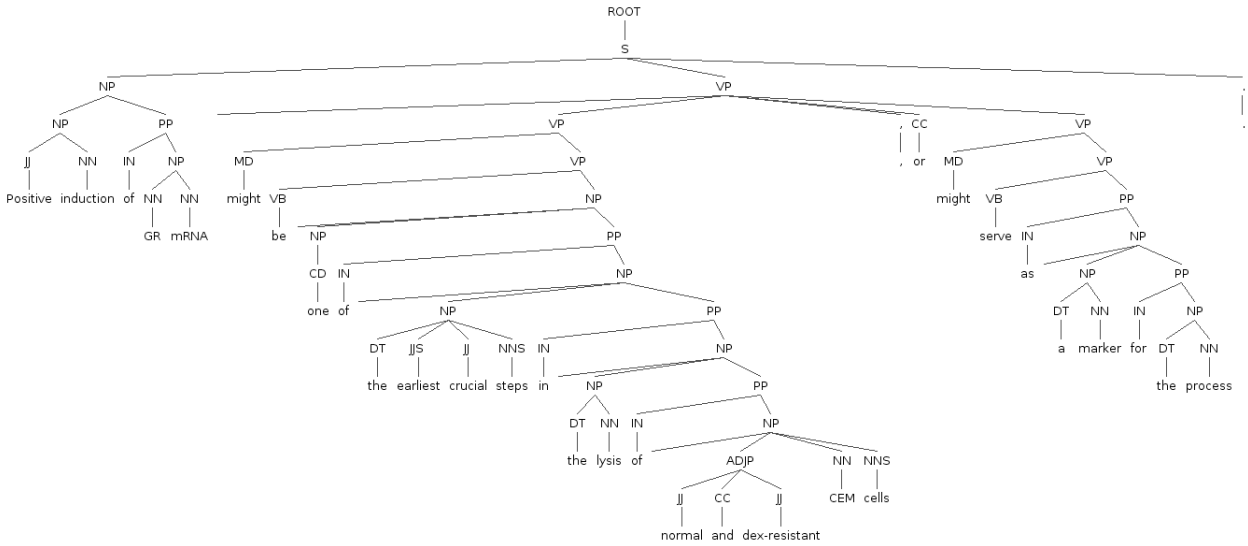

Figure 1: The syntactic parse tree of the sentence "*Positive induction of GR mRNA might be one of the earliest crucial steps in the lysis of normal and dex-resistant CEM cells, or might serve as a marker for the process.*"

clause extends to the whole sentence. For example, the scope of the verb "appears" followed by the "to" infinitival clause is the whole sentence in "[The block of pupariation appears to involve signaling through the adenosine receptor (AdoR)]".

The scope of a verb in passive voice extends to the whole sentence such as the scope of "suggested" in "[The existence of such an independent mechanism has also been suggested in mammals]".

If none of the above rules apply, the scope of a keyword starts with the keyword and ends at the end of the sentence (or clause). An example is the scope of "suggested" in "This [suggested that there is insufficient data currently available to determine a reliable ratio for human]".

6 Evaluation

We evaluated our approach on two different types of scientific text from the biomedical domain, namely the scientific abstracts sub-corpus and the full text articles sub-corpus of the BioScope corpus (see Section 3). We used stratified 10-fold cross-validation to evaluate the performance on the abstracts. In each fold, 90% of the abstracts are used for training and 10% are used to test. To facilitate comparison with future studies the PubMed Identifiers of the abstracts that we used as a test set in each fold are provided[3]. The full text papers sub-corpus consists of nine articles. We used leave-one-out cross-validation to evaluate the performance on the full text papers. In each iteration eight articles are used for training and one article is used to test. We report the average results over the runs for each data set.

6.1 Evaluation of Identifying Speculation Keywords

To classify whether the occurrence of a keyword is in speculative context or not, we built linear SVM models by using various combinations of the features introduced in Section 4.1. Tables 2 and 3 summarize the results obtained for the abstracts and the full text papers, respectively. *BOW N* is the bag-of-words features obtained from the words surrounding the keyword (see Section 4.1.3). N is the window size. We experimented both with the stemmed and non-stemmed versions of this feature type. The non-stemmed versions performed slightly better than the stemmed versions. The reason might be due to the different likelihoods of being used in a speculative context of different inflected forms of words. For example, consider the words "appears" and "appearance". They have the same stems, but "appearance" is less likely to be a real speculation keyword than "appears". Another observation is that, decreasing the window size led to improvement in performance. This suggests that the words right before and right after the candidate speculation keyword are more effective in distinguishing its speculative vs. non-speculative context compared to a wider local context. Wider local context might create sparse data and degrade

[3] http://belobog.si.umich.edu/clair/bioscope/

performance. Consider the example, "it appears that TP53 interacts with AR". The keyword "appears", and BOW1 ("it" and "that") are more relevant for the speculative context of the keyword than "TP53", "interacts", and "with". Therefore, for the rest of the experiments we used the *BOW 1* version, i.e., the non-stemmed surrounding bag-of-words with window size of 1. *KW* stands for the keyword specific features, i.e., the keyword, its stem, and its part-of-speech (discussed in Section 4.1.1). *DEP* stands for the dependency relation features (discussed in Section 4.1.2). *POS* stands for the positional features (discussed in Section 4.1.4) and *CO-KW* stands for the co-occurring keywords feature (discussed in Section 4.1.5).

Our results are not directly comparable with the prior studies about identifying speculative sentences (see Section 2), since we attempted to solve a different problem, which is identifying speculative parts of sentences. Only the substring matching approach that was introduced in (Light et al., 2004) could be adapted as a keyword classification task, since the substrings are keywords themselves and we used this approach as a baseline in the keyword classification sub-problem. We compare the performances of our models with two baseline methods, which are based on the substring matching approach. Light *et al.* (2004) have shown that the substring matching method with a predefined set of 14 strings performs slightly better than an SVM model with bag-of-words features in classifying sentences as speculative vs. non-speculative (see Section 2). In baseline 1, we use the 14 strings identified in (Light et al., 2004) and classify all the keywords in the test set that match any of them as real speculation keywords. Baseline 2 is similar to baseline 1, with the difference that rather than using the set of strings in (Light et al., 2004), we extract the set of keywords from the training set and classify all the words (or phrases) in the test set that match any of the keywords in the list as real speculation keywords.

Baseline 1 achieves high precision, but low recall. Whereas, baseline 2 achieves high recall in the expense of low precision. All the SVM models in Tables 2 and 3 achieve more balanced precision and recall values, with F-measure values significantly higher than the baseline methods. We start with a model that uses only the keyword-specific features (KW). This type of feature alone achieved a significantly better performance than the baseline methods (90.61% F-measure for the abstracts and 80.57% F-measure for the full text papers), suggesting that the keyword-specific features are important in determining its speculative context. We extended the feature set by including the dependency relation (DEP), surrounding words (BOW 1), positional (POS), and co-occurring keywords (CO-KW) features. Each new type of included feature improved the performance of the model for the abstracts. The best F-measure (91.69%) is achieved by using all the proposed types of features. This performance is close to the upper bound, which is the human inter-annotator agreement F-measure of 92.05%.

Including the co-occurring keywords to the feature set for full text articles slightly improved precision, but deceased recall, which led to lower F-measure. The best F-measure (82.82%) for the full text articles is achieved by using all the feature types except the co-occurring keywords. The achieved performance is significantly higher than the baseline methods, but lower than the human inter-annotator agreement F-measure of 90.81%. The lower performance for the full text papers might be due to the small size of the data set (9 full text papers compared to 1273 abstracts).

Method	Recall	Precision	F-Measure
Baseline 1	52.84	92.71	67.25

6.2 Evaluation of Resolving the Scope of a Speculation

We compared the proposed rule-based approach for scope resolution with two baseline methods. Previous studies classify sentences as speculative or not, therefore implicitly assigning the scope of a speculation to the whole sentence (Light et al., 2004; Medlock and Briscoe, 2007; Szarvas, 2008; Kilicoglu and Bergler, 2008). Baseline 1 follows this approach and assigns the scope of a speculation keyword to the whole sentence. Szarvas (2008) suggest assigning the scope of a keyword from its occurrence to the end of the sentence. They state that this approach works accurately for clinical free texts, but no any results are reported (Szarvas, 2008). Baseline 2 follows the approach proposed in (Szarvas, 2008) and assigns the scope of a keyword to the fragment of the sentence that starts with the keyword and ends at the end of the sentence. Table 4 summarizes the accuracy results obtained for the abstracts and the full text papers.

The poor performance of baseline 1, emphasizes the importance of detecting the portions of sentences that are speculative, since less than 5% of the sentences that contain speculation keywords are entirely speculative. Classifying the entire sentences as speculative or not leads to loss in information for more than 95% of the sentences. The rule-based method significantly outperformed the two baseline methods, indicating that the part-of-speech of the keywords and the syntactic parses of the sentences are effective in characterizing the speculation scopes.

Method	Accuracy-Abstracts	Accuracy-Full text
Baseline 1	4.82	4.29
Baseline 2	67.60	42.82
Rule-based method	79.89	61.13

Table 4: Scope resolution results

7 Conclusion

We presented an approach to identify speculative sentence fragments in scientific articles. Our approach is based on solving two sub-problems. The first one is identifying the keywords which are used in speculative context and the second one is determining the scopes of these keywords in the sentences. We evaluated our approach for two types of scientific texts, namely abstracts and full text papers from the BioScope corpus.

We formulated the first sub-problem as a supervised classification task, where the aim is to learn models to classify the candidate speculation keywords as real speculation keywords or not. We focused on identifying different types of linguistic features that capture the contexts of the keywords. We achieved a performance which is significantly better than the baseline methods and comparable to the upper-bound, which is the human inter-annotator agreement F-measure.

We hypothesized that the scope of a speculation keyword can be characterized by its part-of-speech and the syntactic structure of the sentence and developed rules to map the scope of a keyword to the nodes in the syntactic parse tree. We achieved a significantly better performance compared to the baseline methods. The considerably lower performance of the baseline of assigning the scope of a speculation keyword to the whole sentence indicates the importance of detecting speculative sentence portions rather than classifying the entire sentences as speculative or not.

Cross-Cultural Analysis of Blogs and Forums with Mixed-Collection Topic Models

Michael Paul and Roxana Girju

Abstract

This paper presents preliminary results on the detection of cultural differences from people's experiences in various countries from two perspectives: tourists and locals. Our approach is to develop probabilistic models that would provide a good framework for such studies. Thus, we propose here a new model, **ccLDA**, which extends over the Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and cross-collection mixture (ccMix) (Zhai et al., 2004) models on blogs and forums. We also provide a qualitative and quantitative analysis of the model on the cross-cultural data.

1 Introduction

In today's society, people from different cultural backgrounds have to understand each other, interact on a daily base and travel to or work in more than one country. Understanding cultural diversity, as well as addressing the need to communicate effectively across cultural divides, have become imperative in almost every aspect of life. These constitute an important language aspect since the lack of such cultural awareness can lead to misinterpretations.

This paper presents preliminary results on the detection of cultural differences from people's experiences in various countries from two perspectives: tourists and locals. Since the advent of Web 2.0, user-generated data in the form of blogs and newsgroup messages have reached high proportions. In this paper we take advantage of such resources of blogs and forums to perform various cross-cultural analyses.

Our approach is to develop probabilistic models that would provide a good framework for such studies. Thus, we propose here a new model, **ccLDA**, which extends over the Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and cross-collection mixture (ccMix) (Zhai et al., 2004) models. Our contribution is as follows:

(1) Unsupervised topic models such as LDA are elegant and flexible approaches to clustering large collections of unannotated data. These models, however, have conceptually focused on one single collection of text which is inadequate for comparative analyses of text.

We thus develop an LDA-based model that can not only discover topics but also model their similarities and differences across multiple text collections.

(2) We improve on similar previous work by crafting a model that can better generalize data and is less reliant on user-defined parameters.

(3) We apply our new model on blogs and forums to identify cross-cultural differences.

Thus, different models can be compared to reflect different hypotheses about the data.

The paper is organized as follows. In Section 2 we summarize relevant previous work and give a detailed description of the model in Section 3. Section 4 details the model's parameter estimation. Experimental results are presented in Section 5, followed by discussion, future work, and conclusions.

2 Previous Work

A topic model for comparing text collections (ccMix) was previously introduced by Zhai et al. (2004) for a problem called comparative text mining (CTM). Given news articles from different sources (about the same event), ccMix can extract what is common to all the sources and what is unique to one specific source.

Our model improves over ccMix by replacing their probabilistic latent semantic indexing (pLSI) (Hofmann, 1999) framework with that of LDA.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1408–1417,
Singapore, 6-7 August 2009.

Under the ccMix model, the probability of generating the ith word in a document belonging to collection c is:

$$P(w_i) = (1-\lambda_B)\sum_{z\in Z} P(z)(\lambda_C P(w_i|z) + (1-\lambda_C)P(w_i|z,c)) + \lambda_B P(w_i|B),$$

where each topic is denoted z. λ_B is the probability of choosing a word from the background word distribution and is user-defined. λ_C is also defined by the user and is the probability of drawing a word from the collection-independent word distribution instead of the collection-specific distribution. The parameters can be estimated using the Expectation-Maximization algorithm (Dempster et al., 1977).

However, in addition to the advantages of LDA over pLSI such as the incorporation of Dirichlet priors and a natural way to deal with new documents, our model avoids the limitations of using a single user-defined parameter λ_C – this probability is learned automatically under our model. Furthermore, we allow this probability to depend on the collection and topic, which is a less restrictive assumption.

Our model, ccLDA, shares with the LDA-Collocation (Griffiths et al., 2007) and Topical N-Grams (Wang et al., 2007) models the assumption that each word can come from two different word distributions, one of which depends on another observable variable. In these models, a word can come from either its topic's word distribution, or it can come from a word distribution associated with the previous word, in the case that the word is determined to be part of a collocation. The key difference here is that in these models, the alternative word distribution depends on the word preceding a token, while in ccLDA, this depends on the document's collection.

The model is also related to hierarchical variants of LDA, in particular the hierarchical Pachinko allocation (hPAM) (Mimno et al., 2007) model, in which both a topic and hierarchy depth are chosen, and there is a different word distribution at different levels in the hierarchy. A natural way to view our model is as a two-level hierarchy where the top level represents the collection-independent distributions and the bottom level represents the collection-specific distributions. One of the main differences here is that the discovered hierarchies in hPAM can be arbitrary, whereas the graphical structure of our model is pre-determined such that each topic has exactly one "sub-topic" representing each collection.

Wang et al. recently introduced Markov topic models (MTM) (2009), a family of models which can simultaneously learn the topic structure of a single collection while discovering correlated topics in other collections. This is promising in that this type of model makes no assentation that each topic is in some way shared across all collections. However, it does not explicitly model the similarities and differences between collections as we do in this research.

In computational linguistics, topic models have been used in various applications, such as predicting response to political webposts (Yano et al., 2009), analyzing Enron and academic emails (McCallum et al., 2007a), analyzing voting records and corresponding text of resolutions from the U.S. Senate and the U.N. (McCallum et al., 2007b), as well as studying the history of ideas in various research fields (Hall et al., 2008; Paul and Girju, 2009). To our knowledge, the application of topic models to identifying cross-cultural differences is novel.

3 The Model

In this section we first review the basic pLSI and LDA models. We then introduce our extension to LDA: *cross-collection LDA* (ccLDA).

3.1 Basic Topic Modeling

The most basic generative model that assumes document topicality is the standard Naïve Bayes model, where each document is assumed to belong to exactly one topic, and each topic is associated with a probability distribution over words (Mitchell, 1997).

While this single-topic approach can be sufficient for classification tasks, it is often too limiting for unsupervised grouping of semantically related words into topics. A better assumption is that each document is a mixture of topics. For example, a news article about a natural disaster may include topics about the causes of such disasters, the damage/death toll, and relief aid/efforts. Probabilistic latent semantic indexing (pLSI) (Hofmann, 1999) is one such model. Under this model, the probability of seeing the ith word in a document is:

$$P(w_i|d) = \sum_{z\in Z} P(w_i|z)P(z|d)$$

One of the main criticisms of pLSI is that each document is represented as a variable d and it is not clear how to label previously unseen documents. This issue is addressed by Blei et al. with latent Dirichlet allocation (2003). Furthermore, the probabilities under this model have Dirichlet priors, which results in more reasonable mixtures and less overfitting. In LDA, a document is generated as follows:

1) Draw a multinomial distribution of words ϕ_z from Dirichlet(β) for each topic z

2) For each document d[1], draw a topic mixture distribution $\theta^{(d)}$ from Dirichlet(α). Then for each word w_i in d:

a) Sample a topic z_i from $\theta^{(d)}$

b) Sample a word w_i from ϕ_z

The Dirichlet parameters α and β are vectors which represent the average of the respective distributions. In many applications, it is sufficient to assume that these vectors are uniform and to fix them at a value pre-defined by the user. In this case, the Dirichlet priors simply function as smoothing factors.

3.2 Cross-Collection LDA

In this subsection we introduce our extension of LDA for comparing multiple text collections, which we refer to as cross-collection LDA (ccLDA). Under this model, each topic is associated with two classes of word distributions: one that is shared among all collections, and one that is unique to the collection from which the document comes. For example, when modeling reviews of different laptops, the topic describing the preloaded software contains the words "software", "application", "programs", etc. in its shared distribution with high probability, and the Apple-specific word distribution contains the words "itunes", "appleworks", and "iphoto".

When generating a document under this model, one first samples a collection c (which is observable in the data), then chooses a topic z and flips a coin x to determine whether to draw from the shared topic-word distribution or the topic's collection-specific distribution. The probability of x being 1 or 0 comes from a Beta distribution (the bivariate analog of the Dirichlet distribution) and is dependent on the collection and topic of the current token.

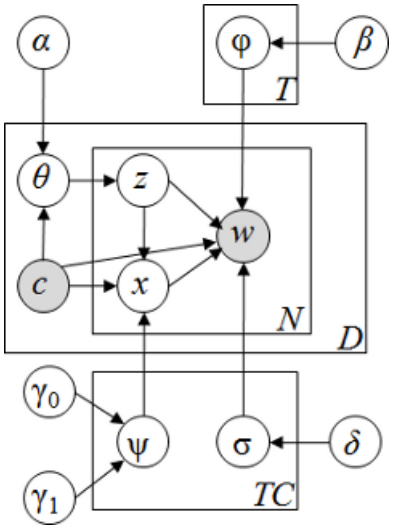

Figure 1: Graphical representation of ccLDA. C is the number of collections, T is the number of topics, D is the number of documents, and N is the length of each document.

The generative process is thus:

1) Draw a collection-independent multinomial word distribution ϕ_z from Dirichlet(β) for each topic z

2) Draw a collection-specific multinomial word distribution $\sigma_{z,c}$ from Dirichlet(δ) for each topic z and each collection c

3) Draw a Bernoulli distribution $\psi_{z,c}$ from Beta(γ_0, γ_1) for each topic z and each collection c

4) For each document d, choose a collection c and draw a topic mixture $\theta^{(d)}$ from Dirichlet(α_c). Then for each word w_i in d:

a) Sample a topic z_i from $\theta^{(d)}$

b) Sample x_i from $\psi_{z,c}$

c) If $x_i = 0$, sample a word w_i from ϕ_z;
else if $x_i = 1$, sample w_i from $\sigma_{z,c}$

As mentioned in section 2, this model is in some respects an LDA-based analog of the Zhai et al. (2004) model (ccMix), and thus it offers the same improvements that LDA offers over pLSI (described in the previous subsection), but there are some other differences. An obvious structural difference between the models is that ccMix has a special topic for background words, whereas we simply address this by removing stop words during preprocessing, which seems to give reasonable performance in this respect. This could easily be incorporated into our model such that x can take a

[1]One should also assume that a document length is sampled from an arbitrary distribution, but this does not affect the derivation of the model, so we ignore this here and elsewhere.

third value that designates that a word comes from the background, but removing stop words hugely reduces the number of tokens in the data, and thus very significantly improves the time needed to estimate the model.

In the ccMix model, the probability that a word comes from the collection-specific distribution versus the shared distribution depends on a single user-defined parameter λ_C. Since it is not clear how to set this parameter[2], in our model, we learn this probability automatically. Furthermore, the nature of the λ_C parameter is quite restrictive in that it is the same regardless of the topic and collection. In our model, this probability depends on the collection and topic, which should allow for a more accurate fitting of the data, as some topics may be shared across the collections to a different degree than others.

Additionally, our model allows the topic distributions for each document to come from non-uniform Dirichlet priors (parameterized by the vector α_c) that depends on the document's collection. Because the learned Dirichlet parameters can be interpreted as the average mixing level of each topic in the different collections, we can easily determine if a topic is not shared among all collections, and thus we can automatically remove or set aside such topics.

4 Parameter Estimation

Exact inference is often intractable in complex Bayesian models and approximate methods must be used. Blei et al. (2003) offer a variational EM algorithm for LDA. Griffiths and Steyvers (2004) show how Gibbs sampling can be used for approximate inference in LDA. Gibbs sampling is a type of Markov chain Monte Carlo algorithm and is what we employ in this paper, as it is simple to derive, comparable in speed to other estimators, and it approximates a global maximum (whereas EM algorithms may only converge to a local maximum).

In a Gibbs sampler, one iteratively samples new assignments of hidden variables by drawing from the distributions conditioned on the previous state of the model (Gilks et al., 1995). In each Gibbs sampling iteration we alternately sample new assignments of z and x with the following equations:

$$P(z_i|x_i = 0, \mathbf{z}_{-i}, \mathbf{w}, \alpha, \beta) \propto (n^d_{z_i} + \alpha_{cz}) \times \frac{n^{z_i}_{w_i} + \beta}{n^{z_i}_{\cdot} + W\beta} \quad (1)$$

$$P(z_i|x_i = 1, \mathbf{z}_{-i}, \mathbf{w}, \alpha, \delta) \propto (n^d_{z_i} + \alpha_{cz}) \times \frac{n^{z_i,c}_{w_i} + \delta}{n^{z_i,c}_{\cdot} + W\delta} \quad (2)$$

$$P(x_i = 0|\mathbf{x}_{-i}, \mathbf{z}, \mathbf{w}, \gamma, \beta) \propto \frac{n^{z,c}_{x=0} + \gamma_0}{n^{z,c}_{\cdot} + \gamma_0 + \gamma_1} \times \frac{n^{z_i}_{w_i} + \beta}{n^{z_i}_{\cdot} + W\beta} \quad (3)$$

$$P(x_i = 1|\mathbf{x}_{-i}, \mathbf{z}, \mathbf{w}, \gamma, \delta) \propto \frac{n^{z,c}_{x=1} + \gamma_1}{n^{z,c}_{\cdot} + \gamma_0 + \gamma_1} \times \frac{n^{z_i,c}_{w_i} + \delta}{n^{z_i,c}_{\cdot} + W\delta} \quad (4)$$

Because of the conjugacy of the Beta/Dirichlet and binomial/multinomial distributions, we can integrate out θ, ϕ, σ and ψ to obtain these equations, a technique known as "collapsed" Gibbs sampling (Heinrich, 2008).

n^b_a denotes the number of times a has been assigned to b, excluding the assignment of the current token i. W is the size of the vocabulary. x should be initialized as 0 for all tokens; that is, we initially assume that everything comes from the shared word distributions, otherwise the collection-specific word distributions will form independently.

α_c is a non-uniform vector that is collection-specific. A simple and efficient way to approximate this is through moment-matching such that $\alpha_{cz} \propto \frac{1}{N_c} \sum_d \frac{n^d_z}{n^d_\cdot}$, where d belongs to collection c and N_c is the number of documents in c (details in (Minka, 2003); (Li and McCallum, 2006)). The other hyperparameters can be updated similarly, although in our research we simply keep that at fixed, uniform values, as they do not largely affect the sampling procedure at small values.

5 Experimental Results

Our experiments focus on discovering cultural differences by running our model on text from or about three countries: the UK, India, and Singapore. We explore the notion of *perspective* by experimenting with datasets with two distinctly different perspectives: one in which the text is about each country (*tourists*), and one in which the text is authored by residents of each country (*locals*).

5.1 The Data

In our first experiment, we model 3,266 discussions from the forums at lonelyplanet.com, the largest blog website for travelers with a forum for nearly every potential travel destination. We show how this can be used for comparative content aggregation and summarization, and we show how

[2]If needed, one can effectively set this probability manually in ccLDA as well by using a large prior.

our model improves upon previous work on such datasets. In the second experiment, we compare by authorship (blogs written by *locals*), and we run our model on 7,388 English-language weblogs from the same set of three different countries[3]. We show how this is a solid step toward automatic discovery of cultural differences.

Moreover, we compare the two perspectives on the topic of food. We show that there are some strong similarities between the topic in each dataset (thereby enforcing our inferences from each experiment individually), but we also show some differences in the foods tourists find interesting and what locals actually eat.

In all of our experiments, we ran the Gibbs sampler for a burn-in period of 3000 iterations, then we collected and averaged 15 samples, each separated by a 100-iteration lag. We used $\beta = \delta = 0.01$ and $\gamma_0 = \gamma_1 = 1.0$.

Our implementation is loosely based on the LDA Gibbs sampler[4] by Phan and Nguyen (2008).

5.2 Analysis Along the *Tourists* Dimension

In the first experiment we consider data about three destination countries. Using the data provided by lonelyplanet.com, we crawled 1,108 threads from the UK forum, 1,112 from the India forum, and 1,046 from the Singapore forum. Messages are predominantly written by people who have traveled or plan to travel to that country.

Since we are not interested in the thread discussions on a particular travel topic, we treated each thread or discussion of multiple messages as a single document. We were able to use simple pattern matching to extract only the discussion text. We removed HTML tags, stop words, and words with a corpus frequency less than 10. There were 703,551 tokens after preprocessing.

We modeled this dataset with 25 topics. General topical words were grouped into the shared word distribution of each topic, but each collection-specific distribution contained words in the topic that best describe that country. For example, the topic on weather is characterized by words like *weather*, *rain* and *snow*, but each collection's distribution might give one a sense of the weather in each country. Table 1 shows that travelers in India, for example, should be aware of monsoon season, and travelers to Singapore can expect to be hot and sweaty. The UK distribution suggests that campers should prepare for potentially hazardous weather with the appropriate clothing and gear.

weather time day going rain summer month high days thanks		
UK	**India**	**Singapore**
wind	leh	hot
waterproof	monsoon	humid
ending	road	humidity
rolling	manali	heat
walkers	ladakh	degree
rochdale	trekking	equator
layers	trek	sweat
snow	season	bring
footwear	rains	rain
ankle	monsoons	umbrella

Table 1: The topic of weather, modeled across travel forums for three different countries.

As another example, let's consider the topic whose shared words are *english*, *school*, *language*, and *speak*. The results show that English is common to all three, but the collection-specific word distributions indicate that Irish language is found in the UK region, Hindi is common in India, and Mandarin is common in Singapore.

Other common topics include immigration requirements, monetary issues, air and rail travel, etc., all containing information specific to each country. This could be used for automatic summarization by topic which would be useful either to travelers who are visiting multiple destinations, or for a potential traveler in the process of choosing where to go. Someone interested in shopping for music should go to the UK while someone interested in electronics should go to Singapore, for example (at least according to one of the topics discovered).

5.3 Analysis Along the *Locals* Dimension

The results of the first experiment offer an unsupervised aggregation of factual information that is important to travelers such as a destination's climate, law, and infrastructure; however, the data did not offer much in terms of cultural information. We would now like to see if we can get better insight into this problem by modeling text *authored* by residents of these same countries. In doing this we can compare what they talk about and in what manner they talk about certain topics.

For this experiment we downloaded 2,715 blogs from the UK, 2,630 blogs from India, and 2,043 blogs from Singapore. We found these English-language blogs through blogcatalog.com, a blog

[3]The dataset is available for download at http://apfel.ai.uiuc.edu/resources.html

[4]http://gibbslda.sourceforge.net

directory which lists a blog's language and country of origin. We downloaded only the front page of each blog, which usually included multiple articles or postings.

We removed HTML tags from the documents, but we made no attempt to segment the documents into article text – there are efficient methods of doing this (Pasternack and Roth, 2009) and this may be worth experimenting with, but we found that noise such as navigation menus and advertisements would mostly get grouped into their own topics. We removed stop words and words with a corpus frequency less than 20. All punctuation was treated as word separators. There were 8,599,751 tokens in the end.

Table 2 shows 3 topics induced from modeling this data with 50 topics. By looking at these we can see some clear differences between the three groups of native bloggers. For example, Topic 1 is about fashion, and we can compare which fashions are popular in each country. Shoes are popular in the UK; leather and jewelry are more popular in India. Singapore bloggers seem to focus on prices and the shopping aspect of apparel.

From Topic 2 (about pets) it seems that Britons slightly prefer dogs and Singaporians slightly prefer cats. In general, it seems that Singaporians have an affinity for small animals, considering the presence of *hamster* and *rabbit* in their word distribution.

Topic 3 is about religion, in which we see that Christianity is common to all of them, but Hinduism is prominent in India as well.

There are many topics not shown here including politics, gardening, health, etc. The health topic is interesting in that homeopathy and herbal medicines are discussed in Indian blogs. Smoking is a bigger topic in the UK than the others.

It is also interesting to compare what technologies and web services people use. Twitter and Facebook are popular in the UK whereas Orkut is more popular in India. Blogging services like Wordpress are popular in Singapore.

From the travel topic, shown in Table 5, we see that people travel close to home, so to speak. Britons travel around Europe, especially Spain, Paris and London, while Singaporians travel to popular destinations in that part of the world, such as Hong Kong, Thailand and Bali.

5.4 Differences in Perspective: *Tourists* vs. *Locals*

Having modeled the same countries from two different perspectives (that of travelers and that of locals), it would be interesting to see how topics compare between the two perspectives.

Do people have the same view of themselves as outsiders see them? Are locals interested in the same things as tourists?

We hope to answer these questions by examining related topics within these two datasets. While the two datasets consist of mostly different topics, there are a few that would be interesting to compare. In particular, we examine the topic of food and eating. The top words from this topic are shown in Table 3.

We first examine this topic from the blog data (that is, from the perspective of residents). By looking at each collection-specific word distribution we can see which foods are more popular in each country – cheese and soup in the UK, curry in India, and seafood in Singapore. We also noticed that tea and coffee are more popular in Singapore, wine and beer are more popular in the UK, while in Indian blogs beverages are not commonly mentioned. Perhaps a less trivial observation is that the words *restaurant* and *chef* are frequent in UK blogs, but the Indian word distribution is dominated by words pertaining to recipes. From this one might infer that people in the UK (and to a lesser extent in Singapore) eat out more often than people in India, who do more home cooking.

Looking now at the topics induced from the lonelyplanet.com forums (that is, from the perspective of travelers), we see some interesting similarities. Most notably, the Indian distribution again consists of words related to cooking, affirming our observation that dining out is not as popular in India. The Singapore distribution also matches that in the other dataset – the common words include seafood and noodles. The UK distribution, however, shows that tourists are mostly interested in local specialties (such as *fish and chips* and *haggis*).

To see where these perspectives on food differ the most, we computed the ratio of the probability of each word given the topic between the two datasets. That is, if $p = P(w|z)$ in the locals data and $q = P(w|z)$ in the tourists data, then $\lambda = p/q$ gives us a measure of how much more (or less) prominent that word is among locals than it

Topic 1			Topic 2			Topic 3		
fashion style look dress wear new collection accessories black			dog dogs pet animals animal comments cat like food plant			god jesus lord life faith holy man christ church love		
UK	**India**	**Singapore**	**UK**	**India**	**Singapore**	**UK**	**India**	**Singapore**
shoes	fashion	price	garden	water	cat	church	krishna	god

clothing	indian	earrings	pet	carbon	dog	john	religious	john
high	designer	length	cat	earth	pet	todd	spiritual	spirit
designer	sarees	item	dogs	green	training	bentley	guru	things
style	leather	sgd	pets	solar	pets	jesus	lord	lamb
love	girls	silver	gardening	jai	hamster	christ	sri	exodus
london	china	clothes	cats	climate	cute	luke	shri	suffering
shirts	jewellery	shop	puppy	environment	hamsters	bible	baba	cross
bag	jewelry	code	flowers	warming	rabbit	christian	hindu	lives

Table 2: A sample of topics induced on a set of blogs from 3 countries. Shown are the top 10 words from the shared topic-word distribution $P(word|x = 0, topic)$ and the top 10 words from $P(word|x = 1, topic, class)$ for each collection.

Perspective of Locals			Perspective of Tourists		
food add chicken recipe cooking taste rice recipes sugar soup			food eat restaurant restaurants tea cheap meal eating cafe drink		
UK	**India**	**Singapore**	**UK**	**India**	**Singapore**
food	recipe	coffee	chips	cooking	hawker[a]
wine	recipes	cup	haggis	spices	satay
restaurant	powder	oil	fish	sick	stalls
coffee	indian	comments	respectability	flour	noodles
cheese	salt	fried	decent	tomato	roti
soup	tsp	add	veggie	batter	stall
eat	rice	restaurant	pudding	ate	seafood
chef	masala	rice	photoblog	cook	malay
english	oil	tea	sausages	olive	rochester
drink	coriander	seafood	sandwiches	recipe	noodle

[a]A hawker centre is an open-air complex with many food stalls, commonly found in Singapore and Malaysia.

Table 3: A comparison of the food topic from two different datasets, one of which comes from a travel forum and the other of which consists of blogs authored by residents of each respective country.

is among tourists in the food topic. Table 4 shows the words with the highest (left) and lowest (right) values of λ.

Preferred by Locals			Preferred by Tourists		
recipe bowl lemon tomato simple spring spoon vanilla stir pour			street cheap couple yeah crowd old road floor run locals		
UK	**India**	**Singapore**	**UK**	**India**	**Singapore**
food	indian	cup	pubs	mother	quay
healthy	recipes	comments	music	ate	coast
shop	cup	tea	lane	tree	parkway
favorite	chicken	mins	brick	party	reasonably
wine	minutes	pot	fish	fields	air
icing	kitchen	note	jazz	base	sultan
coffee	mustard	nice	pints	rock	tum
leeds	fried	salt	dancing	toilet	views
duck	ginger	tarts	arms	bottled	plenty
extra	salt	fish	recommend	olive	rochester

Table 4: This table shows words in the food topic that are more popular in the tourists data than the locals data or vice versa.

The prominent trend, which is largely a logistical matter, is that travelers are more interested in restaurants and locals talk more about cooking. Most of the words that are more prominent from the tourist perspective have to do with eating locations. We also noticed that wine and coffee rank more prominently among the locals, whereas travelers are more likely to ask about beer and liquor.

5.5 Model Evaluation

In this subsection we evaluate ccLDA against ccMix and LDA both qualitatively, through blind judgments of cluster quality, and quantitatively, by measuring the likelihood of held-out data with each model.

5.5.1 Cluster Coherence

Because our research relies on analyses of discovered topics, it is important that we use a model that gives the best empirical quality of word clusters. We compare against ccMix (Zhai et al., 2004), the only related model that is naturally suited to our task. Using blind human judgments we show that ccLDA unquestionably delivers topics that are more coherent than those obtained with the ccMix model.

A direct comparison with ccMix is tricky because it incorporates a model for background words, whereas our model expects stop words to be removed during preprocessing. So that they are fully comparable, we set the parameter λ_B (the probability that a word comes from the background) to 0 and fed the model the same input as we did ccLDA. We set the parameter λ_C, analogous to $P(x = 0)$, to 0.6, which is the average value learned by ccLDA on this data, and it seems quite reasonable. Using an implementation provided by the authors of ccMix, we ran the EM procedure for 20 trials and saved the model with the best log-likelihood.

We performed human judgments of the 25 topics induced by ccLDA in the first experiment

above and by the ccMix model with the number of topics set again to 25. We aligned the topics automatically using a symmetric KL-divergence score computed on the collection-independent distributions – specifically, $D(P||Q) + D(Q||P)$ where $D(P||Q)$ is the KL-divergence[5] of the distributions P and Q.

Each aligned pair of topics (ordered randomly for each topic to avoid bias) was presented to two natural language processing researchers who were asked to choose which one was better, based on the following criteria: (1) semantic coherence of the topic as a whole (e.g. are the words in the clusters related?) and (2) coherence across collections, that is, are the collection-specific distributions related to each other and to the common one? The judges were also given the option to rate a pair as "no opinion" in the case that the aligned topics were too dissimilar to compare (because the two models did not discover the same topic), or that the topics did not carry enough semantic information to judge (i.e. topics composed mostly of function words).

Of the 25 pairs, there were 10 that both judges rated. Of these 10, the judges disagreed on 3. The other 7 were all rated in favor of ccLDA.

Similarly, the 50 topics from the second experiment were judged against 50 topics formed using ccMix. There were 22 topics that both judges rated. Among these, they disagreed on only 3; of the remaining topics they voted in favor of ccMix for 1 topic and in favor of ccLDA for 18 topics.

It has been observed that the performance of a model can largely depend on the estimator used (Girolami and Kabán, 2003), so it may be that the weaker performance of ccMix is because the EM algorithm is getting stuck in local maxima, even after several trials.

Table 5 shows the topic of travel compared with both ccMix and LDA. To compare against LDA, we performed a post-hoc estimation of the topic's word distribution for each collection by considering topic assignments of documents within each collection. We see that the ccLDA distributions are much more coherent than that of ccMix. Furthermore, the advantage over LDA is clear – with LDA, we do not get a separation of the words that are common to all of the collections, and thus it is hard to detect the important differences at a glance.

[5]Kullback-Leibler divergence is a commonly used measurement of the similarity of two probability distributions.

5.5.2 Likelihood Comparison

To measure how well our model can generalize unseen documents, we compute the likelihood of held-out data using ccLDA compared with ccMix and LDA. We partitioned the forum dataset from the first experiment into a subset of 80% of the data on which the models are learned, and an evaluation set of the remaining 20%.

To calculate the likelihood of the held-out documents with ccMix, we use the "fold-in" method (Hofmann, 1999) in which the mixing proportions except for $P(z|d)$ are fixed during the EM process. As with our cluster evaluation above, we set $\lambda_B = 0$ and $\lambda_C = 0.6$. With LDA and ccLDA, we approximate $P(z|d)$ through another Gibbs sampling procedure, by averaging 10 samples collected after 100 iterations with a 10-iteration lag in between each sample.

The log-likelihood of the three models is shown at various numbers of topics in Figure 2. As expected, ccLDA generally achieves a higher likelihood than ccMix, although the difference between them diminishes at higher numbers of topics. This appears to be because the pLSI-based ccMix does not regularize the topic mixtures and can thus achieve higher values of $P(z|d)$, and the smoothing of ccLDA has a greater effect at higher numbers of topics.

Both cross-collection models achieve a higher likelihood than LDA, which is not too surprising, given that these models utilize extra information (specifically, the document's collection) to assign a higher probability to words more likely to appear in a document given that information.

It should be noted that even though the likelihood of both cross-collection models increases with the number of topics up to 100, we observed empirically that the best cluster quality in this dataset occurs around 20 to 30 topics; more than that results in clusters that are repeated and are largely specific to only one collection.

6 Discussion and Future Work

While there are obvious limitations of the unigram approach used here, our system was nevertheless able to capture some interesting details. It is important, however, to point out some limitations for possible future extensions.

Consider Topic 2 in Table 2. The UK and Singapore word distributions are both clearly pertinent

ccLDA			ccMix			LDA		
travel hotel hotels city best place holiday visit trip world			travel hotel comments hotels city posted road trip labels airport			travel city hotel park holiday hotels place beach road visit

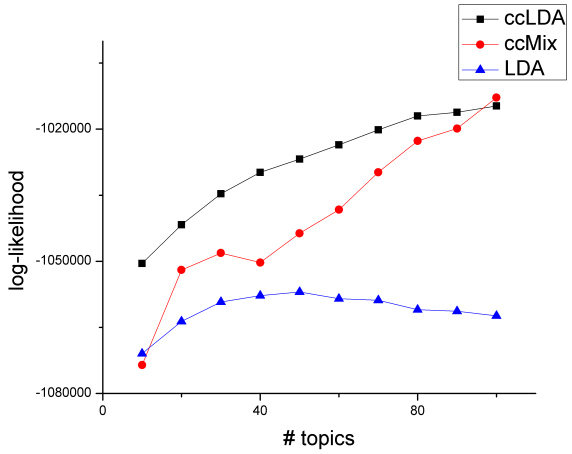

Figure 2: Comparison of the log-likelihood of held-out data with the 3 models.

to the topic of pets, but the India distribution seems entirely unrelated, being about energy and the environment. This could be because the environment topic was statistically too strong to ignore, but not found in other collections, so it made its way into a largely unrelated topic. (In fact, the formation of the environment cluster within this topic is not entirely random, as the pets topic also includes some words related to gardening, including "water" and "plant", which are likely to also co-occur with environmental words.)

This is perhaps the main weakness of the model. If an emerging topic is not shared among all collections, it will either form as a primary topic that is unique to only a subset of collections (and thus some of the collection-specific distributions will be noisy), or it will form as a collection-specific distribution that is not strongly related to the main collection-independent distribution. This can make the results difficult to interpret, although an automated solution would be to remove or flag topics that are not evenly shared, which could be done by comparing the learned collection-dependent Dirichlet parameters α_c.

This is also a matter of how the model performs with different numbers of collections. It would be interesting to see what results we would get by modeling UK-India, UK-Singapore, and India-Singapore as only a pair at a time. The performance should not degrade with larger numbers of collections if the collections are fully comparable, but in practice, with more collections there are likely to be more topics that are difficult to fit across all collections.

In future work, we would like to enrich the model and/or feature set to move beyond the limitations of a bag-of-words analysis. For example, by considering negation and word polarity, we can better capture the opinions of the authors, which is an important component of such cultural analysis.

Certainly, there are many other possible applications of this model, including product comparison, media bias detection, and interdisciplinary literature analysis. Cultural awareness is also important in marketing and we can use this model to investigate, for example what products and what aspects of life people in different regions focus on.

Acknowledgments

We would like to thank ChengXiang Zhai for thoughtful discussions and for providing an implementation of the ccMix model. We would also like to thank the reviewers for their constructive comments.

Consensus Training for Consensus Decoding in Machine Translation

Adam Pauls, John DeNero and **Dan Klein**

{adpauls,denero,klein}@cs.berkeley.edu

Abstract

We propose a novel objective function for discriminatively tuning log-linear machine translation models. Our objective explicitly optimizes the BLEU score of *expected* n-gram counts, the same quantities that arise in forest-based consensus and minimum Bayes risk decoding methods. Our continuous objective can be optimized using simple gradient ascent. However, computing critical quantities in the gradient necessitates a novel dynamic program, which we also present here. Assuming BLEU as an evaluation measure, our objective function has two principle advantages over standard max BLEU tuning. First, it specifically optimizes model weights for downstream consensus decoding procedures. An unexpected second benefit is that it reduces overfitting, which can improve test set BLEU scores when using standard Viterbi decoding.

1 Introduction

Increasing evidence suggests that machine translation decoders should not search for a single top scoring Viterbi derivation, but should instead choose a translation that is sensitive to the model's entire predictive distribution. Several recent consensus decoding methods leverage compact representations of this distribution by choosing translations according to n-gram posteriors and expected counts (Tromble et al., 2008; DeNero et al., 2009; Li et al., 2009; Kumar et al., 2009). This change in decoding objective suggests a complementary change in *tuning* objective, to one that optimizes expected n-gram counts directly. The ubiquitous minimum error rate training (MERT) approach optimizes Viterbi predictions, but does not explicitly boost the aggregated posterior probability of desirable n-grams (Och, 2003).

We therefore propose an alternative objective function for parameter tuning, which we call *consensus* BLEU or CoBLEU, that is designed to maximize the *expected counts* of the n-grams that appear in reference translations. To maintain consistency across the translation pipeline, we formulate CoBLEU to share the functional form of BLEU used for evaluation. As a result, CoBLEU optimizes exactly the quantities that drive efficient consensus decoding techniques and precisely mirrors the objective used for fast consensus decoding in DeNero et al. (2009).

CoBLEU is a continuous and (mostly) differentiable function that we optimize using gradient ascent. We show that this function and its gradient are efficiently computable over packed forests of translations generated by machine translation systems. The gradient includes expectations of *products* of features and n-gram counts, a quantity that has not appeared in previous work. We present a new dynamic program which allows the efficient computation of these quantities over translation forests. The resulting gradient ascent procedure does not require any k-best approximations. Optimizing over translation forests gives similar stability benefits to recent work on lattice-based minimum error rate training (Macherey et al., 2008) and large-margin training (Chiang et al., 2008).

We developed CoBLEU primarily to complement consensus decoding, which it does; it produces higher BLEU scores than coupling MERT with consensus decoding. However, we found an additional empirical benefit: CoBLEU is less prone to overfitting than MERT, even when using Viterbi decoding. In experiments, models trained to maximize tuning set BLEU using MERT consistently degraded in performance from tuning to test set, while CoBLEU-trained models generalized more robustly. As a result, we found that optimizing CoBLEU improved test set performance reliably using consensus decoding and occasionally using Viterbi decoding.

\mathbb{E}_\theta[c(\text{“a rhyme”}, d)|f] &= 0.67 + 0.24 = 0.91 \\
\sum_g \mathbb{E}_\theta[c(g, d)|f] &= 3[0.67 + 0.24 + 0.09] \\
\frac{\sum_g \min\{\mathbb{E}_\theta[c(g, d)|f], c(g, r)\}}{\sum_g \mathbb{E}_\theta[c(g, d)|f]} &= \frac{0.33 + 0.33 + 0.91}{3}
\end{aligned}$$

Figure 1: (a) A simple hypothesis space of translations for a single sentence containing three alternatives, each with two features. The hypotheses are scored under a log-linear model with parameters θ equal to the identity vector. (b) The expected counts of all bigrams that appear in the computation of consensus bigram precision.

2 Consensus Objective Functions

Our proposed objective function maximizes n-gram precision by adapting the BLEU evaluation metric as a tuning objective (Papineni et al., 2002). To simplify exposition, we begin by adapting a simpler metric: bigram precision.

2.1 Bigram Precision Tuning

Let the tuning corpus consist of source sentences $F = f_1 \dots f_m$ and human-generated references $R = r_1 \dots r_m$, one reference for each source sentence. Let e_i be a translation of f_i, and let $E = e_1 \dots e_m$ be a corpus of translations, one for each source sentence. A simple evaluation score for E is its bigram precision $\text{BP}(R, E)$:

$$\text{BP}(R, E) = \frac{\sum_{i=1}^m \sum_{g_2} min\{c(g_2, e_i), c(g_2, r_i)\}}{\sum_{i=1}^m \sum_{g_2} c(g_2, e_i)}$$

where g_2 iterates over the set of bigrams in the target language, and $c(g_2, e)$ is the count of bigram g_2 in translation e. As in BLEU, we “clip” the bigram counts of e in the numerator using counts of bigrams in the reference sentence.

Modern machine translation systems are typically tuned to maximize the evaluation score of Viterbi derivations[1] under a log-linear model with parameters θ. Let $d^*_\theta(f_i) = \arg\max_d P_\theta(d|f_i)$ be the highest scoring derivation d of f_i. For a system employing Viterbi decoding and evaluated by bigram precision, we would want to select θ to maximize $\text{MaxBP}(R, F, \theta)$:

$$\frac{\sum_{i=1}^m \sum_{g_2} min\{c(g_2, d^*_\theta(f_i)), c(g_2, r_i)\}}{\sum_{i=1}^m \sum_{g_2} c(g_2, d^*_\theta(f_i))}$$

On the other hand, for a system that uses expected bigram counts for decoding, we would prefer to choose θ such that expected bigram counts match bigrams in the reference sentence. To this end, we can evaluate an entire posterior distribution over derivations by computing the same clipped precision for expected bigram counts using $\text{CoBP}(R, F, \theta)$:

$$\frac{\sum_{i=1}^m \sum_{g_2} min\{\mathbb{E}_\theta[c(g_2, d)|f_i], c(g_2, r_i)\}}{\sum_{i=1}^m \sum_{g_2} \mathbb{E}_\theta[c(g_2, d)|f_i]} \quad (1)$$

where

$$\mathbb{E}_\theta[c(g_2, d)|f_i] = \sum_d P_\theta(d|f_i) c(g_2, d)$$

is the expected count of bigram g_2 in all derivations d of f_i. We define the precise parametric form of $P_\theta(d|f_i)$ in Section 3. Figure 1 shows proposed translations for a single sentence along with the bigram expectations needed to compute CoBP.

Equation 1 constitutes an objective function for tuning the parameters of a machine translation model. Figure 2 contrasts the properties of CoBP and MaxBP as tuning objectives, using the simple example from Figure 1.

Consensus bigram precision is an instance of a general recipe for converting n-gram based evaluation metrics into consensus objective functions for model tuning. For the remainder of this paper, we focus on consensus BLEU. However, the techniques herein, including the optimization approach of Section 3, are applicable to many differentiable functions of expected n-gram counts.

[1] By *derivation*, we mean a translation of a foreign sentence along with any latent structure assumed by the model. Each derivation corresponds to a particular English translation, but many derivations may yield the same translation.

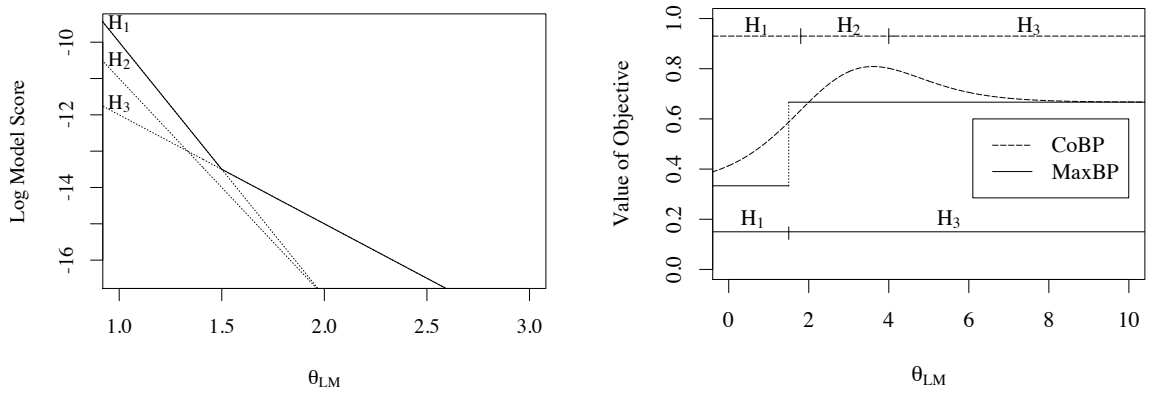

Figure 2: These plots illustrate two properties of the objectives *max bigram precision* (MaxBP) and *consensus bigram precision* (CoBP) on the simple example from Figure 1. (a) MaxBP is only sensitive to the convex hull (the solid line) of model scores. When varying the single parameter θ_{LM}, it entirely disregards the correct translation H_2 because H_2 never attains a maximal model score. (b) A plot of both objectives shows their differing characteristics. The horizontal segmented line at the top of the plot indicates the range over which consensus decoding would select each hypothesis, while the segmented line at the bottom indicates the same for Viterbi decoding. MaxBP is only sensitive to the single point of discontinuity between H_1 and H_3, and disregards H_2 entirely. CoBP peaks when the distribution most heavily favors H_2 while suppressing H_1. Though H_2 never has a maximal model score, if θ_{LM} is in the indicated range, consensus decoding would select H_2, the desired translation.

2.2 CoBLEU

The logarithm of the single-reference[2] BLEU metric (Papineni et al., 2002) has the following form:

$$\ln \text{BLEU}(R, E) = \left(1 - \frac{|R|}{\sum_{i=1}^{m} \sum_{g_1} c(g_1, e_i)}\right)_- + \frac{1}{4} \sum_{n=1}^{4} \ln \frac{\sum_{i=1}^{m} \sum_{g_n} \min\{c(g_n, e_i), c(g_n, r_i)\}}{\sum_{i=1}^{m} \sum_{g_n} c(g_n, e_i)}$$

Above, $|R|$ denotes the number of words in the reference corpus. The notation $(\cdot)_-$ is shorthand for $min(\cdot, 0)$. In the inner sums, g_n iterates over all n-grams of order n. In order to adapt BLEU to be a consensus tuning objective, we follow the recipe of Section 2.1: we replace n-gram counts from a candidate translation with expected n-gram counts under the model.

$$\text{CoBLEU}(R, F, \theta) = \left(1 - \frac{|R|}{\sum_{i=1}^{m} \sum_{g_1} \mathbb{E}_\theta[c(g_1, d)|f_i]}\right)_- + \frac{1}{4} \sum_{n=1}^{4} \ln \frac{\sum_{i=1}^{m} \sum_{g_n} \min\{\mathbb{E}_\theta[c(g_n, d)|f_i], c(g_n, r_i)\}}{\sum_{i=1}^{m} \sum_{g_n} \mathbb{E}_\theta[c(g_n, d)|f_i]}$$

The brevity penalty term in BLEU is calculated using the expected length of the corpus, which equals the sum of all expected unigram counts. We call this objective function *consensus* BLEU, or CoBLEU for short.

3 Optimizing CoBLEU

Unlike the more common MaxBLEU tuning objective optimized by MERT, CoBLEU is continuous. For distributions $P_\theta(d|f_i)$ that factor over synchronous grammar rules and n-grams, we show below that it is also analytically differentiable, permitting a straightforward gradient ascent optimization procedure.[3] In order to perform gradient ascent, we require methods for efficiently computing the gradient of the objective function for a given parameter setting θ. Once we have the gradient, we can perform an update at iteration t of the form

$$\theta^{(t+1)} \leftarrow \theta^{(t)} + \eta_t \nabla_\theta \text{CoBLEU}(R, F, \theta^{(t)})$$

where η_t is an adaptive step size.[4]

[2]Throughout this paper, we use only a single reference, but our objective readily extends to multiple references.

[3]Technically, CoBLEU is non-differentiable at some points because of *clipping*. At these points, we must compute a sub-gradient, and so our optimization is formally sub-gradient ascent. See the Appendix for details.

[4]After each successful step, we grow the step size by a constant factor. Whenever the objective does not decrease after a step, we shrink the step size by a constant factor and try again until a decrease is attained.

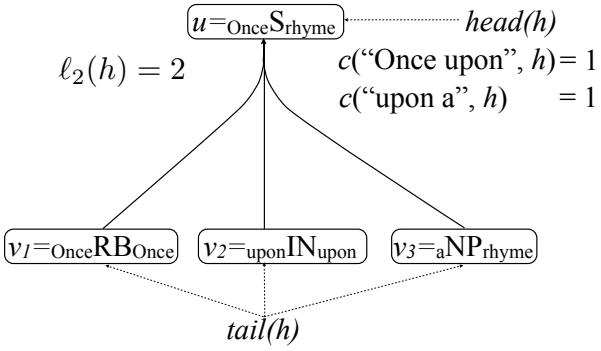

Figure 3: A hyperedge h represents a "rule" used in syntactic machine translation. *tail(h)* refers to the "children" of the rule, while $head(h)$ refers to the "head" or "parent". A forest of translations is built by combining the nodes v_i using h to form a new node $u = head(h)$. Each forest node consists of a grammar symbol and target language boundary words used to track n-grams. In the above, we keep one boundary word for each node, which allows us to track bigrams.

In this section, we develop an analytical expression for the gradient of CoBLEU, then discuss how to efficiently compute the value of the objective function and gradient.

3.1 Translation Model Form

We first assume the general hypergraph setting of Huang and Chiang (2007), namely, that derivations under our translation model form a hypergraph. This framework allows us to speak about both phrase-based and syntax-based translation in a unified framework.

We define a probability distribution over derivations d via θ as:

$$P_\theta(d|f_i) = \frac{w(d)}{Z(f_i)}$$

with

$$Z(f_i) = \sum_{d'} w(d')$$

where $w(d) = \exp(\theta^\top \Phi(d, f_i))$ is the weight of a derivation and $\Phi(d, f_i)$ is a featurized representation of the derivation d of f_i. We further assume that these features decompose over *hyperedges* in the hypergraph, like the one in Figure 3. That is, $\Phi(d, f_i) = \sum_{h \in d} \Phi(h, f_i)$.

In this setting, we can analytically compute the gradient of CoBLEU. We provide a sketch of the derivation of this gradient in the Appendix. In computing this gradient, we must calculate the following expectations:

$$\mathbb{E}_\theta\left[c(\phi_k, d)|f_i\right] \quad (2)$$

$$\mathbb{E}_\theta\left[\ell_n(d)|f_i\right] \quad (3)$$

$$\mathbb{E}_\theta\left[c(\phi_k, d) \cdot \ell_n(d)|f_i\right] \quad (4)$$

where $\ell_n(d) = \sum_{g_n} c(g_n, d)$ is the sum of all n-grams on derivation d (its "length"). The first expectation is an expected count of the kth feature ϕ_k over all derivations of f_i. The second is an expected length, the total expected count of all n-grams in derivations of f_i. We call the final expectation an expected *product of counts*. We now present the computation of each of these expectations in turn.

3.2 Computing Feature Expectations

The expected feature counts $\mathbb{E}_\theta[c(\phi_k, d)|f_i]$ can be written as

$$\begin{aligned}\mathbb{E}_\theta[c(\phi_k, d)|f_i] &= \sum_d P_\theta(d|f_i)c(\phi_k, d) \\ &= \sum_h P_\theta(h|f_i)c(\phi_k, h)\end{aligned}$$

We can justify the second step since feature counts are local to hyperedges, i.e. $c(\phi_k, d) = \sum_{h \in d} c(\phi_k, h)$. The posterior probability $P_\theta(h|f_i)$ can be efficiently computed with inside-outside scores. Let $\mathrm{I}(u)$ and $\mathrm{O}(u)$ be the standard inside and outside scores for a node u in the forest.[5]

$$P_\theta(h|f_i) = \frac{1}{Z(f)}\, w(h)\, \mathrm{O}(head(h)) \prod_{v \in tail(h)} \mathrm{I}(v)$$

where $w(h)$ is the weight of hyperedge h, given by $exp(\theta^\top \Phi(h))$, and $Z(f) = \mathrm{I}(root)$ is the inside score of the root of the forest. Computing these inside-outside quantities takes time linear in the number of hyperedges in the forest.

3.3 Computing n-gram Expectations

We can compute the expectations of any specific n-grams, or of total n-gram counts ℓ, in the same way as feature expectations, provided that target-side n-grams are also localized to hyperedges (e.g. consider ℓ to be a feature of a hyperedge whose value is the number of n-grams on h). If the nodes in our forests are annotated with target-side

[5] Appendix Figure 7 gives recursions for $\mathrm{I}(u)$ and $\mathrm{O}(u)$.

boundary words as in Figure 3, then this will be the case. Note that this is the same approach used by decoders which integrate a target language model (e.g. Chiang (2007)). Other work has computed n-gram expectations in the same way (DeNero et al., 2009; Li et al., 2009).

3.4 Computing Expectations of Products of Counts

While the previous two expectations can be computed using techniques known in the literature, the expected product of counts $\mathbb{E}_\theta[c(\phi_k, d) \cdot \ell_n(d)|f_i]$ is a novel quantity. Fortunately, an efficient dynamic program exists for computing this expectation as well. We present this dynamic program here as one of the contributions of this paper, though we omit a full derivation due to space restrictions.

To see why this expectation cannot be computed in the same way as the expected feature or n-gram counts, we expand the definition of the expectation above to get

$$\sum_d P_\theta(d|f_i)\,[c(\phi_k, d)\ell_n(d)]$$

Unlike feature and n-gram counts, the product of counts in brackets above does not decompose over hyperedges, at least not in an obvious way. We can, however, still decompose the feature counts $c(\phi_k, d)$ over hyperedges. After this decomposition and a little re-arranging, we get

$$\begin{aligned}
&= \sum_h c(\phi_k, h) \sum_{d:h\in d} P_\theta(d|f_i)\ell_n(d) \\
&= \frac{1}{Z(f_i)} \sum_h c(\phi_k, h) \left[\sum_{d:h\in d} w(d)\ell_n(d)\right] \\
&= \frac{1}{Z(f_i)} \sum_h c(\phi_k, h)\hat{\mathrm{D}}^n_\theta(h|f_i)
\end{aligned}$$

The quantity $\hat{\mathrm{D}}^n_\theta(h|f_i) = \sum_{d:h\in d} w(d)\ell_n(d)$ is the sum of the weight-length products of all derivations d containing hyperedge h. In the same way that $P_\theta(h|f_i)$ can be efficiently computed from inside and outside probabilities, this quantity $\hat{\mathrm{D}}^n_\theta(h|f_i)$ can be efficiently computed with two new inside and outside quantities, which we call $\hat{\mathrm{I}}_n(u)$ and $\hat{\mathrm{O}}_n(u)$. We provide recursions for these quantities in Figure 4. Like the standard inside and outside computations, these recursions run in time linear in the number of hyperedges in the forest.

While a full exposition of the algorithm is not possible in the available space, we give some brief intuition behind this dynamic program. We first define $\hat{\mathrm{I}}_n(u)$:

$$\hat{\mathrm{I}}_n(u) = \sum_{d_u} w(d_u)\ell_n(d)$$

where d_u is a derivation rooted at node u. This is a sum of weight-length products similar to $\hat{\mathrm{D}}$. To give a recurrence for $\hat{\mathrm{I}}$, we rewrite it:

$$\hat{\mathrm{I}}_n(u) = \sum_{d_u} \sum_{h\in d_u} [w(d_u)\ell_n(h)]$$

Here, we have broken up the total value of $\ell_n(d)$ across hyperedges in d. The bracketed quantity is a score of a *marked derivation* pair (d, h) where the edge h is some specific element of d. The score of a marked derivation includes the weight of the derivation and the factor $\ell_n(h)$ for the marked hyperedge.

This sum over marked derivations gives the inside recurrence in Figure 4 by the following decomposition. For $\hat{\mathrm{I}}_n(u)$ to sum over all marked derivation pairs rooted at u, we must consider two cases. First, the marked hyperedge could be at the root, in which case we must choose child derivations from regular inside scores and multiply in the local ℓ_n, giving the first summand of $\hat{\mathrm{I}}_n(u)$. Alternatively, the marked hyperedge is in exactly one of the children; for each possibility we recursively choose a marked derivation for one child, while the other children choose regular derivations. The second summand of $\hat{\mathrm{I}}_n(u)$ compactly expresses a sum over instances of this case. $\hat{\mathrm{O}}_n(u)$ decomposes similarly: the marked hyperedge could be local (first summand), under a sibling (second summand), or higher in the tree (third summand).

Once we have these new inside-outside quantities, we can compute $\hat{\mathrm{D}}$ as in Figure 5. This combination states that marked derivations containing h are either marked at h, below h, or above h.

As a final detail, computing the gradient $\nabla C^{\text{clip}}_n(\theta)$ (see the Appendix) involves a clipped version of the expected product of counts, for which a clipped $\hat{D}$ is required. This quantity can be computed with the same dynamic program with a slight modification. In Figure 4, we show the difference as a choice point when computing $\ell_n(h)$.

3.5 Implementation Details

As stated, the runtime of computing the required expectations for the objective and gradient is linear in the number of hyperedges in the forest. The

$$\hat{\mathrm{I}}_n(u) = \sum_{h \in \mathrm{IN}(u)} w(h) \left[\ell_n(h) \prod_{v \in tail(h)} \mathrm{I}(v) + \sum_{v \in tail(h)} \hat{\mathrm{I}}_n(v) \prod_{w \neq v} \mathrm{I}(w) \right]$$

$$\hat{\mathrm{O}}_n(u) = \sum_{h \in \mathrm{OUT}(u)} w(h) \left[\ell_n(h)\, \mathrm{O}(head(h)) \prod_{\substack{v \in tail(h) \\ v \neq u}} \mathrm{I}(v) \;+\; \mathrm{O}(head(h)) \sum_{\substack{v \in tail(h) \\ v \neq u}} \hat{\mathrm{I}}_n(v) \prod_{\substack{w \in tail(h) \\ w \neq v \\ w \neq u}} \mathrm{I}(w) \;+\; \hat{\mathrm{O}}_n(head(h)) \prod_{\substack{w \in tail(h) \\ w \neq u}} \mathrm{I}(w) \right]$$

$$\ell_n(h) = \begin{cases} \sum_{g_n} c(g_n, h) & \text{computing unclipped counts} \\ \sum_{g_n} c(g_n, h)\, \mathbb{1}\left[\mathbb{E}_\theta[c(g_n, d)] \leq c(g_n, r_i)\right] & \text{computing clipped counts} \end{cases}$$

Figure 4: Inside and Outside recursions for $\hat{\mathrm{I}}_n(u)$ and $\hat{\mathrm{O}}_n(u)$. $\mathrm{IN}(u)$ and $\mathrm{OUT}(u)$ refer to the incoming and outgoing hyperedges of u, respectively. $\mathrm{I}(\cdot)$ and $\mathrm{O}(\cdot)$ refer to standard inside and outside quantities, defined in Appendix Figure 7. We initialize with $\hat{\mathrm{I}}_n(u) = 0$ for all terminal forest nodes u and $\hat{\mathrm{O}}_n(root) = 0$ for the root node. $\ell_n(h)$ computes the sum of all n-grams of order n on a hyperedge h.

$$\hat{\mathrm{D}}^n_\theta(h|f_i) =$$

$$w(h) \left[\ell_n(h) \mathrm{O}(head(h)) \prod_{v \in tail(h)} \mathrm{I}(v) + \mathrm{O}(head(h)) \sum_{v \in tail(h)} \hat{\mathrm{I}}_n(v) \prod_{\substack{v \in tail(h) \\ w \neq v}} \mathrm{I}(w) + \hat{\mathrm{O}}_n(head(h)) \prod_{w \in tail(h)} \mathrm{I}(w) \right]$$

Figure 5: Calculation of $\hat{\mathrm{D}}^n_\theta(h|f_i)$ after $\hat{\mathrm{I}}_n(u)$ and $\hat{\mathrm{O}}_n(u)$ have been computed.

number of hyperedges is very large, however, because we must track n-gram contexts in the nodes, just as we would in an integrated language model decoder. These contexts are required both to correctly compute the model score of derivations and to compute clipped n-gram counts. To speed our computations, we use the cube pruning method of Huang and Chiang (2007) with a fixed beam size.

For regularization, we added an L_2 penalty on the size of θ to the CoBLEU objective, a simple addition for gradient ascent. We did not find that our performance varied very much for moderate levels of regularization.

3.6 Related Work

The calculation of expected counts can be formulated using the expectation semiring framework of Eisner (2002), though that work does not show how to compute expected products of counts which are needed for our gradient calculations. Concurrently with this work, Li and Eisner (2009) have generalized Eisner (2002) to compute expected products of counts on translation forests. The training algorithm of Kakade et al. (2002) makes use of a dynamic program similar to ours, though specialized to the case of sequence models.

4 Consensus Decoding

Once model parameters θ are learned, we must select an appropriate decoding objective. Several new decoding approaches have been proposed recently that leverage some notion of consensus over the many weighted derivations in a translation forest. In this paper, we adopt the fast consensus decoding procedure of DeNero et al. (2009), which directly complements CoBLEU tuning. For a source sentence f, we first build a translation forest, then compute the expected count of each n-gram in the translation of f under the model. We extract a k-best list from the forest, then select the translation that yields the highest BLEU score relative to the forest's expected n-gram counts. Specifically, let $\mathrm{BLEU}(e; r)$ compute the similarity of a sentence e to a reference r based on the n-gram counts of each. When training with CoBLEU, we replace e with expected counts and maximize θ. In consensus decoding, we replace r with expected counts and maximize e.

Several other efficient consensus decoding pro-

cedures would similarly benefit from a tuning procedure that aggregates over derivations. For instance, Blunsom and Osborne (2008) select the translation sentence with highest posterior probability under the model, summing over derivations. Li et al. (2009) propose a variational approximation maximizing sentence probability that decomposes over n-grams. Tromble et al. (2008) minimize risk under a loss function based on the linear Taylor approximation to BLEU, which decomposes over n-gram posterior probabilities.

5 Experiments

We compared CoBLEU training with an implementation of minimum error rate training on two language pairs.

5.1 Model

Our optimization procedure is in principle tractable for any syntactic translation system. For simplicity, we evaluate the objective using an Inversion Transduction Grammar (ITG) (Wu, 1997) that emits phrases as terminal productions, as in (Cherry and Lin, 2007). Phrasal ITG models have been shown to perform comparably to the state-of-the art phrase-based system Moses (Koehn et al., 2007) when using the same phrase table (Petrov et al., 2008).

We extract a phrase table using the Moses pipeline, based on Model 4 word alignments generated from GIZA++ (Och and Ney, 2003). Our final ITG grammar includes the five standard Moses features, an n-gram language model, a length feature that counts the number of target words, a feature that counts the number of monotonic ITG rewrites, and a feature that counts the number of inverted ITG rewrites.

5.2 Data

We extracted phrase tables from the Spanish-English and French-English sections of the Europarl corpus, which include approximately 8.5 million words of bitext for each of the language pairs (Koehn, 2002). We used a trigram language model trained on the entire corpus of English parliamentary proceedings provided with the Europarl distribution and generated according to the ACL 2008 SMT shared task specifications.[6] For tuning, we used all sentences from the 2007 SMT shared task up to length 25 (880 sentences for Spanish and 923 for French), and we tested on the subset of the first 1000 development set sentences which had length at most 25 words (447 sentences for Spanish and 512 for French).

[6] See `http://www.statmt.org/wmt08` for details.

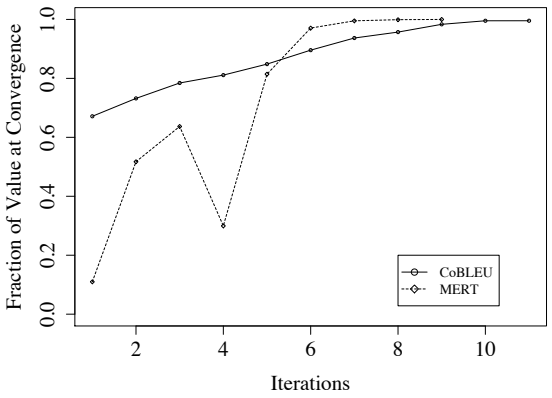

Figure 6: Trajectories of MERT and CoBLEU during optimization show that MERT is initially unstable, while CoBLEU training follows a smooth path to convergence. Because these two training procedures optimize different functions, we have normalized each trajectory by the final objective value at convergence. Therefore, the absolute values of this plot do *not* reflect the performance of either objective, but rather the smoothness with which the final objective is approached. The rates of convergence shown in this plot are not directly comparable. Each iteration for MERT above includes 10 iterations of coordinate ascent, followed by a decoding pass through the training set. Each iteration of CoBLEU training involves only one gradient step.

5.3 Tuning Optimization

We compared two techniques for tuning the nine log-linear model parameters of our ITG grammar. We maximized CoBLEU using gradient ascent, as described above. As a baseline, we maximized BLEU of the Viterbi translation derivations using minimum error rate training. To improve optimization stability, MERT used a cumulative k-best list that included all translations generated during the tuning process.

One of the benefits of CoBLEU training is that we compute expectations efficiently over an entire forest of translations. This has substantial stability benefits over methods based on k-best lists. In Figure 6, we show the progress of CoBLEU as compared to MERT. Both models are initialized from 0 and use the same features. This plot exhibits a known issue with MERT training: because new k-best lists are generated at each iteration, the objective function can change drastically between iterations. In contrast, CoBLEU converges

Consensus Decoding

	Spanish			
	Tune	Test	Δ	Br.
MERT	32.5	30.2	-2.3	0.992
CoBLEU	31.4	30.4	-1.0	0.992
MERT→CoBLEU	31.7	**30.8**	-0.9	0.992
	French			
	Tune	Test	Δ	Br.
MERT	32.5	31.1*	-1.4	0.972
CoBLEU	31.9	30.9	-1.0	0.954
MERT→CoBLEU	32.4	**31.2***	-0.8	0.953

Table 1: Performance measured by BLEU using a consensus decoding method over translation forests shows an improvement over MERT when using CoBLEU training. The first two conditions were initialized by 0 vectors. The third condition was initialized by the final parameters of MERT training. Br. indicates the brevity penalty on the test set. The * indicates differences which are not statistically significant.

smoothly to its final objective because the forests do not change substantially between iterations, despite the pruning needed to track n-grams. Similar stability benefits have been observed for lattice-based MERT (Macherey et al., 2008).

5.4 Results

We performed experiments from both French and Spanish into English under three conditions. In the first two, we initialized both MERT and CoBLEU training uniformly with zero weights and trained until convergence. In the third condition, we initialized CoBLEU with the final parameters from MERT training, denoted MERT→CoBLEU in the results tables. We evaluated each of these conditions on both the tuning and test sets using the consensus decoding method of DeNero et al. (2009). The results appear in Table 1.

In Spanish-English, CoBLEU slightly outperformed MERT under the same initialization, while the opposite pattern appears for French-English. The best test set performance in both language pairs was the third condition, in which CoBLEU training was initialized with MERT. This condition also gave the highest CoBLEU objective value. This pattern indicates that CoBLEU is a useful objective for translation with consensus decoding, but that the gradient ascent optimization is getting stuck in local maxima during tuning. This issue can likely be addressed with annealing, as described in (Smith and Eisner, 2006).

Interestingly, the brevity penatly results in French indicate that, even though CoBLEU did not outperform MERT in a statistically significant way, CoBLEU tends to find shorter sentences with higher n-gram precision than MERT.

Viterbi Decoding

	Spanish		
	Tune	Test	Δ
MERT	32.5	30.2	-2.3
MERT→CoBLEU	30.5	30.9	**+0.4**
	French		
	Tune	Test	Δ
MERT	32.0	31.0	-1.0
MERT→CoBLEU	31.7	30.9	-0.8

Table 2: Performance measured by BLEU using *Viterbi* decoding indicates that CoBLEU is less prone to overfitting than MERT.

Table 1 displays a second benefit of CoBLEU training: compared to MERT training, CoBLEU performance degrades less from tuning to test set. In Spanish, initializing with MERT-trained weights and then training with CoBLEU actually decreases BLEU on the tuning set by 0.8 points. However, this drop in tuning performance comes with a corresponding increase of 0.6 on the test set, relative to MERT training. We see the same pattern in French, albeit to a smaller degree.

While CoBLEU ought to outperform MERT using consensus decoding, we expected that MERT would give better performance under Viterbi decoding. Surprisingly, we found that CoBLEU training actually outperformed MERT in Spanish-English and performed equally well in French-English. Table 2 shows the results. In these experiments, we again see that CoBLEU overfit the training set to a lesser degree than MERT, as evidenced by a smaller drop in performance from tuning to test set. In fact, test set performance actually improved for Spanish-English CoBLEU training while dropping by 2.3 BLEU for MERT.

6 Conclusion

CoBLEU takes a fundamental quantity used in consensus decoding, expected n-grams, and trains to optimize a function of those expectations. While CoBLEU can therefore be expected to increase test set BLEU under consensus decoding, it is more surprising that it seems to better regularize learning even for the Viterbi decoding condition. It is also worth emphasizing that the CoBLEU approach is applicable to functions of expected n-gram counts other than BLEU.

Appendix: The Gradient of CoBLEU

We would like to compute the gradient of

$$\left(1 - \frac{|R|}{\sum_{i=1}^{m}\sum_{g_1}\mathbb{E}_\theta[c(g_1,d)|f_i]}\right)_-$$

$$+\frac{1}{4}\sum_{n=1}^{4}\ln\frac{\sum_{i=1}^{m}\sum_{g_n}\min\{\mathbb{E}_\theta[c(g_n,d)|f_i], c(g_n,r_i)\}}{\sum_{i=1}^{m}\sum_{g_n}\mathbb{E}_\theta[c(g_n,d)|f_i]}$$

To simplify notation, we introduce the functions

$$C_n(\theta) = \sum_{i=1}^{m}\sum_{g_n}\mathbb{E}_\theta[c(g_n,e)|f_i]$$

$$C_n^{\text{clip}}(\theta) = \sum_{i=1}^{m}\sum_{g_n}\min\{\mathbb{E}_\theta[c(g_n,d)|f_i], c(r,g_n)\}$$

$C_n(\theta)$ represents the sum of the expected counts of all n-grams or order n in all translations of the source corpus F, while $C_n^{\text{clip}}(\theta)$ represents the sum of the same expected counts, but clipped with reference counts $c(g_n, r_i)$.

With this notation, we can write our objective function CoBLEU(R, F, θ) in three terms:

$$\left(1 - \frac{|R|}{C_1(\theta)}\right)_-$$

$$+\frac{1}{4}\sum_{n=1}^{4}\ln C_n^{\text{clip}}(\theta) - \frac{1}{4}\sum_{n=1}^{4}\ln C_n(\theta)$$

We first state an identity:

$$\sum_{g_n}\frac{\partial}{\partial\theta_k}\mathbb{E}_\theta[c(g_n,d)|f_i] =$$

$$\mathbb{E}_\theta\left[c(\phi_k,d)\cdot\ell_n(d)|f_i\right]$$
$$-\mathbb{E}_\theta\left[\ell_n(d)|f_i\right]\cdot\mathbb{E}_\theta[c(\phi_k,d)|f_i]$$

which can be derived by expanding the expectation on the left-hand side

$$\sum_{g_n}\sum_{d}\frac{\partial}{\partial\theta_k}P_\theta(d|f_i)c(g_n,d)$$

and substituting

$$\frac{\partial}{\partial\theta_k}P_\theta(d|f_i) =$$

$$P_\theta(d|f_i)c(\phi_k,d) - P_\theta(d|f_i)\sum_{d'}P_\theta(d'|f_i)c(\phi_k,d')$$

Using this identity and some basic calculus, the gradient $\nabla C_n(\theta)$ is

$$\sum_{i=1}^{m}\mathbb{E}_\theta\left[c(\phi_k,d)\cdot\ell_n(d)|f_i\right] - C_n(\theta)\mathbb{E}_\theta[c(\phi_k,d)|f_i]$$

$$\begin{aligned}
\mathrm{I}(u) &= \sum_{h\in\mathrm{IN}(u)} w(h)\left[\prod_{v\in tail(h)}\mathrm{I}(v)\right] \\
\mathrm{O}(u) &= \sum_{h\in OUT(u)} w(h)\left[\mathrm{O}(head(h))\prod_{\substack{v\in tail(h)\\ v\neq u}}\mathrm{I}(v)\right]
\end{aligned}$$

Figure 7: Standard Inside-Outside recursions which compute $\mathrm{I}(u)$ and $\mathrm{O}(u)$. $\mathrm{IN}(u)$ and $\mathrm{OUT}(u)$ refer to the incoming and outgoing hyperedges of u, respectively. We initialize with $\mathrm{I}(u) = 1$ for all terminal forest nodes u and $\mathrm{O}(root) = 1$ for the root node. These quantities are referenced in Figure 4.

and the gradient $\nabla C_n^{\text{clip}}(\theta)$ is given by

$$\sum_{i=1}^{m}\sum_{g_n}\Bigg[\mathbb{E}_\theta\left[c(g_n,d)\cdot c(\phi_k,d)|f_i\right]$$

$$\cdot\mathbb{1}\Big[\mathbb{E}_\theta[c(g_n,d)|f_i]\leq c(g_n,r_i)\Big]\Bigg]$$

$$-C_n^{\text{clip}}(\theta)\mathbb{E}_\theta[c(\phi_k,d)+f_i]$$

where $\mathbb{1}$ denotes an indicator function. At the top level, the gradient of the first term (the brevity penalty) is

$$\frac{|R|\nabla C_1(\theta)}{C_1(\theta)^2}\mathbb{1}\Big[C_1(\theta)\leq|R|\Big]$$

The gradient of the second term is

$$\frac{1}{4}\sum_{n=1}^{4}\frac{\nabla C_n^{\text{clip}}(\theta)}{C_n^{\text{clip}}(\theta)}$$

and the gradient of the third term is

$$-\frac{1}{4}\sum_{n=1}^{4}\frac{\nabla C_n(\theta)}{C_n(\theta)}$$

Note that, because of the indicator functions, CoBLEU is non-differentiable when $\mathbb{E}_\theta[c(g_n,d)|f_i] = c(g_n,r_i)$ or $C_n(\theta) = |R|$. Formally, we must compute a sub-gradient at these points. In practice, we can choose between the gradients calculated assuming the indicator function is 0 or 1; we always choose the latter.

Abstract

Three methods are proposed to classify queries by intent (CQI), e.g., navigational, informational, commercial, etc. Following mixed-initiative dialog systems, search engines should distinguish navigational queries where the user is taking the initiative from other queries where there are more opportunities for system initiatives (e.g., suggestions, ads). The query intent problem has a number of useful applications for search engines, affecting how many (if any) advertisements to display, which results to return, and how to arrange the results page. Click logs are used as a substitute for annotation. Clicks on ads are evidence for commercial intent; other types of clicks are evidence for other intents. We start with a simple Naïve Bayes baseline that works well when there is plenty of training data. When training data is less plentiful, we back off to nearby URLs in a click graph, using a method similar to Word-Sense Disambiguation. Thus, we can infer that *designer trench* is commercial because it is close to *www.saksfifthavenue.com*, which is known to be commercial. The baseline method was designed for precision and the backoff method was designed for recall. Both methods are fast and do not require crawling webpages. We recommend a third method, a hybrid of the two, that does no harm when there is plenty of training data, and generalizes better when there isn't, as a strong baseline for the CQI task.

1 Classify Queries By Intent (CQI)

Determining query intent is an important problem for today's search engines. Queries are short (consisting of 2.2 terms on average (Beitzel et al., 2004)) and contain ambiguous terms. Search engines need to derive what users want from this limited source of information. Users may be searching for a specific page, browsing for information, or trying to buy something. Guessing the correct intent is important for returning relevant items. Someone searching for *designer trench* is likely to be interested in results or ads for trench coats, while someone searching for *world war I trench* might be irritated by irrelevant clothing advertisements.

Broder (2002) and Rose and Levinson (2004) categorized queries into those with *navigational*, *informational*, and *transactional* or *resource-seeking* intent. Navigational queries are queries for which a user has a particular web page in mind that they are trying to navigate to, such as *greyhound bus*. Informational queries are those like *San Francisco*, in which the user is trying to gather information about a topic. Transactional queries are those like *digital camera* or *download adobe reader*, where the user is seeking to make a transaction or access an online resource.

Knowing the intent of a query greatly affects the type of results that are relevant. For many queries, Wikipedia articles are returned on the first page of results. For informational queries, this is usually appropriate, as a Wikipedia article contains summaries of topics and links to explore further. However, for navigational or transactional queries, Wikipedia is not as appropriate. A user looking for the *greyhound bus* homepage is probably not interested in facts about the company. Similarly, someone looking to *download adobe reader* will not be interested in Wikipedia's description of the product's history. Conversely, for informational queries, Wikipedia articles tend to be appropriate while advertisements are not. The user searching for *world war I trench* might find the Wikipedia article on trench warfare useful, while he is prob-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1428–1436,
Singapore, 6-7 August 2009.

(a) The advertisements and related searches are probably more likely to be clicked on than the top result for *designer trench*.

(b) The top result will receive more clicks than the spelling suggestion. Wikipedia often receives lots of clicks, but not for commercial queries like *bestbuy*.

Figure 1: Results pages from two major search engines. A search results page has limited real estate that must be divided between search results, spelling suggestions, query suggestions, and ads.

ably not interested in purchasing clothing, or even World War I related products. We noticed empirically that queries in the logs tend to have a high proportion of clicks on the Wikipedia article or the ads, but almost never both. The Wikipedia page for Best Buy in Figure 1(b) is probably a waste of space. Knowing whether a particular query is navigational, informational, or transactional would improve search and advertising relevance.

After a query is issued, search engines return a list of results, and possibly also advertisements, suggestions of related searches, and spelling suggestions. For different queries, these alternatives have varying utilities to the users. Consider the queries in Figures 1(a) and 1(b). For *designer trench*, the advertisements may well be more useful to the user than the standard set of results. The query suggestions for *designer trench* all would help refine the query, whereas the suggestions for *bestbuy* are less useful, as they would either return the same set of results or take the user to Best Buy's competitors' sites. The spelling suggestion for *best buy* instead of *bestbuy* is also unnecessary. Devoting more page space to the content that is likely to be clicked on could help improve the user experience.

In this paper we consider the task of: given a class of queries, which types of answer (standard search, ads, query suggestions, or spelling sug-

gestions) are likely to be clicked on? Typos will tend to have more clicks on the spelling suggestions, informational queries will have more clicks on Wikipedia pages, and commercial queries will have more clicks on the ads. The observed behavior of where users click tells us something about the hidden intentions of the users when they issue that query.

We focus on *commercial intent* (Dai et al., 2006), the intent to purchase a product or service, to illustrate our method of predicting query intent. The business model of web search today is heavily dependent on advertising. Advertisers bid on queries, and then the search results page also contains "sponsored" sites by the advertisers who won the auction for that query. It is thus advantageous for the advertisers to bid on queries which are most likely to result in a commercial transaction. If a query is classified as likely implying commercial intent, but the advertisers have overlooked this query, then the search engine may want to suggest that advertisers bid on that query. The search engine may also want to treat queries classified as having commercial intent differently, by rearranging the appearance of the page, or by showing more or fewer advertisements.

This paper starts with a simple Naïve Bayes baseline to classify queries by intent (CQI). Supervised methods work well, especially when there is plenty of annotated data for testing and training. Unfortunately, since we don't have as much annotated data as we might like, we propose two workarounds:

1. Use click logs as a substitute for annotated data. Clicks on ads are evidence for commercial intent; other types of clicks are evidence for other intents.

2. We propose a method similar to Yarowsky (1995) to generalize beyond the training set.

2 Related Work

Click logs have been used for a variety of tasks involved in information retrieval, including predicting which pages are the best results for queries (Piwowarski and Zaragoza, 2007; Joachims, 2002; Xue et al., 2004), choosing relevant advertisements (Chakrabarti et al., 2008), suggesting related queries (Beeferman and Berger, 2000), and personalizing results (Tan et al., 2006). Queries that have a navigational intent tended to have a highly skewed click distribution, while users clicked on a wider range of results after issuing informational queries. Lee et al. (2005) used the click distributions to classify navigational versus informational intents.

While navigational, informational, and resource-seeking are very broad intentions, other researchers have looked at personalization and intent on a per user basis. Downey et al. (2008) use the last URL visited in a session or the last search engine result visited as a proxy for the user's information goal, and then looked at the correspondence between information needs and queries (how the goals are expressed).

We are interested in a granularity of intent in between navigational/informational/resource-seeking and personalized intents. For these sorts of intents, the web pages associated with queries provide useful information. To classify queries into an ontology of commercial queries, Broder et al. (2007) found that a classifier that used the text of the top result pages performed much better than a classifier that used only the query string. While the results are quite good on their hierarchy of 6000 types of commercial intents, they manually constructed about 150 hand-picked examples each for each of the 6000 intents. Beitzel et al. (2005) do semi-supervised learning over the query logs to classify queries into topics, but also train with hundreds of thousands of manually annotated queries. Thus, while we also use the query logs and the identities of web pages of associated with each query, we are interested in finding methods that can be applied when that much annotation is prohibitive.

Semi-supervised methods over the click graph make it possible to train classifiers after starting from a much smaller set of seed queries. Li et al. (2008) used the semi-supervised learning method described in Zhou et al. (2004) to gain a much larger training set of examples, and then trained classifiers for product search or job search on the expanded set. Random walk methods over the click graph have also been used to propagate relations between URLs, for tasks such as finding "adult" content (Craswell and Szummer, 2007) and suggesting related queries (Antonellis et al., 2008) and content (Baluja et al., 2008). In our work we also seek to classify query intent using the click graph, but we demonstrate the effectiveness of a simple method by building deci-

sion lists of URLs. In addition, we evaluate our method automatically by using user click rates, rather than assembling hand-labeled examples for training and testing.

Dai et al. (2006) also classified queries by commercial intent, but their method involved crawling the top landing pages for each query, which can be quite time-consuming. In this paper we investigate the commercial intent problem when crawling pages is not feasible, and use only the identities of the top URLs.

3 Using Click Logs as a Substitute for Annotation

Prior work has used click logs in lieu of manual annotations of relevance ratings, either of webpages (Joachims, 2002) or of sponsored search advertisements (Ciaramita et al., 2008). Here we use the click logs as a large-scale source of intents. Logs from Microsoft's Live Search are used for training and test purposes. Logs from May 2008 were used for training, and logs from June 2008 were used for testing.

The logs distinguish four types of clicks: (a) search results, (b) ads, (c) spelling suggestions and (d) query suggestions. Some prototypical queries of each type are shown in Table 1. As mentioned above, clicks on ads are evidence for commercial intent; other types of clicks are evidence for other intents. The query, *ebay official*, is assumed to be commercial intent, because a large fraction of the clicks are on ads. In contrast, typos tend to have relatively more clicks on "did-you-mean" spelling suggestions.

The query logs contain over a terabyte of data for each day, and our experiments were done using months of logs at a time. We used SCOPE (Chaiken et al., 2008), a scripting programming language designed for doing Map-Reduce (Dean and Ghemawat, 2004) style computations, to distribute the task of aggregating the counts of each query over thousands of servers. As the same query is often issued several times by multiple users across an entire month of search logs, we summarize each query with four ratios–search results clicks:overall clicks, ad clicks:overall clicks, spelling suggestion clicks:overall clicks, and query suggestion clicks:overall clicks.

A couple of steps were taken to ensure reliable ratios. We are classifying types, not tokens, and so limited ourselves to those queries with 100 or more clicks. This still leaves us with over half a million distinct queries for training and for testing, yet allows us to use click ratios as a substitute for annotating these huge data sets. If a query was only issued once and the user clicked on an ad, that may be more a reflection of the user, rather than reflecting that the query is 100% commercial. In addition, the ratios compare clicks of one type with clicks of another, rather than comparing clicks with impressions. There is less risk of a failure to find fallacy if we count events (clicks) instead of non-events (non-clicks). There are many reasons for non-clicks, only some of which tell us about the meaning of the query. There are bots that crawl pages and never click. Many links can't be seen (e.g., if they are below the fold).

Queries are labeled as positive examples of commercial intent if their ratio is in the top half of the training set, and negative otherwise. A similar procedure is used to label queries with the three other intents.

Our task is to predict future click patterns based on past click patterns. Note that a query may appear in both the test set and the training set, although not necessarily with the same label. In fact, because of the robustness requirement of 100+ clicks, many queries appear in both sets; 506,369 out of 591,122 of the test queries were also present in the training month. The overlap reflects natural processes on the web, with a long tail (of queries that will never be seen again) and a big fat head (of queries that come up again and again). Throwing away the overlap would both drastically reduce the size of the data and make the problem less realistic for a commercial application.

We therefore report results on various training set sizes so that we can show both: (a) the ability of the proposed method to generalize to unseen queries, and (b) the high performance of the baselines in a realistic setting. We vary the number of new queries by training the methods on subsets of 20%, 40%, 60%, 80%, and 100% of the positive examples (along with all the negative examples) in the training set. This led to the test set having 17%, 34%, 52%, 67%, and 86% actual overlap of these queries, respectively, with the training sets.

Click Type (Area on Results Page)	Query Type (Intent)	Example
Spelling Suggestion	Typo	www.lastmintue.com.au
Ad	Commercial Intent	ebay official
Query Suggestion	Suggestible	sears employees (where there are some popular query suggestions indicating how current employees can navigate to the benefits site, as well as how others can apply for employment)
Search Result	Standard Search	craigslist, denver, co

Table 1: Queries with a high percentage of clicks in each category

4 Three CQI Methods

4.1 Method 1: Look-up Baseline

The baseline method checks if a query was present in the training set, and if so, outputs the label from the training set. If the query was not present, it backs off to the appropriate default label: "non-commercial" for the commercial intent task (and "non-suggestible", "not a typo", etc. for the other CQI tasks). This very simple baseline method is effective because the ratios tend to be fairly stable from one month to the next. The query, *ebay official*, for example, has relatively high ad clicks in both the training month as well as the test month. The next section will propose an alternative method to address the main weakness of the baseline method, the inability to generalize beyond the queries in the training set.

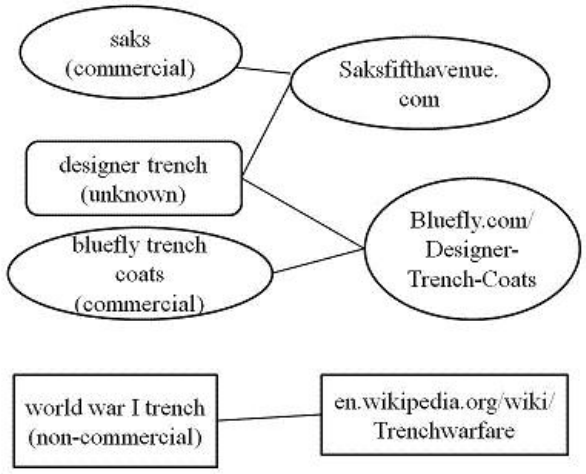

Figure 2: *saks* and *bluefly trench coats* are known to be commercial, while *world war I trench* is known to be non-commercial. What about *designer trench*? We can classify it as commercial because it shares URLs with the known commercial queries.

4.2 Method 2: Using Click Graph Context to Generalize Beyond the Queries in the Training Set

To address the generalization concern, we propose a method inspired by Yarowsky (1994). Word sense disambiguation is a classic problem in natural language processing. Some words have multiple senses; for instance, *bank* can either mean a riverbank or a financial institution, and for various tasks such as information retrieval, parsing, or information extraction, it is useful to be able to differentiate between the possible meanings.

When a word is being used in each sense, it tends to appear in a different context. For example, if the word *muddy* is nearby *bank*, the author is probably using the riverbank sense of the term, while if the word *deposit* is nearby, the word is probably being used with the financial sense.

Yarowksy (1995) thus creates a list of each possible context, sorted by how strong the evidence is for a particular sense. To classify a new example, Yarowsky (1994) finds the most informative collocation pattern that applies to the test example.

In this work, rather than using the surrounding words as context as in text classification, we consider the surrounding URLs in the click graph as context. A sample portion of the click graph is shown in figure 2. The figure shows queries on the left and URLs on the right. The click graph was computed on a very large sample of logs computed well before the training period. There is an edge from a query q to a URL u if at least 10 users issued q and then clicked on u.

For each URL, we look at its neighboring queries and calculate the log likelihood ratio of their labels in the training set. We classify a new query q according to URL^*, the neighboring URL with the strongest opinion (highest absolute value of the log likelihood ratio). That is, we compute URL^* with:

$$\text{argmax}_{U_i \in Nbr(q)} \left| \log \frac{\Pr(Intent|U_i)}{\Pr(\neg Intent|U_i)} \right|$$

If the neighboring opinion is positive (that is, $\Pr(Intent|URL^*) > \Pr(\neg Intent|URL^*)$), then the query q is assigned a positive label. Otherwise, q is assigned a negative label.

In Figure 2, we classify *designer trench* as a commercial query based on the neighbor with the strongest opinion. In this case, there was a tie between two neighbors with equally strong opinions: *www.saksfifthavenue.com* and *www.bluefly.com/Designer-Trench-Coats*. Both neighbors are associated with queries that were labeled commercial in the training set: *saks* and *bluefly trench coats*, respectively.

This method allows the labels of training set queries to propagate through the URLs to new test set queries.

4.3 Method 3: Hybrid ("Better Together")

We recommend a hybrid of the two methods:

- Method 1: the look-up baseline
- Method 2: use click graph context to generalize beyond the queries in the training set

Method 1 is designed for precision and method 2 is designed for recall. The hybrid uses method 1 when applicable, and otherwise, backs off to method 2.

5 Results

5.1 Commercial Intent

Table 2 and Figures 3(a) and 3(b) compare the performance on the proposed hybrid method with the baseline. When there is plenty of training material, both methods perform about equally well (the look-up baseline has an F-score of 84.1%, compared with the hybrid method's F-score of 85.3%), but generalization becomes important when training data is severely limited. Figure 3(a) shows that the proposed method does no harm and might even help a little when there is plenty of training data. The hybrid's main benefit is generalization to queries beyond the training set. If we severely limit the size of the training set to just 20% of the month, as in Figure 3(b), then the proposed hybrid method is substantially better than the baseline. In this case, the proposed hybrid method's F-score is 65.8%, compared with the look-up method's F-score of 28.4%.

5.2 Other types of clicks

Table 3 and Figures 4(a) and 4(b) show a similar pattern for the query suggestion task. In fact, the pattern is perhaps even stronger for the query suggestion task than commercial intent. When the full training set is used, the hybrid method achieves an F-score of 91.9% (precision = 91.5%, recall = 92.3%). When only 20% of the training data is used, the hybrid method has an F-score of 73.9%, compared with the baseline's F-score of 29.6%. A similar pattern was observed for clicks on search results.

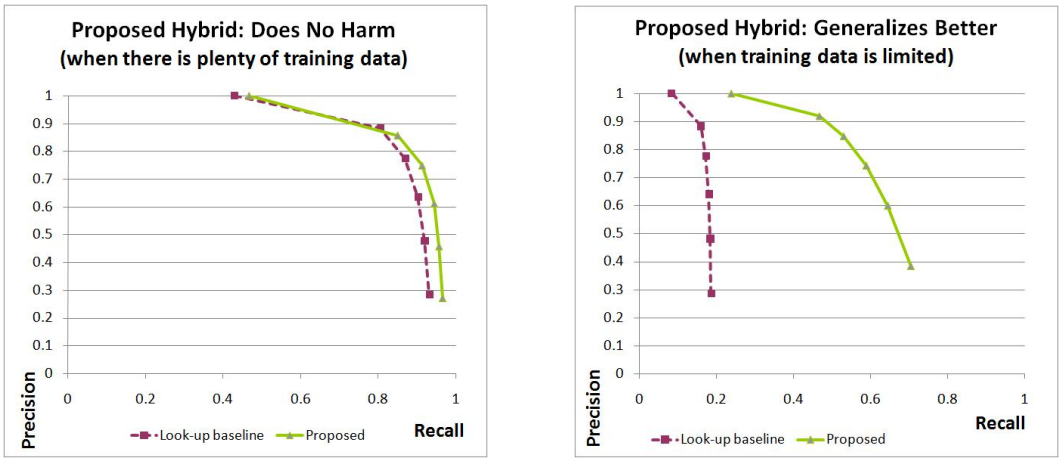
The one exception is the spelling suggestion task, where the context heuristic proved ineffective, for reasons that should not be surprising in retrospect. Click graph distance is an effective heuristic for many intents, but not for typos. Users who issue misspelled the query have the same goals as users who correctly spell the query, so we shouldn't expect URLs to be able to differentiate them. For misspelled queries, for example, *yuotube*, there are correctly spelled queries, like *youtube*, with the same intent that will tend to be associated with the same set of URLs (such as *www.youtube.com*).

6 Conclusion and Future Work

We would like to be able to distinguish web queries by intent. Unfortunately, we don't have annotated data for query intent, but we do have access to large quantities of click logs. The logs distinguish four types of clicks: (a) search results, (b) ads, (c) spelling suggestions and (d) query suggestions. Clicks on ads are evidence for commercial intent; other types of clicks are evidence for other intents. Click logs are huge sources of data, and while there are privacy concerns, anonymized logs are beginning to be released for research purposes (Craswell et al., 2009).

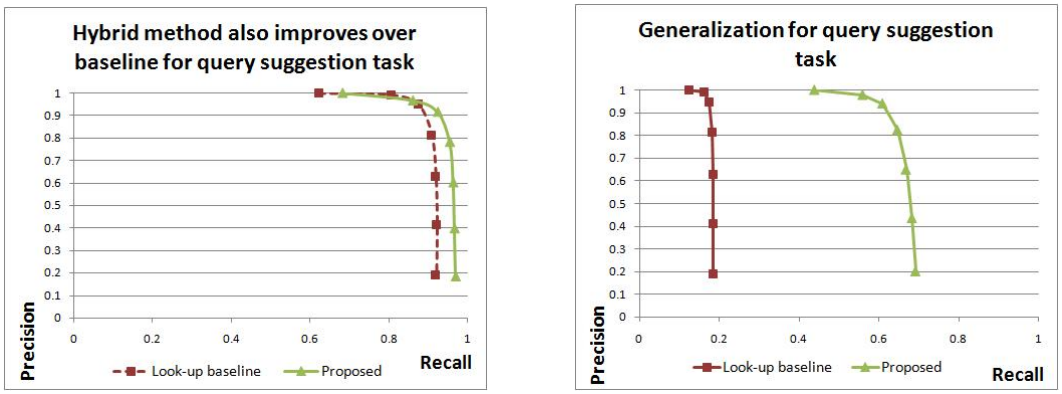
Besides commercial intent, queries can also be divided into two broader classes: queries in which the user is browsing and queries for which the user is navigating. Clicks on the ads and query suggestions indicate that users are browsing and willing to look at these alternative suggestions, while clicks on the search results indicate that the users were navigating to what they were searching for. Clicks on typos indicate neither, as presumably the users are not entering typos on purpose.

Just as dialogue management systems learn policies for when to allow *user* initiative (the user



(a) (b)

Figure 3: Better together: proposed hybrid is no worse than baseline (left) and generalizes better to unseen tail queries (right). The two panels are the same, except that the training set was reduced on the right to test generalization error.



(a) (b)

Figure 4: Similar to Figures 3(a) and 3(b), adding the decision list method generalizes over the look-up method for the "suggestible" task.

can respond in an open way) versus *system* initiative (the system asks the user questions with a restricted set of possible answers) (Relaño et al., 1999; Scheffler and Young, 2002; Singh et al., 2002), search engines may want to learn policies for when the user just wants the search results or when the user is open to suggestions. When users want help (they want the search engine to suggest results), more space on the page should be devoted to the ads and the query suggestions. When the users know what it is they want, more of the page should be given to the search results they asked for.

We started with a simple baseline for predicting click location that had great precision, but didn't generalize well beyond the queries in the training set. To improve recall, we proposed a context heuristic that backs off in the click graph. The backoff method is similar to Yarowsky's Word Sense Disambiguation method, except that context is defined in terms of URLs nearby in click graph distance, as opposed to words nearby in the text.

Our third method, a hybrid of the baseline method and the backoff method, is the strongest baseline we have come up with. The evaluation showed that the hybrid does no harm when there is plenty of training data, and generalizes better when there isn't.

A direction for further research would be to see if propagating query intent through URLs that are not direct neighbors but are further away, perhaps through random walk methods (Baluja et al., 2008;

Training Size	F-score			Precision / Recall		
	Baseline	Method 2	Hybrid	Baseline	Method 2	Hybrid
100%	84.1	75.6	**85.3**	88.2 / 80.4	76.6 / 74.6	85.7 / 85.0
80%	74.4	74.8	**83.5**	88.2 / 64.3	79.3 / 70.7	86.7 / 80.6
60%	62.4	72.9	**80.7**	88.3 / 48.2	82.5 / 65.3	87.9 / 74.6
40%	47.9	70.1	**76.0**	77.5 / 34.7	78.5 / 63.3	80.7 / 66.0
20%	28.4	62.5	**65.8**	77.6 / 17.4	75.9 / 53.1	74.3 / 59.1

Table 2: The baseline and hybrid methods have comparable F-scores when there is plenty of training data, but generalization becomes important when training data is severely limited. The proposed hybrid method generalizes better as indicated by the widening gap in F-scores with smaller and smaller training sets.

Training Size	F-score			Precision / Recall		
	Baseline	Method 2	Hybrid	Baseline	Method 2	Hybrid
100%	91.0	86.2	**91.9**	94.9 / 87.4	90.7 / 82.3	91.5 / 92.3
80%	80.5	85.2	**90.6**	94.9 / 69.9	91.6 / 79.7	91.9 / 89.4
60%	67.6	83.3	**88.6**	94.9 / 52.4	92.6 / 75.8	92.3 / 85.1
40%	51.0	79.5	**84.7**	94.9 / 34.9	87.6 / 72.7	93.0 / 77.8
20%	29.6	69.8	**73.9**	81.5 / 18.1	90.6 / 56.8	94.0 / 60.8

Table 3: F-scores on the query suggestion task. As in the commercial intent task, the proposed hybrid method does no harm when there is plenty of training data, but generalizes better when training data is severely limited.

Antonellis et al., 2008) improves classification.

Similar methods could be applied in future work to many other applications such labeling queries and URLs by: language, market, location, time, intended for a search vertical (such as medicine, recipes), intended for a type of answer (maps, pictures), as well as inappropriate intent (porn, spam).

In addition to click type, there are many other features in the logs that could prove useful for classifying queries by intent, e.g., who issued the query, when and where. Similar methods could also be used to personalize search (Teevan et al., 2008); for queries that mean different things to different people, the Yarowsky method could be applied to variables such as user, time and place, so the results reflect what a particular user intended in a particular context.

Abstract

This paper presents a new approach to selecting the initial seed set using stratified sampling strategy in bootstrapping-based semi-supervised learning for semantic relation classification. First, the training data is partitioned into several strata according to relation types/subtypes, then relation instances are randomly sampled from each stratum to form the initial seed set. We also investigate different augmentation strategies in iteratively adding reliable instances to the labeled set, and find that the bootstrapping procedure may stop at a reasonable point to significantly decrease the training time without degrading too much in performance. Experiments on the ACE RDC 2003 and 2004 corpora show the stratified sampling strategy contributes more than the bootstrapping procedure itself. This suggests that a proper sampling strategy is critical in semi-supervised learning.

1 Introduction

With the dramatic increase in the amount of textual information available in digital archives and the WWW, there has been growing interest in techniques for automatically extracting information from text documents. Information Extraction (IE) is such a technology that IE systems are expected to identify relevant information (usually of pre-defined types) from text documents in a certain domain and put them in a structured format.

According to the scope of the NIST Automatic Content Extraction (ACE) program (ACE, 2000-2007), current research in IE has three main objectives: Entity Detection and Tracking (EDT), Relation Detection and Characterization (RDC), and Event Detection and Characterization (EDC). This paper focuses on the ACE RDC subtask, where many machine learning methods have been proposed, including supervised methods (Miller et al., 2000; Zelenko et al., 2002; Culotta and Soresen, 2004; Kambhatla, 2004; Zhou et al., 2005; Zhang et al., 2006; Qian et al., 2008), semi-supervised methods (Brin, 1998; Agichtein and Gravano, 2000; Zhang, 2004; Chen et al., 2006; Zhou et al., 2008), and unsupervised methods (Hasegawa et al., 2004; Zhang et al., 2005).

Current work on semantic relation extraction task mainly uses supervised learning methods, since it achieves relatively better performance. However this method requires a large amount of manually labeled relation instances, which is both time-consuming and laborious. In the contrast, unsupervised methods do not need definitions of relation types and hand-tagged data, but it is difficult to evaluate their performance since there are no criteria for evaluation. Therefore, semi-supervised learning has received more and more attention, as it can balance the advantages and disadvantages between supervised and unsupervised methods. With the plenitude of unlabeled natural language data at hand, semi-supervised learning can significantly reduce the need for labeled data with only limited sacrifice in performance. Specifically, a bootstrapping algorithm chooses the unlabeled instances with the highest probability of being correctly labeled and use them to augment labeled training data iteratively.

Although previous work (Yarowsky, 1995; Blum and Mitchell, 1998; Abney, 2000; Zhang, 2004) has tackled the bootstrapping approach from both the theoretical and practical point of view, many key problems still remain unresolved, such as the selection of initial seed set. Since the size of the initial seed set is usually small (e.g.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1437–1445,
Singapore, 6-7 August 2009.

100 instances), the imbalance of relation types or manifold structure (cluster structure) in it will severely weaken the strength of bootstrapping. Therefore, it is critical for a bootstrapping approach to select the most appropriate initial seed set. However, current systems (Zhang, 2004; Chen et al., 2006) use a randomly sampling strategy, which fails to explore the affinity nature among the training instances. Alternatively, Zhou et al. (2008) bootstrap a set of weighted support vectors from both labeled and unlabeled data using SVM. Nevertheless, the initial labeled data is still randomly generated only to ensure that there are at least 5 instances for every relation subtype.

This paper presents a new approach to selecting the initial seed set based on stratified sampling strategy in the bootstrapping procedure for semi-supervised semantic relation classification. The motivation behind the stratified sampling is that every relation type should be as much as possible represented in the initial seed set, thus leading to more instances with diverse structures being added to the labeled set. In addition, we also explore different strategies to augment reliably classified instances to the labeled data iteratively, and attempt to find a stoppage criterion for the iteration procedure to greatly decrease the training time, other than using up all the unlabeled set.

The rest of this paper is organized as follows. First, Section 2 reviews related work on semi-supervised relation extraction. Then we present an underlying supervised learner in Section 3. Section 4 details various key aspects of the bootstrapping procedure, including the stratified sampling strategy. Experimental results are reported in Section 5. Finally we conclude our work in Section 6.

2 Related Work

Within the realm of information extraction, currently there are several representative semi-supervised learning systems for extracting relations between named entities.

DIPRE (Dual Iterative Pattern Relation Expansion) (Brin, 1998) is a system based on bootstrapping that exploits the duality between patterns and relations to augment the target relation starting from a small sample. However, it only extracts simple relations such as (*author, title*) pairs from the WWW. Snowball (Agichtein and Gravano, 2000) is another bootstrapping-based system that extracts relations from unstructured text. Snowball shares much in common with DIPRE, including the use of both the bootstrapping framework and the pattern matching approach to extract new unlabeled instances. Due to pattern matching techniques, their systems are hard to be adapted to the general problem of relation extraction.

Zhang (2004) approaches the relation classification problem with bootstrapping on top of SVM. He uses various lexical and syntactic features in the *BootProject* algorithm based on random feature projection to extract top-level relation types in the ACE corpus. Evaluation shows that bootstrapping can alleviate the burden of hand annotations for supervised learning methods to a certain extent.

Chen et al. (2006) investigate a semi-supervised learning algorithm based on label propagation for relation extraction, where labeled and unlabeled examples and their distances are represented as the nodes and the weights of edges respectively in a connected graph, then the label information is propagated from any vertex to nearby vertices through weighted edges iteratively, finally the labels of unlabeled examples are inferred after the propagation process converges.

Zhou et al. (2008) integrate the advantages of SVM bootstrapping in learning critical instances and label propagation in capturing the manifold structure in both the labeled and unlabeled data, by first bootstrapping a moderate number of weighted support vectors through a co-training procedure from all the available data, and then applying label propagation algorithm via the bootstrapped support vectors.

However, in most current systems, the initial seed set is selected randomly such that they may not adequately represent the inherent structure of unseen examples, hence the power of bootstrapping may be severely weakened.

This paper presents a simple yet effective approach to generate the initial seed set by applying the stratified sampling strategy, originated from statistics theory. Furthermore, we try to employ the same stratified strategy to augment the labeled set. Finally, we attempt to find a reasonable criterion to terminate the iteration process.

3 Underlying Supervised Learning

A semi-supervised learning system usually consists of two relevant components: an underlying supervised learner and a

bootstrapping algorithm on top of it. In this section we discuss the former, while the latter will be described in the following section.

In this paper, we select Support Vector Machines (SVMs) as the underlying supervised classifier since it represents the state-of-the-art in the machine learning research community, and there are good implementations of the algorithm available. Specifically, we use LIBSVM (Chang et al., 2001), an effective tool for support vector classification, since it supports multi-class classification and provides probability estimation as well.

For each pair of entity mentions, we extract and compute various lexical and syntactic features, as employed in a state-of-the-art relation extraction system (Zhou et al., 2005).

(1) Words: According to their positions, four categories of words are considered: a) the words of both the mentions; b) the words between the two mentions; c) the words before M1; and d) the words after M2.

(2) Entity type: This category of features concerns about the entity types of both the mentions.

(3) Mention Level: This category of features considers the entity level of both the mentions.

(4) Overlap: This category of features includes the number of other mentions and words between two mentions. Typically, the overlap features are usually combined with other features such as entity type and mention level.

(5) Base phrase chunking: The base phrase chunking is proved to play an important role in semantic relation extraction. Most of the chunking features concern about the headwords of the phrases between the two mentions.

In this paper, we do not employ any deep syntactic or semantic features (such as dependency tree, full parse tree etc.), since they contribute quite limited in relation extraction.

4 Bootstrapping & Stratified Sampling

We first present the self-bootstrapping algorithm, and then discuss several key problems on bootstrapping in the order of initial seed selection, augmentation of labeled data and stoppage criterion for iteration.

4.1 Bootstrapping Algorithm

Following Zhang (2004), we define a basic self-bootstrapping strategy, which keeps augmenting the labeled data set with the models straightforwardly trained from previously available labeled data as follows:

Algorithm self-bootstrapping

Require: labeled seed set L
Require: unlabeled data set U
Require: batch size S
Repeat
  Train a single classifier on L
  Run the classifier on U
  Find at most S instances in U that the classifier has the highest prediction confidence
  Add them into L
Until: no data points available or the stoppage condition is reached

Figure 1. Self-bootstrapping algorithm

In order to measure the confidence of the classifier's prediction, we compute the entropy of the label probability distribution that the classifier assigns to the class label on an example (the lower the entropy, the higher the confidence):

$$H = -\sum_{i}^{n} p_i \log p_i \qquad (1)$$

Where n denotes the total number of relation classes, and p_i denotes the probability of current example being classified as the ith class.

4.2 Stratified Sampling for Initial Seeds

Normally, the number of available labeled instances is quite limited (usually less than 100 instances) when the iterative bootstrapping procedure begins. If the distribution of the initial seed set fails to approximate the distribution of the test data, the augmented data generated from bootstrapping would not capture the essence of relation types, and the performance on the test set will significantly decrease even only after one or two rounds of iterations. Therefore, the selection of initial seed set plays an important role in bootstrapping-based semantic relation extraction.

Sampling is a part of statistical practice concerned with the selection of individual observations, which is intended to yield some knowledge about a population of interest. When dealing with the task of semi-supervised semantic relation classification, the population is the training set of relation instances from the ACE RDC corpora. We compare two practical sampling strategies as follows:

(1) *Randomly sampling*, which picks the initial seeds from the training data using a random scheme. Each element thus has an equal probability of selection, and the population is not

subdivided or partitioned. Currently, most work on semi-supervised relation extraction employs this method. However, since the size of the initial seed set is very small, they are not guaranteed to capture the statistical properties of the whole training data, let alone of the test data.

(2) *Stratified sampling*. When the population embraces a number of distinct categories, *stratified sampling* (Neyman, 1934) can be applied to this case. First, the population can be organized by these categories into separate "strata", then a sample is selected within each "stratum" separately, and randomly. Generally, the sample size is normally proportional to the relative size of the strata. The main motivation for using a stratified sampling design is to ensure that particular groups within a population are adequately represented in the sample.

It is well known that the number of the instances for each relation type in the ACE RDC corpora is greatly unbalanced (Zhou et al., 2005) as shown in Table 1 for the ACE RDC 2004 corpus. When the relation instances for a specific relation type occurs frequently in the initial seed set, the classifier will achieve good performance on this type, otherwise the classifier can hardly recognize them from the test set. In order for every type of relations to be properly represented, the stratified sampling strategy is applied to the seed selection procedure.

Table 1. Numbers of relations on the ACE RDC 2004: break down by relation types and subtypes

Figure 2 illustrates the stratified sampling strategy we use in bootstrapping, where *RSET* denotes the training set, *V* is the stratification variable, and *SeedSET* denotes the initial seed set. First, we divide the relation instances into different strata according to available properties, such as major relation type (considering reverse relations or not) and relation subtype (considering reverse relations or not). Then within every stratum, a certain number of instances are sampled randomly, and this number is normally proportional to the size of that stratum in the whole population. However, when this number is 0 due to the rounding of real numbers, it is set to 1. Also it must be ensured that the total number of instances being sampled is N_S. Finally, these instances form the initial seed set and can be used as the input to the underlying supervised learning for the bootstrapping procedure.

Require: $RSET = \{R_1, R_2, \ldots, R_N\}$
Require: $V = \{v_1, v_2, \ldots, v_K\}$
Require: *SeedSET* with the size of N_S (100)
Initialization:
$SeedSET = NULL$
Steps:

- Group *RSET* into *K* strata according to the stratified variable *V*, i.e.:
  $RSET = \{RSET_1, RSET_2, \ldots, RSET_K\}$
- Calculate the class prior probability for each stratum i={1,2,…,*K*}
  $P_i = NUM(RSET_i) / NUM(RSET)$
- Caculate the number of intances being sampled for each stratum
  $N_i = P_i * N$
  If $N_i = 0$ then $N_i = 1$
- Calculate the difference of numbers as follows:
  $$N_\Delta = N_S - \sum_{i=1}^{K} N_i$$
- If $N_\triangle > 0$ then add N_i (i=1,2,…,$|N_\triangle|$) by 1
  If $N_\triangle < 0$ then subtract 1 from N_i (i=1,2,...,$|N_\triangle|$)
- For each *i* from 1 to *K*
  Select N_i instances from $REST_i$ randomly
  Add them into *SeedSET*

Figure 2. Stratefied Sampling for initial seeds

4.3 Augmentation of labeled data

After each round of iteration, some newly classified instances with the highest confidence can be augmented to the labeled training data. Nevertheless, just like the selection of initial seed set, we still wish that every stratum would be represented as appropriately as possible in the

instances added to the labeled set. In this paper, we compare two kinds of augmentation strategies available:

(1) *Top n* method: the classified instances are first sorted in the ascending order by their entropies (i.e. decreasing confidence), and then the top *n* (usually 100) instances are chosen to be added.

(2) *Stratified* method: in order to make the added instances representative for their stratum, we first select *m* (usually greater than *n*) instances with the highest confidence, then we choose *n* instances from them using the stratified strategy.

4.4 Stoppage of Iterations

In a self-bootstrapping procedure, as the iterations go on, both the reliable and unreliable instances are added to the labeled data continuously, hence the performance will fluctuate in a relatively small range. The key question here is how we can know when the bootstrapping procedure reaches its best performance on the test data. The bootstrapping algorithm by Zhang (2004) stops after it runs out of all the training instances, which may take a relatively long time. In this paper, we present a method to determine the stoppage criterion based on the mean entropy as follows:

$$H_i <= p \qquad (2)$$

Where H_i denotes the mean entropy of the confidently classified instances being augmented to the labeled data in each iteration, and p denotes a threshold for the mean entropy, which will be fixed through empirical experiments. This criterion is based on the assumption that when the mean entropy becomes less than or equal to a certain threshold, the classifier would achieve the most reliable confidence on the instances being added to the labeled set, and it may be impossible to yield better performance since then. Therefore, the iteration may stop at that reasonable point.

5 Experimentation

This section aims to empirically investigate the effectiveness of the bootstrapping-based semi-supervised learning we discussed above for semantic relation classification. In particular, different methods for selecting the initial seed set and augmenting the labeled data are evaluated.

5.1 Experimental Setting

We use the ACE corpora as the benchmark data, which are gathered from various newspapers, newswire and broadcasts. The ACE 2004 corpus contains 451 documents and 5702 positive relation instances. It defines 7 relation types and 23 subtypes between 7 entity types. For easy reference with related work in the literature, evaluation is also done on 347 documents (including nwire and bnews domains) and 4305 relation instances using 5-fold cross-validation. That is, these relation instances are first divided into 5 sets, then, one of them (about 860 instances) is used as the test data set, while the others are regarded as the training data set, from which the initial seed set is sampled. In the ACE 2003 corpus, the training set consists of 674 documents and 9683 positive relation instances while the test data consists of 97 documents and 1386 positive relation instances. The ACE RDC 2003 task defines 5 relation types and 24 subtypes between 5 entity types.

The corpora are first parsed using Collins's parser (Collins, 2003) with the boundaries of all the entity mentions kept. Then, the parse trees are converted into chunklink format using chunklink.pl [1]. Finally, various useful lexical and syntactic features, as described in Subsection 3.1, are extracted and computed accordingly. For the purpose of comparison, we define our task as the classification of the 5 or 7 major relation types in the ACE RDC 2003 and 2004 corpora.

For LIBSVM parameters, we adopted the polynomial kernel, and *c* is set to 10, *g* is set to 0.15. Under this setting, we achieved the best classification performance.

5.2 Experimental Results

In this subsection, we compare and discuss the experimental results using various sampling strategies, different augmentation methods, and iteration stoppage criterion.

Comparison of sampling strategies in selecting the initial seed set

Table 2 and Table 3 show the initial and the highest classification performance of Precision/Recall/F-measure for various sampling strategies of the initial seed set on 7 major relation types of the ACE RDC 2004 corpus respectively when the size of initial seed set *L* is 100, the batch size *S* is 100, and the top 100

[1] http://ilk.kub.nl/~sabine/chunklink/

instances with the highest confidence are added at each iteration. Table 2 also lists the number of strata for stratified sampling methods from which the initial seeds are randomly chosen respectively. Table 3 additionally lists the time needed to complete the bootstrapping process (on a PC with a Pentium IV 3.0G CPU and 1G memory). In this paper, we consider the following five experimental settings when sampling the initial seeds:

- *Randomly* Sampling: as described in Subsection 4.2.
- *Stratified-M* Sampling: the strata are grouped in terms of major relation types without considering reverse relations.
- *Stratified-MR* Sampling: the strata are grouped in terms of major relation types, including reverse relations.
- *Stratified-S* Sampling: the strata are grouped in terms of relation subtypes without considering reverse subtypes.
- *Stratified-SR* Sampling: the strata are grouped in terms of relation subtypes, including reverse subtypes.

For each sampling strategies, we performed 20 trials and computed average scores and the total time on the test set over these 20 trials.

Sampling strategies for initial seeds	# of strat.	P(%)	R(%)	F
Randomly	1	66.1	65.9	65.9
Stratified-M	7	69.1	66.5	67.7
Stratified-MR	13	69.3	67.3	68.2
Stratified-S	30	69.8	67.7	68.7
Stratified-SR	39	69.9	68.5	69.2

Table 2. The initial performance of applying various sampling strategies to selecting the initial seed set on the ACE RDC 2004 corpus

Sampling strategies for initial seeds	Time (min)	P(%)	R(%)	F
Randomly	52	68.6	66.2	67.3
Stratified-M	65	71.0	66.9	68.8
Stratified-MR	65	71.6	67.0	69.2
Stratified-S	71	72.7	67.8	70.1
Stratified-SR	77	72.9	68.4	70.6

Table 3. The highest performance of applying various sampling strategies in selecting the initial seed set on the ACE RDC 2004 corpus

These two tables jointly indicate that the self-bootstrapping procedure for all sampling strategies can moderately improve the classification performance by ~1.2 units in F-score, which is also verified by Zhang (2004). Furthermore, they show that:

- The most improvements in performance come from improvements in precision. Actually, for some settings the recalls even decrease slightly. The reason may be that due to the nature of self-bootstrapping, the instances augmented at each iteration are always those which are the most similar to the initial seed instances, therefore the models trained from them would exhibit higher precision on the test set, while it virtually does no help for recall.
- All of the four stratified sampling methods outperform the randomly sampling method to various degrees, both in the initial performance and the highest performance. This means that sampling of the initial seed set based on stratification by major/sub relation types can be helpful to relation classification, largely due to the performance improvement of the initial seed set, which is caused by adequate representation of instances for every relation type.
- Of all the four stratified sampling methods, the Stratified-SR sampling achieves the best performance of 72.9/68.4/70.6 in P/R/F. Moreover, the more the number of strata generated by the sampling strategy, the more appropriately they would be represented in the initial seed set, and the better performance it will yield. This also implies that the hierarchy of relation types/subtypes in the ACE RDC 2004 corpus is fairly reasonably defined.
- An important conclusion, which can be draw accordingly, is that the F-score improvement of *Stratified-SR* sampling over Randomly sampling in initial performance (3.3 units) is significantly greater than the F-score improvement gained by bootstrapping itself using *Randomly* sampling (1.4 units). This means that the sampling strategy of the initial seed set is even more important than the bootstrapping algorithm itself for relation classification.
- It is interesting to note that the time needed to bootstrap increases with the number of strata. The reason may be that due to more diverse structures in the labeled data for stratified sampling, the SVM needs more time to differentiate between instances, i.e. more time to learn the models.

Comparison of different augmentation strategies of training data

Figure 3 compares the performance of F-score for two augmentation strategies: the *Top n* method and the *stratified* method, over various initial seed sampling strategies on the ACE RDC 2004 corpus. For each iteration, a variable

number (*m* is ranged from 100 to 500) of classified instances in the decreasing order of confidence are first chosen as the base examples, then at most 100 examples are selected from the base examples to be augmented to the labeled set. Specifically, when *m* is equal to 100, the whole set of the base example is added to the labeled data, i.e. degenerated to the *Top n* augmentation strategy. On the other hand, when *m* is greater than 100, we wish we would select examples of different major relation types from the base examples according to their distribution in the training set, in order to achieve the performance improvement as much as the stratified sampling does in the selection of the initial seed set.

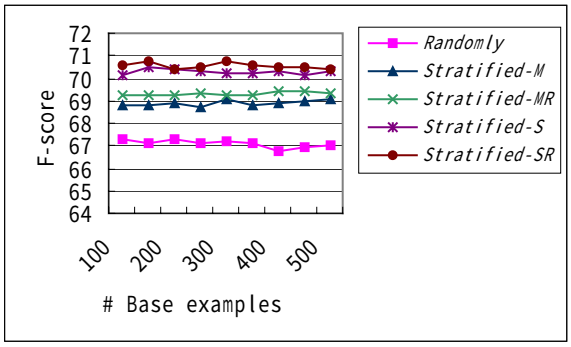

Figure 3. Comparison of two augmentation strategies over different sampling strategies in selecting the initial seed set.

This figure shows that, except for *randomly* sampling strategy, the stratified augmentation strategies improve the performance. Nevertheless, this result is far from our expectation in two ways:

- The performance improvement in F-score is trivial, at most 0.4 units on average. The reason may be that, although we try to add as many as 100 classified instances to the labeled data according to the distribution of every major relation type in the training set, the top *m* instances with the highest confidence are usually focused on certain relation types (e.g. PHSY and PER-SOC), this leads to the stratified augmentation failing to function effectively. Hence, all the following experiments will only adopt *Top n* method for augmenting the labeled data.
- With the increase of the number of the base examples, the performance fluctuates slightly, thus it is relatively difficult to recognize where the optima is. We think there are two contradictory factors that affect the performance. While the reliability of the instances extracted from the base examples decreases with the increase of the number of base examples, the probability of extracting instances of more relation types increases with the increase of the number of the base examples. These two factors inversely interact with each other, leading to the fluctuation in performance.

Comparison of different threshold values for stoppage criterion

We compare the performance and bootstrapping time (20 trials with the same initial seed set) when applying stoppage criterion in Formula (2) with different threshold *p* over various sampling strategies on the ACE RDC 2004 corpus in Figure 4 and Figure 5 respectively. These two figures jointly show that:

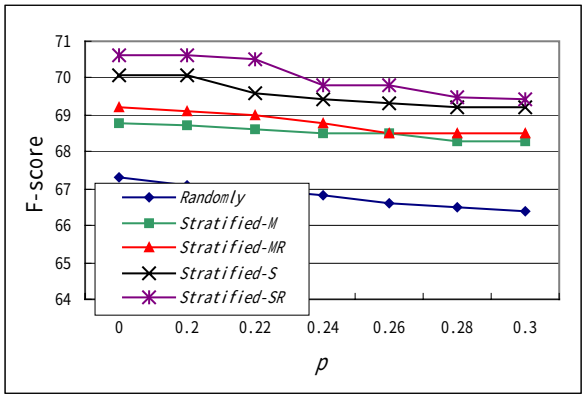

Figure 4. Performance for different *p* values

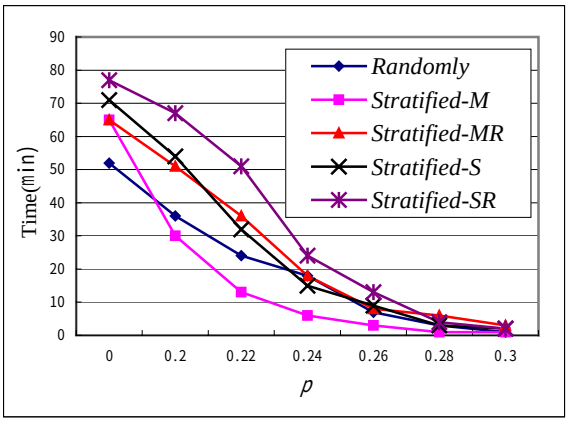

Figure 5. Bootstrapping time for different *p* values

- The performance decreases slowly while the bootstrapping time decreases dramatically with the increase of p from 0 to 0.3. Specifically, when the p equals to 0.3, the bootstrapping time tends to be neglected, while the performance is almost similar to the initial performance. It implies that we can find a reasonable point for each sampling strategy, at which the time falls greatly while the performance nearly does not degrade.

Relation types	*Bootproject*			*LP-js*			*Stratified Bootstrapping*		
	P	R	F	P	R	F	P	R	F
ROLE	78.5	69.7	73.8	81.0	74.7	77.7	74.7	86.3	80.1
PART	65.6	34.1	44.9	70.1	41.6	52.2	66.4	47.0	55.0
AT	61.0	84.8	70.9	74.2	79.1	76.6	74.9	66.1	70.2
NEAR	-	-	-	13.7	12.5	13.0	100.0	2.9	5.6
SOC	47.0	57.4	51.7	45.0	59.1	51.0	65.2	79.0	71.4
Average	67.9	67.4	67.6	73.6	69.4	70.9	73.8	73.3	73.5

Table 4. Comparison of semi-supervised relation classification systems on the ACE RDC 2003 corpus

● Clearly, if the performance is the primary concern, then p=0.2 may be the best choice in that we can get ~30% saving on the time at the cost of only ~0.08 loss in F-score on average. If the time is a primary concern, then p=0.22 is a reasonable threshold in that we get ~50% saving on the time at the cost of ~0.25 units loss in F-score on average. This suggests that our proposed stoppage criterion is effective to terminate the bootstrapping procedure with minor performance loss.

Comparison of *Stratified Bootstrapping* with *Bootproject* and *Label propagation*

Table 4 compares *Bootproject* (Zhang, 2004), *Label propagation* (Chen et al., 2006) with our *Stratified Bootstrapping* on the 5 major types of the ACE RDC 2003 corpus.

Both *Bootproject* and *Label propagation* select 100 initial instances randomly, and at each iteration, the top 100 instances with the highest confidence are added to the labeled data. Differently, we choose 100 initial seeds using stratified sampling strategy; similarly, the top 100 instances with the highest confidence are augmented to the labeled data at each iteration. Due to the lack of comparability followed from the different size of the labeled data used in (Zhou et al., 2008), we omit their results here.

This table shows that our *stratified bootstrapping* procedure significantly outperforms both *Bootproject* and *Label Propagation* methods on the ACE RDC corpus, with the increase of 5.9/4.1 units in F-score on average respectively. *Stratified bootstrapping* consistently outperforms *Bootproject* in every major relation type, while it outperforms *Label Propagation* in three of the major relation types, especially SOC type, with the exception of AT and NEAR types. The reasons may be follows. Although there are many AT relation instances in the corpus, they are scattered divergently in multi-dimension space so that they tend to be relatively difficult to be recognized via SVM. For the NEAR relation instances, they occur least frequently in the whole corpus, so it is very hard for them to be identified via SVM. By contrast, even small size of labeled instances can be fully utilized to correctly induce the unlabeled instances via LP algorithm due to its ability to exploit manifold structures of both labeled and unlabeled instances (Chen et al., 2006).

In general, these results again suggest that the sampling strategy in selecting the initial seed set plays a critical role for relation classification, and stratified sampling can significantly improve the performance due to proper selection of the initial seed set.

6 Conclusion

This paper explores several key issues in semi-supervised learning based on bootstrapping for semantic relation classification. The application of stratified sampling originated from statistics theory to the selection of the initial seed set contributes most to the performance improvement in the bootstrapping procedure. In addition, the more strata the training data is divided into, the better performance will be achieved. However, the augmentation of the labeled data using the stratified strategy fails to function effectively largely due to the unbalanced distribution of the confidently classified instances, rather than the stratified sampling strategy itself. Furthermore, we also propose a mean entropy-based stoppage criterion in the bootstrapping procedure, which can significantly decrease the training time with little loss in performance. Finally, it also shows that our method outperforms other state-of-the-art semi-supervised ones.

Abstract

There is plenty of evidence that emotion analysis has many valuable applications. In this study a blog emotion corpus is constructed for Chinese emotional expression analysis. This corpus contains manual annotation of eight emotional categories (expect, joy, love, surprise, anxiety, sorrow, angry and hate), emotion intensity, emotion holder/target, emotional word/phrase, degree word, negative word, conjunction, rhetoric, punctuation and other linguistic expressions that indicate emotion. Annotation agreement analyses for emotion classes and emotional words and phrases are described. Then, using this corpus, we explore emotion expressions in Chinese and present the analyses on them.

1 Introduction

Textual emotion analysis is becoming increasingly important due to augmented communication via computer mediated communication (CMC) internet sources such as weblogs, email, websites, forums, and chat rooms. Especially, blogspace consists of millions of users who maintain an online diary, containing frequently-updated views and personal remarks about a range of issues.

Despite the increased focus on analysis of web content, there has been limited emotion analysis of web contents, with the majority of studies focusing on sentiment analysis or opinion mining. Classifying the mood of a single text is a hard task; state-of-the-art methods in text classification achieve only modest performance in this domain (Mishne, 2005). In this area, some of the hardest problems involve acquiring basic resources. Corpora are fundamental both for developing sound conceptual analyses and for training these emotion-oriented systems at different levels: to recognize emotions, to express appropriate emotions, to anticipate emotions, and other emotion processing applications.

In this study we propose a relatively fine-grained annotation scheme, annotating emotion in text at three levels: document, paragraph, and sentence. We select eight emotion classes (expect, joy, love, surprise, anxiety, sorrow, angry and hate) for this annotation, and explore various linguistic expressions that indicate emotion in Chinese. The annotation scheme has been employed in the manual annotation of a corpus containing 1,487 documents, with 11,255 paragraphs, 35,096 sentences, and 878,164 Chinese words. Then, using this corpus, we explore and present data analyses on emotions, involving emotion states, accompanying emotions, transfer emotions, independent emotions in texts.

The remainder of this paper is organized as follows. Section 2 describes the emotion corpus annotation scheme. Section 3 presents the inter-annotator agreement study. Section 4 describes the analysis of emotion expressions. Section 5 presents a review of current emotion corpora for textual emotion analysis. Section 6 concludes this study with closing remarks and future directions.

2 Blog Emotion Corpus Annotation Scheme

Weblogs are an increasingly popular mode of communication in the ever changing online world. Writing suits the recording of facts and the communication of ideas, and their textual basis makes them equally suitable for recording emotions and opinions. So, we select blogs as object and data source for this emotion corpus annotation.

2.1 Emotional Expression in Text

An important starting point in constructing this corpus is to represent emotion in text. One of the biggest questions in affect recognition is, "What

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1446–1454,
Singapore, 6-7 August 2009.

are the couplings between affective states and their patterns of expressions" (Picard, 1997).

In this study we propose an emotional expression space model to represent emotion in text, which is hierarchical in consistent with the natural structure of a document. Emotion of a document is represented by a vector

$$\overrightarrow{d} =< e_1, e_2, ..., e_i, ..., e_n > \quad (1)$$

Here, e_i is a basic emotion class contained in document d. The values of e_i range from 0.0 to 1.0 (discrete), indicating the intensities of the basic emotion classes. Similar to a document, emotion of each paragraph and each sentence in a document is represented by an emotion vector.

Basic emotions may be defined in many ways. To decrease confusions on emotion categories' selection and to contain the most common emotion classes in blogs, we select eight emotion classes (expect, joy, love, surprise, anxiety, sorrow, angry and hate) for this manual annotation, and they are agreed by eleven annotators through a testing annotation period. Table 1 shows the numbers of the eight emotion classes in documents, paragraphs, and sentences in this corpus.

Emotions	Doc	Para	Sen
Expect	656	2,145	4,588
Joy	565	2,740	6,211
Love	911	4,991	11,866
Surprise	124	503	1,118
Anxiety	732	4,128	10,115
Sorrow	693	3643	8,166
Angry	189	900	2,221
Hate	335	1,589	3,555
Sum	4,205	20,639	47,840

Table 1: Num. of the eight emotion classes

As shown in Table 1, we have reasonably large counts for all 8 emotions in all 3 units of text. And we also can get the average value for the numbers of emotion classes in each document, each paragraph and each sentence; they are 2.83, 1.84, and 1.36 respectively.

2.2 The Multi-level Annotation Frame

The annotation frame includes 3 levels: document, paragraph, and sentence. Sentence level is the basic level for emotion annotation; the annotation includes intensities of the eight basic emotion classes, emotion holder/target, emotional words/phrases, rhetoric, emotional punctuations, emotion objective/subjective and emotion polarity. Paragraph level is the upper level of sentence level; the annotation includes intensities of the eight basic emotion classes, topic words to reflect the topic of a paragraph, and the number of topic sentence that can express the main points of this paragraph. Document level is the uppermost level; its annotation is similar to paragraph level. The tokenized text files are organized into XML documents. An example document is listed in Figure 1.

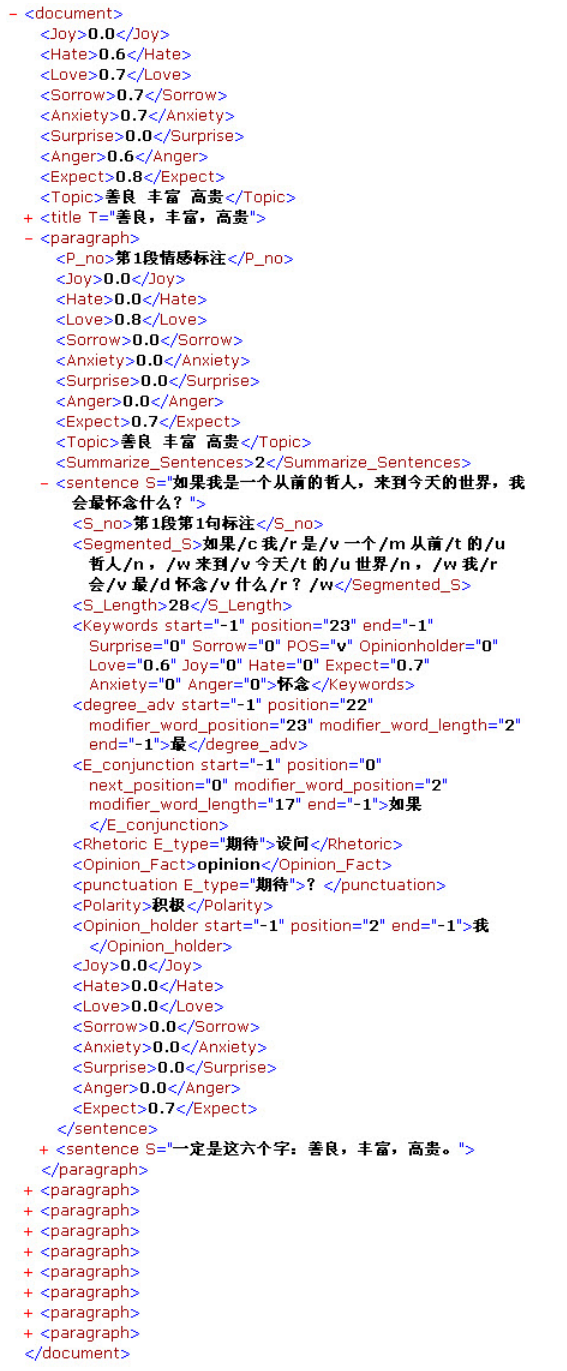

Figure 1: An annotated document in XML format

2.3 Sentence Level Annotation

Sentences are basic units for emotional expression. The central aim of sentence level annotation is to explore as much linguistic expressions for reflecting emotion in Chinese as possible.

a) Emotion holder/target

In the task of opinion analysis, the problem of opinion holder identification has also been studied, (Bethard, Steven et al., 2004; Choi, Cardie, et al., 2005; Kim and Hovy, 2005). As for emotion holder/target identification, little research has been conducted, but we believe it is important for exploring emotional expression and emotion analysis. Emotion holder is the one who holds the emotions, and an emotion target is the object of an emotion holder. For instance,

(1) 我喜欢这个老师。(English: I like this teacher.) In sentence (1),我" (English: I)" is the emotion holder, and 这个老师"(English: this teacher.)" is the emotion target.

In this corpus, not every sentence is annotated with emotion holder or emotion target, and emotion holder or emotion target may not appear in pairs in one sentence. If one sentence has more than one emotion holders or emotion targets, they are all annotated.

b) Emotional words and phrases

Lexicon-based methods have received a lot of attention in opinion analysis task. There are many lexical resources for these tasks. For emotion analysis tasks, the function of words is equally fundamental. In most sentimental lexicons, the words usually bear direct emotions or opinions, such as happy or sad, good or bad. However, there are a lot of sentences can evoke emotions without direct emotional words, for example,

(2) 春天在孩子们的眼里、在孩子们的心里。(English: Spring is in children's eyes, and in their hearts.)

In sentence (2), we may feel joy, love or expect delivered by the writer. Indeed, as (Ortony, Andrew, et al., 1987) indicates, besides words directly referring to emotional states and for which an appropriate lexicon would help, there are words that act only as an indirect reference to emotions depending on the context.

In this annotation scheme, direct emotional words and indirect emotional words in a sentence are all annotated. In sentence (2), 春天"(English: spring)", 孩子们"(English: children)" are labeled. An emotional word or phrase is represented as a vector to record its intensities of the eight basic emotional classes. For instance, the vector for the word 喜欢"(English: like)" $\overrightarrow{w} = (0.0, 0.3, 0.9, 0.0, 0.0, 0.0, 0.0, 0.0)$ indicates the emotions of weak joy and strong love. For indirect emotional words, we annotate their emotion vectors according to their contexts, for example, the possible emotion vector for the word "春天(English: spring)" $\overrightarrow{w} = (0.1, 0.3, 0.3, 0.0, 0.0, 0.0, 0.0, 0.0)$ indicates the emotions of weak expect, joy and love. (The emotions and intensity values may be different because of different annotators).

Emotional phrases are combination of words, such as Chinese proverbs, like "世上无难事，只要肯攀登(English: Where there is a will, there is a way) ". For an emotional phrase, the positions of its first and character in a sentence are labeled, and also for emotional words if there are Chinese word segmentation mistakes.

The statistics show that 84.9% of all emotional words have one emotion, and 14.7% have two emotions, only 0.4% have three or four emotions, but they are indispensable for expressing complex feelings in use of language.

Table 2 shows the numbers of emotional words with different POS (part-of-speech) tags. The set of POS includes 35 classes; Table 2 lists the top five classes.

POS	**Num. of words** (have repeat)
Verb	37,572
Noun	21,308
Adj.	20,265
Adv.	4,223
Gerund	2,789

Table 2: Emotional words with different POS

As shown in Table 2, verbs, nouns, adjectives and adverbs are strong markers of emotion in Chinese.

c) Degree words, negative words, conjunctions

Degree words are associated with the intensities of emotions. In Chinese, degree words appear with high frequency. In this corpus, there are 1,039 different degree words annotated, the total occurring number of them is 16,713, in which, 8,294 degree words modify emotional words or phrases directly. Degree words and the modifying

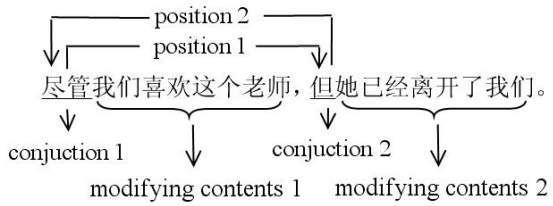
contents are all labeled.

Negative words can be placed almost everywhere in a sentence to change the meaning, also to change the emotions. Negative words are frequently used in Chinese. The statistical data shows that there are 645 different negative words annotated in this corpus, the total occurring number of them is 13,750, in which, 3,668 negative words modify emotional words or phrases directly.

Besides, conjunctions may change the emotion of a sentence. for example,

(3) **尽管**我们喜欢这个老师，**但**她已经离开了我们。(Jin guan wo men xi huan zhe ge lao shi, dan ta yi jing li kai le wo men; English: Although we like this teacher, she has leaved.)

Sentence (3) uses the conjunctions "尽管...但...(jin guan...dan..., English: although)" express emotions of love and sorrow. There are 297 different conjunctions annotated in this corpus. Conjunctions and the modifying contents are all labeled. If conjunctions appear in pairs in a sentence, the position of pairing words for each conjunction are also labeled. For the above sentence (3), conjunctions are annotated as follows (Figure. 2).



English: Although we like this teacher, she has leaved.

Figure 2: An example of conjunctions annotation

Figure 3 shows the growth curve of word number with document number from 300 to 1487. As can be seen from Figure 3, the increase numbers of emotional words/phrases slow down with the increase in the number of documents, and the numbers of negative words, degree words and conjunctions basically remained stable. We can look forward to containing most of common emotional expressions in weblogs articles.

d) Rhetorics, punctuations

Chinese rhetoric has been well studied from the view of linguistics and literature. We select nine common rhetoric categories to annotate: 比喻(English: metaphor), English: 夸张(exaggeration), 拟人(English: personification), 对偶(English: antithesis or parallel), 排比(English: parallelism sentence), 设问(English: rhetorical question with answer), 反问(English: rhetorical question), 重复(English: repeat), 讽刺(English: irony). Especially, 讽刺(English: irony) is a way as to imply the contrary of what one says, if a sentence is annotated with irony, its emotions maybe totally different from the emotions of words that it contains. We annotate rhetoric category and the corresponding emotion category.

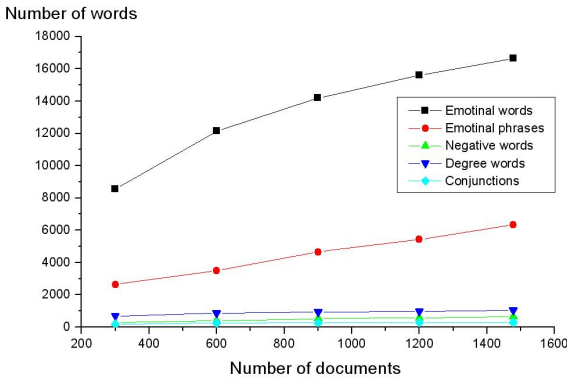


Figure 3: Growth curve of word number

Punctuation is the use of standard marks and signs in writing to separate words into sentences, clauses, and phrases in order to clarify meaning. Some punctuation marks can express emotions, for example, an exclamation mark (!) or a question mark (?) is used at the end of a sentence to show strong emotion. Balog, Mishne, et al. (2006) suggests that people relied on four strategies including punctuation to express happiness versus sadness. Punctuation effect is also shown in (Leshed and Kaye, 2006) to extend to emoticon placement in website text messages. We annotate punctuation with emotion and the corresponding emotion category.

e) Emotion objective/subjective, emotion polarity

Distinguishing a sentence between factual and subjective information could support for many natural language processing applications. Objective and subjective in our annotation scheme is to distinguish a sentence between writer's emotion and non-writer's emotion.

There is a positive side or a negative side on emotion. We call this an emotional polarity. Emotion polarity of a sentence is determined by integrating its emotions. A sentence without emotion is annotated with neutral.

An annotation tool is developed for this corpus

annotation. Input files are text files with Chinese segmentation and part-of-speech tags, the annotated output files are XML files.

3 Annotation Agreement analysis

Emotion annotation is a hard task because the nature of emotion is inherently ambiguous. In the process of annotation, annotators were encouraged to follow their "first intuition". To measure agreement on various aspects of the annotation scheme, three annotators independently annotated 26 documents with a total of 270 paragraphs, 701 sentences.

3.1 Agreement for Emotion Classes

The kappa coefficient of agreement is a statistic adopted by the Computational Linguistics community as a standard measure for this purpose (Carletta, 1996). We measured two agreements for emotion classes' annotation:

Agreement (a): the agreement on classification of containing or not containing some emotions. In this case, we distinguish two classes: emotion intensity $e_i \in \{0.0\}$ or $e_i \in \{0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0\}$;

Agreement (b): the agreement on classification of emotion intensity. In this case, we distinguish four classes: $e_i \in \{0.0\}$ or $e_i \in \{0.1, 0.2, 0.3, 0.4\}$, or $e_i \in \{0.5, 0.6, 0.7\}$, or $e_i \in \{0.8, 0.9, 1.0\}$.

Table 3 shows Agreement (a) and (b) measure on documents, paragraphs and sentences.

	Agreement(a)	Agreement(b)
documents	0.831	0.695
paragraphs	0.705	0.616
sentences	0.756	0.648
Average	0.764	0.653

Table 3: Agreement on emotion classes

As shown in Table 3, it is easier for annotators to agree at the coarser levels of granularity, and it is more difficult to agree on the level of emotion intensity.

3.2 Agreement for Emotional Words and Phrases

Measuring agreement for emotional words and phrases is to verify that annotators agree on which expressions should be marked. To illustrate this agreement problem, consider the emotional words and phrases identified by annotators **a** and **b**. This sentence was preprocessed by Chinese segmentation and tagged with part-of-speech.

(4) 今晨/t ， /w 当/d 我/v 沐浴/n 着/u 阳光/n 前往/v 会场/n 时/Ng ， /w 脑中/v 突然/ad 浮现/v 出/v 多年/m 不用/d 的/u 优美/a 词语/n ， /w 那/r 就/d 是/v ： /w 秋高气爽/n 、/w 金光/n 璀璨/z 。(English: This morning, when I walked to the meeting with sunshine, some wonderful words that have not been used for many years crossed my mind, which are "the autumn sky is clear, the air is crisp" and "shinning with gold color")

a: 阳光, 优美, 秋高气爽, 金光, 璀璨;

b: 沐浴, 阳光, 优美, 秋高气爽, 璀璨;

In sentence (4), the two annotators agree that "阳光", "优美", "秋高气爽" and "璀璨" can express emotion. In addition, annotator **a** marked the word "金光", and annotator **b** marked the word "沐浴".

In this task, there is no guarantee that the annotators will identify the same set of expressions. Thus, to measure agreement we want to consider how much intersection there is between the sets of expressions identified by the annotators. We use the following voting-agreement metric to measure agreement in identifying emotional words and phrases.

Metric voting-agreement is defined as follows. Let A, B and C be the sets of expressions annotated by annotators a, b and c respectively. The expert coder is the set of expressions that agreed by at least two annotators, see Equation 2.

$$voting\_agreement = Avg(\frac{count(t_i = e_j)}{count((t_i)}) \quad (2)$$

In which, $t_i \in T, e_j \in E, T = A \bigcup B \bigcup C$, $E = (A \bigcap B) \bigcup (A \bigcap C) \bigcup (B \bigcap C)$.

The agreement for emotional words and phrases is 0.785.

4 Emotional Expressions Analysis

4.1 Emotion State

"Emotion state in text" is the state of combined emotions in a text unit. An emotion state is represented by 8 binary digits, each digit corresponding to a basic emotion class respectively. As an example, a document emotion state "01100000" is the state of combined emotions by joy and love.

The statistics show that, in this corpus, there are 149 different emotion states in all of the 1,487

documents, 165 different emotion states in all of the 11,255 paragraphs, and 143 different emotion states in all of the 35,096 sentences respectively. That indicates the set of emotion state in texts is relatively small. We also found some basic emotions tend to combine together, such as {expect, joy, love}, {anxiety, sorrow}, {angry, hate}. However, some emotions have small or scarce possibility appear together, such as joy and hate, surprise and angry.

4.2 Accompanying Emotions

In an emotion state, some basic emotions are mixed together. When an emotion e_j arise, emotion $e_i (i \neq j)$ arise with accompany, then, e_i is an accompanying emotion of e_j. To compute the probability of the accompanying emotion given an emotion e_j, we count the cooccurrence of e_i and e_j in a text unit (a document, a paragraph, or a sentence).

$$P(e_i|e_j) = \frac{count(e_i \quad with \quad e_j)}{count(e_j)} \tag{3}$$

Table 4 shows the accompanying emotions with the highest probabilities for the eight basic emotions in documents, paragraphs and sentences.

Emotions	Docs	Paras	Sens
Expect	Love	Love	Love
Joy	Love	Love	Love
Love	Joy	Joy	Joy
Surprise	Anxiety	Love	Love
Anxiety	Sorrow	Sorrow	Sorrow
Sorrow	Anxiety	Anxiety	Anxiety
Angry	Anxiety	Hate	Hate
Hate	Anxiety	Sorrow	Angry

Table 4: Accompanying emotions

In Table 4, the accompanying emotions has shown a high uniformity in the 3 units of text.

4.3 Transfer Emotions

When emotion change from one emotion class to another one, we call this emotion transfer. Using the context relation of paragraphs and sentences, we compute the probability $P(e_i \rightarrow e_j)$.

$$P(e_i \rightarrow e_j) = \frac{count(e_t = e_i, \quad e_{t+1} = e_j)}{count(e_t = e_i)} \tag{4}$$

In which, e_t is an emotion class in paragraph t (or sentence t), and e_{t+1} is another emotion class in paragraph $t + 1$ (or sentence $t + 1$). Table 4 shows the transfer emotions with the highest probabilities for the eight basic emotions in paragraphs and sentences.

Emotions	Paras	Sens
Expect	Love	Expect
Joy	Love	Love
Love	Love	Love
Surprise	Love	Love
Anxiety	Anxiety	Anxiety
Sorrow	Sorrow	Sorrow
Angry	Anxiety	Angry
Hate	Hate	Hate

Table 5: Transfer emotions

Similar to this, we can compute the probability of emotion state transfer $P(e\_state_i \rightarrow e\_state_j)$. This may help a lot for emotion prediction, for example, if we know the current emotion state is "00000110" (sorrow an angry), we can estimate the probability of this emotion state to another emotion state "00000001" (hate).

4.4 Independent Emotion

When a text unit (a document, a paragraph, or a sentence) only contains one emotion class, this emotion class is an independent emotion. The statistics show that emotion of love has high independence, however, joy, surprise and angry has relative low independence. The intuition is love can be the only topic emotion in a text unit, but emotions of joy, surprise and anxiety more incline to combine with other emotions.

5 Related work

Previous approaches to textual emotion analysis have employed some different corpora. Mishne (2005) experimented mood classification in blog posts on a corpus of 815,494 blog posts from Livejournal (http://www.livejournal.com), a free weblog service with a large community. Livejournal also used as data source for finding happiness (Mihalcea and Liu, 2006), capturing global mood levels (Mishne and De Rijke, 2006), classifying mood (Jung, Park, et al., 2006; Jung, Choi, et al., 2007), discovering mood irregularities (Balog, Mishne, et al., 2006), recognizing affect (Leshed and Kaye, 2006). A similar emotion corpus in Chinese is Yahoo!'s Chinese news (http://tw.news.yahoo.com), which is used

for Chinese emotion classification of news readers (Lin, Yang, et al., 2007) and emotion lexicon building (Yang, Lin, et al., 2007). Tokuhima (2008) also use web as data resources to obtain a huge collection of emotion-provoking event instances for Japanese emotion classification. More and more weblogs have added mood column to record blog users' moods when they read or write a blog.

Two merits let them well accepted as emotion corpora: a large number of weblogs contained and moods annotated by blog users. However, there is a great inconsistency on emotion categories given by different websites. Livejournal gives a predefined list of 132 common moods, while Yahoo!'s Chinese news provides readers 8 emotion categories. Too many mood classes may confuse users, and Mishne (2005) also pointed out one obvious drawback of the mood "annotation" in this corpora is that they are not provided in a consistent manner; the blog writers differ greatly from each other, and their definitions of moods differ accordingly. In addition, some words are not fitted to be taken as emotion classes, such as "useful" in Yahoo!'s emotion categories. These corpora may be helpful for analyzing the global moods on a full text, but the inconsistent emotion categories is a problem, and no more labeled information can be exploited from them.

The emotion analysis on sentence level may also be important for more detailed emotion analysis systems. Alm, Roth, et al. (2005) explore the text-based emotion prediction problem; they annotated a corpus of 22 Grimms' tales on sentence level with eight emotion categories (angry, disgusted, fearful, happy, sad, positively surprised, negatively surprised), contain 1580 sentences. Neviarouskaya, Prendinger et al. (2007) address the tasks of recognition and interpretation of affect communicated through text messaging. They collected 160 sentences labeled with one of nine emotions categories (anger, disgust, fear, guilt, interest, joy, sadness, shame, and surprise) from a corpus of online diary-like blog posts and a corresponding intensity value. Aman and Szpakowicz (2007) classify emotional and non-emotional sentences based on a knowledge-based approach. They used a corpus with tags of emotion category, emotion intensity and the words/phrases that indicate emotion in text. An emotion corpus for Japanese was built for recognizing emotions and emotion estimation (Ren, 2009; Matsumoto, 2006). However, the sizes of these corpora seem not enough for large scale textual emotion analysis, a lot of linguistic features are not reflected from them. A more fine-grained opinion and emotion corpus is the MPQA Corpus (Wiebe, Wilson, et al., 2005), which contains 535 news articles (10,000-sentence) from a wide variety of news sources, manually annotated at the sentential and subsentential level for opinions and other private states. But emotion categories are not included in it.

To the best of our knowledge, at present, there's no relatively large corpora annotated with detailed linguistic expressions for emotion in Chinese, and we believe that such corpora would support the development and evaluation of emotion analysis systems.

6 Conclusions and Future Work

In this study we proposed an emotional expression space model. Emotion of a document, a paragraph, a sentence, or even a word is represented by an emotional vector. Based on this model, we described a relatively fine-grained annotation scheme and annotated emotion in text. We also gave the inter-annotator agreement study on annotation. Then, we explore the emotional expressions in texts.

This annotated dataset can be obtained for free with license [1]. Eleven annotators made efforts on it spanning a period of ten months (They are Ph.D and M.S. candidates specialize in Natural Language Processing and Emotion Analysis). To ensure the quality of this dataset, each document was performed a three pass annotation, in which the first pass is annotated by one annotator and then the second and the third verification pass were performed by other two annotators. The process of this corpus annotation is easy to make mistakes because of a lot of information should be annotated. The verification pass is to check the annotation mistakes (such as the start and end positions of emotional phrases in sentences), but not to change the choices of emotion classes or emotional words which had been annotated by other annotators.

Using this corpus, we will make a more extensive study of textual emotion analysis in Chinese,

[1] http://a1-www.is.tokushima-u.ac.jp/member/ren/Ren-CECps1.0/Ren-CECps1.0.html

for example, the influence of degree words, negative words, or other elements on emotional expression; the difference between subjective emotion and objective emotion; emotion transfer tracking. More applications also will be explored, such as emotional summarization, emotional question answering; emotional topic discovering. At the same time, new research problems will arise, for examples, how to acquiring more emotional words and to generate their emotional vectors automatically; how to generate emotional vectors for sentences, paragraphs and documents with known emotional elements in them? There is need to immerge further into these problems.

Acknowledgments

We are grateful to our annotators: Huana Li, Ye Wu, Lei Chen, Yu Zhang, Ji Li, Ziliang Du, Yuanlu Fu, Rong Mu, Yan Sun, Cheng Wang, Yunong Wu, and other participants and supporters. We are also grateful to Dr. Suzuki and Dr. Matsumoto for the helpful advice. A Probabilistic Model for Associative Anaphora Resolution

Ryohei Sasano and **Sadao Kurohashi**
Graduate School of Informatics, Kyoto University,
Yoshida-honmachi, Sakyo-ku, Kyoto
{sasano,kuro}@i.kyoto-u.ac.jp

Abstract

This paper proposes a probabilistic model for associative anaphora resolution in Japanese. Associative anaphora is a type of bridging anaphora, in which the anaphor and its antecedent are not coreferent. Our model regards associative anaphora as a kind of zero anaphora and resolves it in the same manner as zero anaphora resolution using automatically acquired lexical knowledge. Experimental results show that our model resolves associative anaphora with good performance and the performance is improved by resolving it simultaneously with zero anaphora.

1 Introduction

The correct interpretation of anaphora is vital for natural language understanding. Bridging anaphora (Clark, 1975) represents a special part of the general problem of anaphora resolution, which has been studied and discussed for various languages and domains (Hahn et al., 1996; Murata et al., 1999; Poesio et al., 2004; Gasperin and Vieira, 2004; Gasperin and Briscoe, 2008).

Usually bridging anaphora considers two types:[1] **associative anaphors** are noun phrases (NPs) that have an antecedent that is necessary to their interpretation but the relation between the anaphor and its antecedent is different from identity; and **indirect anaphors** are those that have an identity relation with their antecedents but the anaphor and its antecedent have different head nouns. In this paper, we focus on associative anaphora in Japanese.

Associative anaphora resolution is decomposed into two steps: acquiring lexical knowledge for associative anaphora resolution, and resolving associative anaphora using the acquired knowledge.

Grammatical salience plays a lesser role for resolving anaphors with full lexical heads, than for pronominal anaphora (Strube and Hahn, 1999; Modjeska, 2002). Furthermore, since associative anaphors and their antecedents usually have different head nouns, string matching technique cannot be applied. Therefore, a large and diverse amount of lexical knowledge is essential to understand associative anaphora. For example, to recognize the meronymic relation between "a house" and "the roof" in (1), such knowledge as "a roof" is a part of a building or vehicle is required. To recognize the attributive relation between "Prius" and "the price" in (2), such knowledge as "price" is a price of some goods or service is required.

(1) There was a house. **The roof** was white.

(2) Toyota launched the hybrid car Prius in 1997. **The price** was 21.5 million yen.

To acquire such lexical knowledge, various studies have been carried out. Early studies used hand-crafted lexical knowledge such as WordNet (Strube and Hahn, 1999; Vieira and Poesio, 2000; Meyer and Dale, 2002), but obtained poor or mediocre results. Hence, Poesio et al. (2002) proposed to exploit "N_h of N_m" phrases in large corpora to resolve associative anaphora in English; Murata et al. (1999) proposed to exploit "N_m *no* N_h" phrases to resolve associative anaphora in Japanese. Here, the Japanese postposition "*no*" roughly corresponds to "of," but it has

[1] The terminology that we use here is introduced by Hawkins (1978), which is also used in (Vieira et al., 2006).

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1455–1464,
Singapore, 6-7 August 2009.

much broader usage. These studies obtained reasonable results, but the coverage of the acquired knowledge was not sufficient. Recently, a number of researchers argued for using the Web as a source of lexical knowledge, and the Web has been shown to be a useful resource for anaphora resolution (Bunescu, 2003; Markert et al., 2003; Poesio et al., 2004).

Hence, in this study, we acquire the lexical knowledge for associative anaphora resolution from "N_m *no* N_h" phrases in the Web by using the method described in (Sasano et al., 2004). We proposed a method for acquiring such lexical knowledge, called *nominal case frames* (NCFs), using an ordinary language dictionary and "N_m *no* N_h" phrases, and constructed NCFs from newspaper corpora. In this study, we aim to acquire a sufficient amount of lexical knowledge by constructing NCFs from the Web.

As for associative anaphora resolution itself, we propose an integrated probabilistic model for zero anaphora and associative anaphora resolution, in which associative anaphora is regarded as a kind of zero anaphora and resolved by using the same model as zero anaphora. Our model assumes zero pronouns that represent indispensable entities of target noun phrases, which are called *zero adnominal* in (Yamura-Takei, 2003), and conducts zero pronoun resolution.

Let us consider the associative anaphoric relation between "*Prius*" and "*kakaku*" (price). Although "*kakaku*" itself is considered as the anaphor from a conventional point of view (3a), our model assumes a zero pronoun ϕ and considers it as the anaphor (3b).

(3) a. *Prius* - *kakaku* (price)
[antecedent: Prius, anaphor: *kakaku* (price)]

b. *Prius* - *(ϕ-no) kakaku* (price (of ϕ))
[antecedent: Prius, anaphor: ϕ]

The point of this study is three-fold: the acquisition of the lexical knowledge for associative anaphora resolution from the Web, the application of zero anaphora resolution model to associative anaphora resolution, and the integrated resolution of zero anaphora and associative anaphora.

2 Construction of Nominal Case Frames

Most nouns have their indispensable entities: "price" is a price of some goods or service, "roof" is a roof of some building, and "coach" is a coach of some sports. The relation between a noun and its indispensable entities is parallel to that between a verb and its arguments or obligatory cases. In this paper, we call indispensable entities of nouns *obligatory cases*. Note that, *obligatory* does not mean grammatically obligatory but obligatory to interpret the meaning of the noun. Associative anaphora resolution needs comprehensive information of obligatory cases of nouns. *Nominal case frames* (NCFs) describe such information, and we construct them from the Web.

2.1 Automatic Construction of NCFs

First, we briefly introduce our method for constructing NCFs from raw corpora proposed in (Sasano et al., 2004).

Whereas verbal case frame construction uses arguments of each verb (Kawahara and Kurohashi, 2002), nominal case frame construction basically uses adnominal constituents of each noun. However, while the meaning of a verbal argument can be distinguished by the postposition, such as "*ga*" (nominative), "*wo*" (accusative), and "*ni*" (dative), the meaning of an adnominal constituent can not be distinguished easily, because most adnominal constituents appear with the same postposition "*no*" (of). Thus, we first conduct a semantic analysis of adnominal constituents, and then construct NCFs using the results as follows:

1. Collect syntactically unambiguous noun phrases "N_m *no* N_h" from the automatic resulting parses of large corpora.
2. Analyze the relation between N_m and N_h by Kurohashi and Sakai's method (1999) that exploits an ordinary language dictionary.
3. Depending on the results, classify N_m, and obtain preliminary case slots for N_h.
4. Merge case slots if two preliminary case slots of N_h are similar.
5. Consider frequent case slots as obligatory cases of N_h. The frequency thresholds are varied according to semantic analyses.
6. For each meaning of N_h, collect case slots and construct case frames.

The point of this method is the integrated use of an ordinary dictionary and example phrases from

Table 1: Examples of constructed nominal case frames.

	Case slot	Examples with freq	Generalized examples with rate
kakaku (1) (price)	Definition: the amount of money you have to pay for **something**.		
	[something]	*shôhin*(goods):9289, *seihin*(product):2520, *buhin*(part):341, *yunyuhin*(importation):232, · · ·	[CT:ARTIFACT]:0.93, · · ·
yane (1) (roof)	Definition: the structure that covers or forms the top of a **building** etc.		
	[building]	*ie*(house):2505, *kuruma*(car):1565, *koya*(hut):895, *tatemono*(building):883,*minka*(private house):679, · · ·	[CT:FACILITY]:0.44, [CT:VEHICLE]:0.13,· · ·
shusho (1) (prime minister)	Definition: the elected leader of the government in a **country** that has a parliament.		
	[country]	*nihon*(Japan):2355, *kuni*(country):272, *doitsu*(Germany):157, *chûgoku*(China):130, · · ·	[NE:LOCATION]:0.82, [CT:VEHICLE]:0.13,· · ·
imouto (1) (sister)	Definition: a girl or woman who has the same parents as you.		
	<relationship>	*watashi*(me):3385, *ore*(me):1188, *boku*(me):898, *jibun*(oneself):341, *tomodachi*(friend):537, · · ·	[CT:PERSON]:0.74, [NE:PERSON]:0.22, · · ·
rebâ(1) (lever)	Definition: a stick or handle on a **machine**.		
	[machine]	*buŕeki*(brake):122, *sokketo*(sochet):67, *waipâ*(wiper):54, *souchi*(device):52,· · ·	[CT:ARTIFACT]:0.61, [CT:VEHICLE]:0.04, · · ·
rebâ(2) (liver)	Definition: the liver of an **animal**, used as food.		
	[animal]	*niwatori*(chicken):153, *buta*(pig):153, *ushi*(cattle):62, *doubutsu*(animal):25,· · ·	[CT:ANIMAL]:0.98, · · ·
senshu(1) (player)	Definition: someone who takes part in a **sport**.		
	[sport]	*yakyû*(baseball):1252, *rirê*(relay):736, *kyôgi*(competition):430, *sakkâ*(soccer):394, · · ·	[CT:ABSTRACTION]:0.56, · · ·
	<affiliation>	*chîmu*(team):4409, *nihon*(Japan):3222, *reddu*(Reds):771, *kankoku*(Korea):644,*rîgu*(league) · · ·	[NE:LOCATION]:0.33, [CT:ORGANIZATION]:0.30, · · ·

* "[]" and "<>" denote dictionary-based and semantic feature-based analysis respectively. For details see (Sasano et al., 2004).

large corpora. Dictionary definition sentences are an informative resource to recognize obligatory cases of nouns. However, it is difficult to resolve associative anaphora by using a dictionary as it is, because all nouns in a definition sentence are not an obligatory case, and only the frequency information of noun phrases tells us which is the obligatory case. On the other hand, a simple method that just collects and clusters "N_m *no* N_h" phrases based on some similarity measure of nouns cannot construct comprehensive nominal case frames, because of polysemy and multiple obligatory cases. For details see (Sasano et al., 2004).

It is desirable to use a probability distribution for deciding whether a case slot is obligatory or not. However, it is difficult to estimate a probability distribution, since we construct nominal case frames not by using the examples of associative anaphora itself but by using the examples of noun phrases "N_m *no* N_h" (N_h of N_m). We use such noun phrases because indispensable entities of noun "N_h" often appear as "N_m." However, we can say neither frequently appeared "N_m" is an indispensable entity of "N_h." nor an indispensable entity frequently appears as "N_m." For example, the name of a country is considered as an indispensable entity of "*shusho*" (prime minister), but does not frequently appear as "N_m."[2] Thus, it is difficult to estimate a probability distribution and we use a hard decision.

2.2 NCF Construction from the Web

We constructed nominal case frames from the Web Corpus (Kawahara and Kurohashi, 2006), which comprises 1.6 billion unique Japanese sentences. In this corpus, there were about 390 million noun phrases "N_m *no* N_h," about 100 million unique noun phrases, and about 17 million unique head nouns "N_h." There were about 4.07 million head nouns that appeared more than 10 times in the corpus, and we used only such head nouns.

The resultant nominal case frames consisted of about 564,000 nouns including compound nouns. We show examples of constructed nominal case frames in Table 1. The average number of case frames for a noun that has case frames was 1.0031, and the average number of case slots for a case frame was 1.0101. However, these statistics differed with the frequency of the noun. Therefore, we investigated the statistics of constructed nominal case frames for each group classified by the frequency of the nouns. Table 2 shows the re-

[2] It is because "the prime minister of Japan" is often mentioned by simply "the prime minister" in Japanese.

Table 2: The statistics of constructed NCFs.

Frequency ranking	Proportion of nouns with NCF	# of NCFs per noun with NCF	# of CSs per NCF	Coverage
-100	56.0%	1.34	1.07	17.3%
-1000	68.8%	1.17	1.16	25.6%
-10000	51.7%	1.11	1.17	27.0%
-100000	14.8%	1.05	1.13	17.6%
100001-	13.7%	1.0009	1.0053	12.5%
all	13.9%	1.0031	1.0101	100%

Table 3: Evaluation of constructed NCFs.

Precision	Recall	F-measure
62/70 (0.89)	62/84 (0.74)	0.81

sult. As for the 10,000 most frequently appeared nouns, which occupied about 70% of all noun appearances, the average number of case frames for a noun was 1.11, and the average number of case slots for a case frame was 1.17.

For evaluating the resultant case frames, we randomly selected 100 nouns from the 10,000 most frequent nouns, and created gold standard case frames for these nouns by hand. For each noun, case frames were given if the noun was considered to have any indispensable entity, and for each case frame, obligatory case slots were given manually: 70 case frames were created that had 84 case slots; 56 case frames had only one case slot, the other 14 case frames had two case slots. 30 nouns had no case frames.

We then evaluated the automatically constructed case slots for these selected nouns. The evaluation result is shown in Table 3: the system output 70 case slots, and out of them, 62 case frames were judged as correct. The F-measure was 0.81. Since the boundary between indispensable cases and optional cases of a noun is not always obvious, this score is considered to be reasonable.

2.3 Generalization of Examples

By using nominal case frames constructed from the Web, sparseness problem was alleviated to some extent, but still remained. For instance, there were thousands of named entities (NEs), which could not be covered intrinsically. To deal with this sparseness problem, we generalized the examples of case slots.

First, we used the categories that Japanese morphological analyzer JUMAN[3] adds to common nouns. In JUMAN, about twenty categories are defined and tagged to common nouns. For example, "*kuruma* (car)," "*niwatori* (chicken)," and "*tatemono* (building)" are tagged as "VEHICLE," "ANIMAL" and "FACILITY," respectively. For each category, we calculated the rate of categorized examples among all case slot examples, and added it to the case slot as "[CT:VEHICLE]:0.13."

We also generalized NEs. We used a common standard NE definition for Japanese provided by IREX workshop (1999). We first recognized NEs in the source corpus by using an NE recognizer (Sasano and Kurohashi, 2008), and then constructed NCFs from the NE-recognized corpus. As well as categories, for each NE class, we calculated the NE rate among all case slot examples, and added it to the case slot as "[NE:PERSON]:0.22." The generalized examples are also included in Table 1.

3 Probabilistic Model

In this study, we apply a lexicalized probabilistic model for zero anaphora resolution proposed in (Sasano et al., 2008) to associative anaphora resolution.

3.1 A Lexicalized Probabilistic Model for Zero Anaphora Resolution

In English, overt pronouns such as "she" and definite noun phrases such as "the company" are anaphors that refer to preceding entities (antecedents). On the other hand, in Japanese, anaphors are often omitted, which are called *zero pronouns*, and zero anaphora resolution is one of the most important techniques for semantic analysis in Japanese.

Here, we introduce our model for zero anaphora resolution (Sasano et al., 2008). This model first resolves coreference and identifies discourse entities; then from the end of each sentence, analyzes each predicate by the following steps:

1. Select a case frame temporarily.
2. Consider all possible correspondences between each input argument and a case slot of the selected case frame.
3. Regard case slots that have no correspondence as zero pronoun candidates.

[3] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/juman-e.html

4. Consider all possible correspondences between zero pronoun candidates and existing entities.

5. For each possible case frame, estimate each correspondence probabilistically, and select the most likely case frame and correspondence.

Figure 1 shows an example of correspondences between case frames and discourse entities.

The probabilistic model gives a probability to each possible case frame CF and case assignment CA when target predicate v, input arguments IA and existing discourse entities ENT are given, and outputs the case frame and case assignment that have the highest probability. That is to say, their model selects the case frame CF_{best} and the case assignment CA_{best} that maximize the probability $P(CF, CA|v, IA, ENT)$:

$$(CF_{best}, CA_{best}) = \underset{CF,CA}{\operatorname{argmax}} P(CF, CA|v, IA, ENT) \quad \text{(i)}$$

By decomposing case assignment (CA) into direct case assignment (DCA) and the indirect case assignment (ICA) and using several independence assumptions, Equation (i) is transformed into the following equation:[4]

$$(CF_{best}, DCA_{best}, ICA_{best}) = \underset{CF,DCA,ICA}{\operatorname{argmax}} \Big(P(CF|v) \times P(DCA, IA|CF) \times P(ICA|ENT, CF, DCA) \Big) \quad \text{(ii)}$$

Here, $P(CF_l|v)$ denotes the probability to select CF_l when target predicate v is given, and estimated by using case structure analysis of large raw corpora.

$P(DCA_k, IA|CF_l)$ denotes the probability to generate direct case assignment and input arguments when a case frame is given, and estimated by using case structure analysis of large raw corpora, the frequency of a case slot example in the automatically constructed verbal case frames, and the web corpus in which the relation between a surface case marker and a case slot is manually annotated.

$P(ICA_k|ENT, CF_l, DCA_k)$ denotes the probability to generate indirect case assignment when existing discourse entities, a case frame and direct case assignments are given, and estimated by using several preferences on the relation between a zero pronoun and an antecedent, such as a lexical preference, a surface case preferences, and a locational preference.

[4]For details see (Sasano et al., 2008).

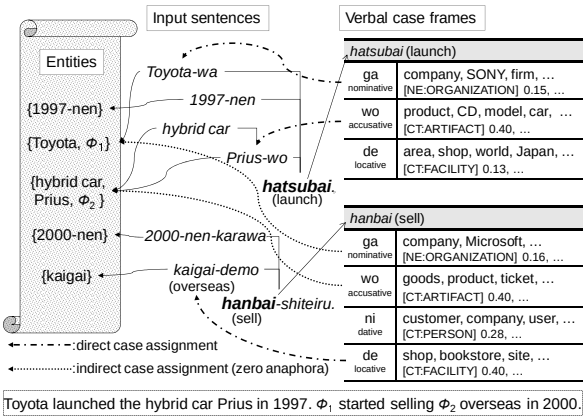

Figure 1: An example of correspondences between verbal case frames and discourse entities.

For example, the lexical preference represents how likely an entity that contains n_{j_m} as a content part is considered to be an antecedent and is estimated by the following equation.

$$\frac{P(n_{j_m}|CF_l, s_j, A'(s_j)=1)}{P(n_{j_m})} \quad \text{(iii)}$$

where, the function $A'(s_j)$ returns 1 if a case slot s_j is filled with an antecedent of a zero pronoun; otherwise 0. $P(n_j|CF_l, s_j, A'(s_j) = 1)$ is calculated by using case frames and denotes the probability of generating a content part n_j of a zero pronoun, when a case frame and a case slot are given and the case slot is filled with an antecedent of a zero pronoun.

3.2 Extension to Associative Anaphora Resolution

We then extend this probabilistic model to associative anaphora resolution. In this model, associative anaphora is regarded as a kind of zero anaphora, that is, the relation between a noun and its obligatory cases is considered to be parallel to that between a verb and its arguments. Omitted obligatory cases are considered to be zero pronouns and resolved by the same process as zero anaphora resolution.

We conduct associative anaphora resolution for only non-coreferent noun phrases. This is because most of the relationships between coreferent noun

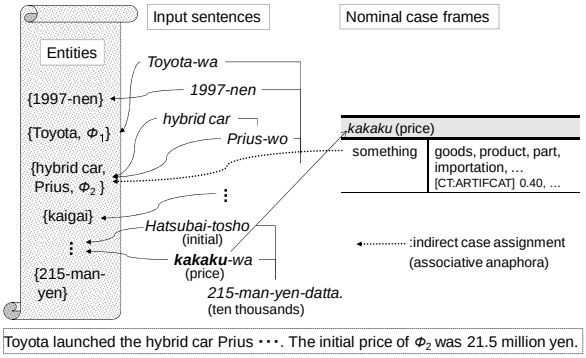

Figure 2: An example of correspondences between a nominal case frame and discourse entities.

phrases and its obligatory entities are easy to recognize by following up the coreference chains. For example, the second appearance of "the roof" in (4) means "the roof of the house," and it is easy to recognize by looking the first appearance of "the roof."

(4) I saw the roof of the house. **The roof** was painted dark green.

While verbal case frames describe both obligatory and optional cases, nominal case frames describe only obligatory cases. Therefore, we consider all case slots of nominal case frames as the target of associative anaphora resolution.

Let us consider following example:

(5) *Toyota-wa 1997-nen hybrid car Prius-wo*
year
hatsubai. 2000-nen-kara-wa kaigai-demo
launched year overseas
hanbai-shiteiru. Hatsubai tosho,
selling initial
(*φ-no*) *kakaku-wa 215-man yen-datta.*
price ten thousands

(Toyota$_1$ launched the hybrid car Prius$_2$ in 1997. ϕ_1 started selling ϕ_2 overseas in 2000. The initial price of ϕ_2 was 21.5 million yen.)

"*Kakaku*" (price) in this example has an omitted obligatory case "[something]" as shown in Table 1. Therefore, our model assumes a zero pronoun and identifies the antecedent from the existing discourse entities, such as {*Toyota*}, {*hybrid-car*, *Prius*},[5] and {*kaigai*}. Figure 2 shows an example of correspondences between the nominal case frame of "*kakaku*" (price) and discourse entities.

In addition, as well as zero anaphora resolution, we exploit generalized examples to estimate lexical preference. When one mention of an entity is tagged any category or recognized as an NE, our model also uses the category or the NE class as the content part of the entity. Specifically, for estimating Equation (iii), our model also calculates:

$$\frac{P(NE{:}ARTIFACT|kakaku(1), no, A'(no){=}1)}{P(NE{:}ARTIFACT)}$$

besides:

$$\frac{P(Prius|kakaku(1), no, A'(no) = 1)}{P(Prius)}$$

and uses the geometric mean of them.

3.3 Salience Score Filtering

Previous work has reported the usefulness of salience for anaphora resolution (Lappin and Leass, 1994; Mitkov et al., 2002). In order to consider the salience of a discourse entity, we introduce the concept of salience score, which is calculated by the following set of simple rules, and only consider the entities that have the salience score no less than 1 as candidate antecedents of an associative anaphor.

- $+2$: mentioned with topical marker "*wa*," or at the end of a sentence.
- $+1$: mentioned without topical marker "*wa*."
- $+1$: assigned to a zero pronoun.
- $\times\alpha$: beginning of each sentence.

We call α a **decay rate**. If $\alpha \geq 1$, we do not filter out any entities. If $\alpha = 0$, we only consider the entities that appears in the same sentence as candidate antecedents. For example, we consider the salience score of the discourse entity {*hybrid-car*, *Prius*} in the example (5) when using $\alpha = 0.6$. In the first sentence, since {*hybrid-car*, *Prius*} is mentioned twice, the salience score is 2.0. At the beginning of the second sentence it becomes 1.2, and after the zero anaphora resolution of "*hanbai*" it becomes 2.2. At the beginning of the third sentence it becomes 1.32.

Note that, this is an ideal case. Practically, some zero pronouns are not detected and some pronouns are assigned wrong antecedent; thus the salience score varies according to the preceding analysis. In addition, the salience score also depends on whether we resolve only associative anaphora or resolve associative anaphora simultaneously with zero anaphora. If zero pronoun resolution is not

[5] "*Hybrid car*" and "*Prius*" are in apposition and these two phrases are considered to refer to the same discourse entity.

conducted, zero pronouns that represent omitted cases of verbs are not considered.

For example, in case of {*hybrid-car*, *Prius*} with $\alpha = 0.6$, if zero anaphora resolution is not conducted, the salience score at the beginning of the third sentence becomes 0.72, because the zero anaphora resolution of "*hanbai*" is not considered; and thus {*hybrid-car*, *Prius*} is not considered as an antecedent candidate.

In order to recognize discourse structure more properly, our model basically resolves associative anaphora simultaneously with zero anaphora, and aims to consider zero pronouns that represent omitted cases of verbs.

3.4 Summary of Our model

Our model is summarized as follows:

1. Parse an input text using the Japanese parser KNP[6] and recognize NEs.

2. Resolve coreference, and link each mention to an entity or create a new entity.

3. From the end of each sentence, zero anaphora and associative anaphora resolution is conducted for each verb and non-coreferent noun by the following steps:

   (a) Select a case frame temporarily.

   (b) Consider all possible correspondences between each input argument and a case slot of the selected case frame.

   (c) Regard case slots that have no correspondence as zero pronoun candidates.

   (d) Consider all possible correspondences between zero pronoun candidates and existing entities that has a salience score no less than 1.0.

   (e) Estimate each correspondence probabilistically, and select the most likely case frame and a correspondence.

4 Experiments

4.1 Setting

We created an anaphoric relation-tagged corpus consisting of 186 web documents (979 sentences), in which all predicate-argument relations and relations between nouns were manually tagged. We show some examples:

[6] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/knp-e.html

(6) *Toyota-wa* *1997-nen* *Prius-wo* *hatsubai.*
year launch
2000-nen-kara-wa *kaigai-demo* *hanbai.*
year overseas sell
(Toyota launched Prius in 1997.
ϕ_1 started selling ϕ_2 overseas in 2000.)

TAG: *hatsubai* $\Leftarrow$ *ga*(NOM):*Toyota*, *wo*(ACC):*Prius*,
hanbai $\Leftarrow$ ***ga*(NOM):*Toyota***, ***wo*(ACC):*Prius***

For the predicate "*hatsubai*" (launch), "*Toyota*" is tagged as *ga* (nominative) case and "*Prius*" is tagged as *wo* (accusative) case. For the predicate "*hanbai*" (sell), "*Toyota*" is tagged as omitted *ga* (nominative) case and "*Prius*" is tagged as omitted *wo* (accusative) case, which are indicated in bold, and such omitted cases are the target of zero anaphora resolution.

As for relations between nouns, both overt and implicit relations are tagged with the Japanese case marker "*no*" (adnominal). In addition, relations between nouns are classified into three categories: indispensable, possible, and adjunct. Since it is not always obvious whether the relations are indispensable or not, borderline relations between indispensable and adjunct are tagged possible. We consider only the implicit relations that are tagged indispensable as the target of associative anaphora resolution.

(7) *Ken-wa* *imouto-to* *yatte-kita.*
sister came.
(Ken came with ϕ's sister.)

TAG: *imouto* $\Leftarrow$ ***no*(ADN):*Ken*** **(indispensable)**

(8) *Kôen-ni* *ikuto* *benchi-ga* *atta.*
park went bench was
(I went to the park. There was a bench in ϕ.)

TAG: *benchi* $\Leftarrow$ *no*(ADN):*kôen* (possible)

We used 62 documents for testing and used the other 124 documents for calculating several probabilities. In the 62 test documents, 110 associative anaphoric relations were tagged. Each parameter for the proposed model was estimated using maximum likelihood from raw corpora, the tagged corpus, and case frames. As verbal case frames, we used the case frames constructed from the Web corpus comprising 1.6 billion sentences (Sasano et al., 2009).

In order to concentrate on associative anaphora resolution, we used the correct morphemes, named entities, syntactic structures, and coreference re-

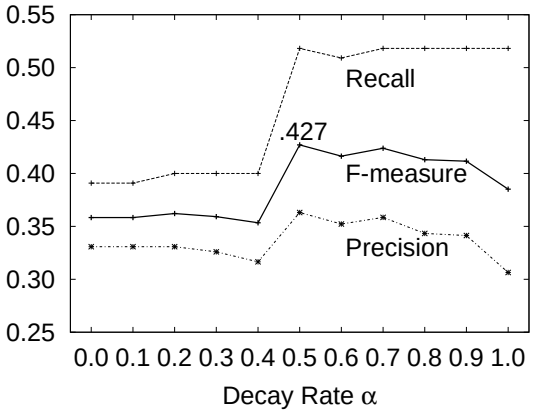

Figure 3: Experimental results of associative anaphora resolution on several salience decay rates α.

lations that were annotated by hand. Since correct coreference relations were given, the number of created entities was the same between the gold standard data and the system output because zero anaphora and associative anaphora resolution did not create new entities.

4.2 Results

Figure 3 shows the experimental results of associative anaphora resolution, in which we used generalized examples, resolved zero anaphora automatically, and varied the decay rate α introduced in Section 3.3 from 0 to 1. When we used the decay rates smaller than 0.5, the recall score worsened clearly. On the other hand, although we expected to obtain higher precision with small decay rate, the highest precision was achieved by the decay rate 0.5. Consequently, we obtained the highest F-measure of 0.427 with the decay rate 0.5. In the following experiments, we fixed the decay rate 0.5.

We utilized two baseline models for demonstrating the effectiveness of our approach: a random model and a salience-based model. The random model selects a case frame and its correspondence randomly from all possible case frames and correspondences. The salience-based model selects a case frame and its correspondence that assign a zero pronoun candidate the existing entity that have highest salience score. In addition, in order to confirm the effectiveness of generalized examples of NCFs, we conducted experiments without using generalized examples. Table 4 shows the experimental results. We can confirm that our proposed model outperforms two baseline models. Without using any generalized examples, the

Table 4: Experimental results of associative anaphora resolution with two baseline models and our model with/without generalized examples.

Model		Recall	Precision	F-measure
Random*		0.148 (16.3/110)	0.035 (16.3/467.5)	0.056

CT: Using examples generalized by categories.
NE: Using examples generalized by named entities.
* The average of 10 trials is shown.

F-measure was about 0.14 lower than the method using generalized examples, and we can also confirm the effectiveness of the generalized examples. While generalization of categories much improved the F-measure, generalization of NEs contributed little. This is because the NE rate was smaller than the common noun rate, and so the effect was limited. This tendency was also seen in zero anaphora resolution (Sasano et al., 2008).

In order to investigate the effects of zero anaphora resolution, we tested our model under three conditions: without zero anaphora resolution (no resolution), with zero anaphora resolution (automatically resolved), and with using correct zero anaphora relations that are manually tagged (manually identified). The performance of automatic zero anaphora resolution resulted in a recall of 0.353, a precision of 0.375, and an F-measure of 0.364. Table 5 shows the experimental results. To resolve associative anaphora simultaneously with zero anaphora improved F-measure by 0.072; using correct zero anaphora relations improved F-measure by 0.103. We can confirm that the performance of associative anaphora resolution is improved by considering zero anaphora.

Note that, strictly speaking, these comparisons are not fair because we set the decay rate α to maximize the performance when using generalized examples and resolving zero anaphora automatically. However, these tendencies described above were also seen with other decay rates.

Table 5: The effects of zero anaphora resolution.

Zero anaphora	Recall	Precision	F-measure
No resolution	0.373 (41/110)	0.339 (41/121)	0.355
Automatically resolved	0.518 (57/110)	0.363 (57/157)	0.427
Manually identified	0.573 (63/110)	0.382 (63/165)	0.458

Table 6: Causes of false negatives.

Causes	Num	
Filtered by salience score	22	(15)
Judge as non-anaphoric	13	(14)
Select false antecedents	13	(13)
Case frame sparseness	5	(5)
Total	53	(47)

*"()" denotes the number of causes when using correct zero anaphora tags.

4.3 Discussion

By using generalized examples and resolving simultaneously with zero anaphora, our model achieved a recall of 0.518 (57/110), but there were still 53 associative anaphoric relations that were not recognized. Table 6 shows the causes of them.

22 false negatives were caused by salience score filtering. Note that, it does not mean that these 22 associative anaphoric relations were always recognized correctly if the correct antecedents were not filtered by salience score.

Case frame sparseness caused only 5 false negatives. Considering that the recall of nominal case frames was 74% as shown in Table 3, this seems to be too few. This is because we do not considered the relations that tagged possible, and only considered obviously indispensable relations. From this result, we can say that coverage of nominal case frames for nouns that have obviously indispensable entities is much higher than 74%, which is considered to achieve a coverage of about 95% (105/110).

4.4 Comparison with previous work

Murata et al. (1999) proposed a method of utilizing "N_m *no* N_h" phrases for associative anaphora resolution.[7] They basically used all "N_m *no* N_h" phrases from corpora as a lexical knowledge, and used rule-based approach. They obtained a recall of 0.63 and a precision of 0.68 by using examples of "*X no Y*" (Y of X), a recall of 0.71 and a precision of 0.82 by assuming ideal nominal case frames. One reason of such high performance may be that they considered referential properties of noun phrases, such as generic, indefinite, and definite, while our model does not. We can also say that their experiments were conducted on small and supposedly easy corpora. Half of their corpora were occupied by fairy tale, against which domain specific rules are considered to be effective.

We proposed a rule-based approach for associative anaphora resolution based on automatically acquired nominal case frames (Sasano et al., 2004).[7] We obtained a recall of 0.633 and a precision of 0.508 against news paper articles. However, we regarded some additional relations that can be interpreted by considering coreference relations as associative anaphoric relations.

(9) *Chechen Kyôwakoku-no* ***shuto****-ni ...*
Chechen Republic capital

... ***shuto*** *seiatsu-no saishu dankai-ni ...*
capital conquer last stage

(... to **the capital** of Chechen Republic ... in the last stage to conquer **the capital** ...)

For example, although the second mention of "*shuto*" (capital) in example (9) means "*Chechen Kyôwakoku-no shuto*" (the capital of Chechen Republic), it can be interpreted by recognizing the coreference relation between the first and second mentions of "*shuto*" (capital). Therefore, as mentioned in Section 3.2, we do not consider such relations as associative anaphora in this study; we included such relations as associative anaphora in (Sasano et al., 2004). The relatively high score is caused by this criterion.

5 Conclusion

In this paper, we proposed a probabilistic model for associative anaphora resolution. Our model regards associative anaphora as a kind of zero anaphora and resolves it in the same manner as zero anaphora resolution that uses automatically acquired case frames. We also showed that the performance of associative anaphora resolution can be improved by resolving it simultaneously with zero anaphora. As future work, we plan to consider referential properties of noun phrases in associative anaphora resolution.

[7] Murata et al. (1999) and we (Sasano et al., 2004) used the terminology *indirect anaphora*, but concerned with the same phenomena as we concerned with in this paper.

Abstract

It is well known that pragmatic knowledge is useful and necessary in many difficult language processing tasks, but because this knowledge is difficult to acquire and process automatically, it is rarely used. We present an open information extraction technique for automatically extracting a particular kind of pragmatic knowledge from text, and we show how to integrate the knowledge into a Markov Logic Network model for quantifier scope disambiguation. Our model improves quantifier scope judgments in experiments.

1 Introduction

It has long been a goal of the natural language processing (NLP) community to be able to interpret language utterances into logical representations of their meaning. Quantifier scope ambiguity has been recognized as one particularly challenging aspect of this problem. For example, the following sentence has two possible readings, depending on the scope of its quantifiers:

Every boy wants a dog.

One reading of this sentence is that there exists a single dog in the world which all boys want. The second, and usually preferred, reading is that the sentence is describing a separate "wanting" relation for each boy, and that the dog in question is a function of the boy who wants it. In this reading, there may be as many different dogs as boys, although it leaves open the possibility that several of the boys want the same dog. In logic, these two readings can be represented as follows:

1. $\exists_{d \in Dogs} \ \forall_{b \in Boys}$ wants(b, d)
2. $\forall_{b \in Boys} \ \exists_{d \in Dogs}$ wants(b, d)

The readings differ only in the order of the quantifiers. The quantifier that comes first in each expression is said to have *wide scope*; the second quantifier has *narrow scope*.

Linguists and NLP researchers have come up with several theories and mechanisms for automatically determining the scope of quantified linguistic expressions. Despite a long history of proposed solutions, however, researchers have for the most part abandoned this task as hopeless because of "overwhelming evidence suggesting that quantifier scope is a phenomenon that must be treated at the pragmatic level" (Saba and Corriveau, 2001). For example, in active voice clauses, the quantifier for the subject noun is usually preferred for wide scope over the quantifier of the predicate noun (Kurtzman and MacDonald, 1993). But such preferences can easily be overruled by world knowledge:

A doctor lives in every city.

1. $\exists_{d \in Docs} \ \forall_{c \in Cities}$ lives in(d, c)
   (A single doctor lives in all cities.)
2. $\forall_{c \in Cities} \ \exists_{d \in Docs}$ lives in(d, c)
   (Each city has a different doctor living there.)

Syntactic preferences would normally indicate that reading 1 is better, but in this particular case common-sense knowledge of the world overrules that preference and makes reading 2 far more probable.

Open-domain pragmatic knowledge is usually not available to language processing systems, but that is beginning to change. Recent research in open information extraction (Banko and Etzioni, 2008; Davidov and Rappaport, 2008) has shown that we can extract large amounts of relational data from open-domain text with high accuracy. Here, we show how we can connect the two fields, by extracting a targeted form of pragmatic knowledge for use in quantifier scope disambiguation. Our contributions are:

1) We build an extraction mechanism for extracting pragmatic knowledge about relations. In par-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1465–1474,
Singapore, 6-7 August 2009.

ticular, we extract knowledge about the expected sizes of the sets of objects that participate in the relations. The task of identifying functional relationships is a subtask of our extraction problem that has received recent attention in the literature (Ritter et al., 2008).
2) We devise a novel probabilistic model in the Markov Logic Network framework for reasoning over possible readings of sentences that involve quantifier scope ambiguities. The model is able to assign a probability that a particular reading is plausible, given the pragmatic knowledge we extract.
3) We provide an empirical demonstration that our system is able to resolve quantifier scope ambiguities in cases where the syntactic and lexical features used by previous systems are of no help.

The remainder of this paper is organized as follows. The next section describes previous work. Section 3 shows how the problem can be formulated as a task of assigning probabilities to possible worlds, and that the crucial difference between them has to do with the number of objects participating in individual relationships. Section 4 discusses our techniques for extracting the pragmatic knowledge that allows us to make judgments about quantifier scope. Section 5 presents our probabilistic model for resolving scope ambiguities. We present an empirical study in section 6, and section 7 concludes and suggests items for future work.

2 Related Work

Quantifier scope disambiguation has received attention in linguistics and computational linguistics since at least the 1970s. Montague (1973) gave a seminal treatment of quantifier ambiguities, and argued that a particular syntax-based mechanism known as "quantifying-in" could resolve scope ambiguities. Since then, most work on disambiguation has focused on syntactic clues for determining which readings of an ambiguous statement are possible, and of the set of possible readings, which ones are preferred (Van Lehn, 1978; Hobbs and Shieber, 1987; Poesio, 1993a; Hurum, 1988; Moran, 1988). For instance, one linguistic study (Kurtzman and MacDonald, 1993) determined that in active voice sentences where quantifiers in the subject and object give rise to scope ambiguity, there is a preference for the reading in which the subject quantifier has wide scope — the direct reading is acceptable 70-80% of the time, whereas the indirect reading is acceptable 30-40% of the time. Sentences that are similar in all respects except that they are passive voice have no such preference. Nevertheless, in these studies both readings are often quite plausible. In addition to syntactic clues, other studies have noted that the choice of quantifier has a significant effect on scope disambiguation (*e.g.*, "each" has a greater tendency for wide scope than "every") (Van Lehn, 1978; Alshawi, 1990). Most authors have noted that both syntactic and lexical evidence fall short of a full solution, and that pragmatic knowledge (knowledge about the world) is necessary for this task (Van Lehn, 1978; Saba and Corriveau, 1997; Moran, 1988). Saba and Corriveau (2001) recently proposed a test for quantifier scope disambiguation using pragmatic knowledge. However, they do not show how to extract the necessary information, nor do they implement or evaluate their proposed test.

Due to the difficulty of the problem, several authors have devised techniques for "underspecified" logical representations that can efficiently store multiple ambiguous readings, and they devise techniques for automated reasoning using underspecified representations (Reyle, 1995; Latecki, 1992; Poesio, 1993b). Others (Hobbs and Shieber, 1987; Park, 1988) have devised computational mechanisms for generating all of the possible readings of statements exhibiting quantifier ambiguity, especially in cases involving more than two quantifiers.

Detecting functions in extracted relational data has been studied in several contexts. Ritter *et al.*(2008) use knowledge of functions to determine when two extracted relationships contradict one another. Knowledge of functions has also been important in finding synonyms (Yates and Etzioni, 2009) and in review mining (Popescu, 2007). We extend this work by extracting not just a binary determination of whether a relation is functional, but a distribution over the expected number of arguments for that relation. Our technique also differs from previous work based on extracted relationships between named entities. We leverage domain-independent extraction patterns involving numeric phrases, as discussed below; our technique is complementary to existing approaches and could in fact be combined with them for even greater accuracy. Finally, we apply the extracted knowledge in a novel way to quantifier scope disambiguation.

Our work is similar in spirit to several recent

projects that use semantic reasoning over extracted knowledge for a novel approach to well-known tasks. For example, Schoenmackers *et al.*(2008) have recently used extracted knowledge for the task of predicting whether a new extracted fact is correct. Yates *et al.*(2006) use extracted knowledge to determine whether a parse of a sentence has a plausible semantic interpretation. We extend this new line of attack to a hard problem in language understanding.

3 Possible Worlds Framework

We now present a framework for reasoning about quantifier scope ambiguities, and for choosing among possible readings based on pragmatic knowledge (or world knowledge — we use the terms interchangeably). We first present a formal description of the quantifier scope disambiguation (QSD) problem. We then describe the crucial differences between the "possible worlds" evoked by different readings of an ambiguous statement.

3.1 Representation of Readings

We follow Copestake *et al.* (2005), among others, in representing quantifiers as modal operators with three arguments: a variable name for the variable being quantified; a logical formula, called the *restriction*, which defines the set of objects over which the variable may range; and a second logical formula, called the *body*, which defines the expression in which the quantified variable takes part. For example, we represent the sentence "Every dog barks" as: $\texttt{every}(x, \texttt{dog}(x), \texttt{barks}(x))$.

For the sake of clarity and convenience, we restrict our attention to a common syntactic form of sentences, where the semantic representation is relatively well-understood: active-voice English sentences in which the subject noun phrase is quantified, and a noun phrase in the predicate (either an object of the verb, or an object of a preposition attached to the verb) is also quantified. For a sentence with the following structure, in which p_i and q_j represent predicates introduced by modifiers like adjectives and prepositional phrases,

$$(_S\ (_{NP}\ (_{DET}\ Q_1)(_{\overline{N}}\ [p_1, \ldots, p_n]C_1))\\ (_{VP}\ (_V\ R)(_{NP}\ (_{DET}\ Q_2)(_{\overline{N}}\ [q_1, \ldots, q_m]C_2))$$

we can represent the two possible readings of the sentence as:

direct reading:

$$Q_1(x, C_1(x) \wedge p_1(x) \wedge \ldots \wedge p_n(x), \\ Q_2(y, C_2(y) \wedge q_1(y) \wedge \ldots \wedge q_m(y), \\ R(x, y))) \quad (1)$$

indirect reading:

$$Q_2(y, C_2(y) \wedge q_1(y) \wedge \ldots \wedge q_m(y), \\ Q_1(x, C_1(x) \wedge p_1(x) \wedge \ldots \wedge p_n(x), \\ R(x, y))) \quad (2)$$

By making the restriction to this type of sentences, we can isolate the effects of pragmatics on scope disambiguation decisions from the effects of syntax, since all test cases have essentially the same syntax. As we show below, for certain types of relations, the preference for interpretations may be drastically different from the general preference for the direct reading, even though the syntax of the sentences we investigate matches the syntax studied by Kurtzman and MacDonald (1993).

3.2 Readings, Possible Worlds, and World Knowledge

The different logical forms for the direct and indirect readings describe different "possible worlds." For instance, the direct reading of "A doctor lives in every city" describes worlds in which there is a single doctor who manages to reside in each city of the world simultaneously. This reading is "possible" in the sense that it does not contradict itself. In logical terms, if ϕ represents the direct reading of this sentence, $\phi \nvdash \bot$. Using some imagination one could devise a scenario, perhaps in an online game world, that satisfies ϕ.

Nevertheless, the indirect reading is strongly preferred for this statement in the absence of any context that indicates an abnormal world. The indirect reading ϕ' describes worlds where every city is inhabited by some doctor, but potentially a different doctor per city. Using pragmatic knowledge, the reader can easily deduce that this logical statement is a much more likely reading than ϕ. Let B represent the reader's pragmatic knowledge, including facts like "People don't simultaneously live in more than one city," and, "There are at least hundreds of cities in the world." The reader can easily deduce that $B \models \neg\phi$. We now turn to methods for extracting the necessary pragmatic knowledge B from text.

4 Extraction Techniques to Support QSD Decisions

Saba and Corriveau (2001) point out that there is a restricted form of pragmatic knowledge that can be used in many instances of QSD. Consider the facts that were used above to determine that ϕ' is preferable to ϕ. The facts fall into two basic categories of knowledge: 1) the size of class C (*e.g.*, how many cities are there?), and 2) the expected number of Y participants in a relationship R, given that there is exactly 1 X participant (*e.g.*, how many cities does 1 doctor live in?). In both cases, we are concerned with extracting sizes of sets.

Previous extraction systems have attempted to estimate set sizes based on extracted named entities. Downey *et al.* (2005)estimate the size of classes based on the number of named-entities extracted for the class. As far as we are aware, finding the expected size of an argument set for a relation is a novel task for information extraction, but several researchers (Ritter et al., 2008; Yates and Etzioni, 2009) have investigated the special case of detecting functional relations — those relations where the expected size of the Y argument set is precisely 1. As with class size extraction, they use extractions involving named-entity arguments to find functional relations.

Approaches that depend on named-entity extractions have several disadvantages: they must find a large set of named-entities for every set, which can be time-consuming and difficult. Also, many classes, like "trees" and "hot dogs," have no or very few named instances, but many un-named instances, so approaches based on named entities have little hope. In fact, besides classes like people, locations, and organizations (and their subclasses), there are few classes that have a large number of named instances. For classes that do have named instances, synonymy, polysemy, and extraction errors are common problems that can all affect estimates of size (Ritter et al., 2008).

Rather than indirectly determining set sizes from extracted instances, our system directly extracts estimates of set sizes. It uses *numeric phrases*, like "two trees," "hundreds of students," or "billions of stars," to associate numeric values with sets. Table 1 lists the numeric phrases we use. Currently, we use only numeric phrases with explicit values or ranges of values, but it may be possible to increase the recall of our extraction technique by incorporating more approximate phrases like "several," "many," or even bare plurals. We do not match numbers expressed in digits (*e.g.*, 1234) because we found that they produced too many noisy extractions, such as dates and times. For words like "hundreds," we set the value of the word to be the lower limit (*i.e.*, 100). This gives a conservative estimate of the value, but our techniques described below can help to compensate for this bias.

Numeric Phrase	Value
no | none | zero	0
a | one | this | the	1
two	2
⋮	⋮
one hundred | a hundred	100
⋮	⋮
hundreds of	100
thousands of	1,000
tens of thousands of	10,000
⋮	⋮

Table 1: **Numeric phrases used in our extraction patterns.** For the word "the", we require that it be followed directly by a singular noun, to try to weed out plural usages.

Table 2 lists examples of the hand-crafted, domain-independent extraction patterns we use. Our extraction patterns generate two types of extractions, one for classes and one for relations. For classes, each extraction E consists of a class name E_c and a number E_n indicating the size of some subset $S \subseteq E_c$. For instance, the 4gram "hundreds of students are" matches our first pattern. The numeric phrase "hundreds of" here indicates that some subset $S \subseteq E_c =$ students has a size in the hundreds. After processing a large corpus, our system can determine a probability distribution for the size of a class given by:

$$P_C\left(\texttt{size}(C) = N\right) = \frac{|\{E \mid E_c = C \wedge E_n = N\}|}{|\{E \mid E_c = C\}|}$$

In practice, we only include the largest 20% of the numbers N in the set of extractions for a class to estimate that class's size.

The second type of extraction we get from our patterns are relational extractions. Each relational extraction F consists of a relation name F_r, and possibly names for the classes of its two arguments, F_{c1}, F_{c2}. In addition, the extraction contains values for the size of both arguments, F_{n1}

Pattern	Extraction
<numeric> <word>+ (`of` | `are` | `have`)	$E_c =$ <word>+, $E_n = value($<numeric>$)$
(`I` | `he` | `she`) <word>+ <numeric> <noun>	$F_r =$ <word>+, $F_{c1} =$ people, $F_{c2} =$ <noun>, $F_{n1} = 1, F_{n2} = value($<numeric>$)$
`it is` *pastParticiple*(<verb>) `by` <numeric>	$F_r =$ <verb>, $F_{c2} =$ thing, $F_{n1} = value($<numeric>$), F_{n2} = 1$
`is the` <word> `of` <numeric>	$F_r =$ `is the` <word> `of`, $F_{n1} = 1, F_{n2} = value($<numeric>$)$

Table 2: **Sample extraction patterns for discovering classes (E_c) and their sizes (E_n), or relations (F_r) and the expected set size of their arguments (F_{n1} and F_{n2}).**

and F_{n2} respectively. For example, the fragment "she visited four countries" matches the second pattern in Table 2, with $F_r =$ visited, $F_{n1} = 1$, and $F_{n2} = 4$. Note that in our extraction patterns, one of of the arguments is always constrained to be a singleton set, like "he" or "it." This restriction allows us to avoid quantifier scope ambiguity in the extraction process: if we extracted phrases like "Two men married two women," it would be unclear which quantifier has wide scope, and therefore how many men and women are participating in each "married" relationship. By using singular pronouns, we avoid this confusion; in almost all cases, these pronouns have wide scope, and indicate a single element.[1]

Based on these extractions, our system determines two distributions for each relation: $P_R^{Left}(n)$ and $P_R^{Right}(n)$. The P_R^{Left} distribution represents the probability that the left argument of R is a set of size n, given that the right argument is a singleton set, and likewise for P_R^{Right}. We determine the distributions from the extractions by maximum likelihood estimation:

$$P_R^{Left}(n) = \frac{|\{F \mid F_r = R, F_{n1} = n, F_{n2} = 1\}|}{|\{F \mid F_r = R, F_{n2} = 1\}|}$$

$$P_R^{Right}(n) = \frac{|\{F \mid F_r = R, F_{n2} = n, F_{n1} = 1\}|}{|\{F \mid F_r = R, F_{n1} = 1\}|}$$

For example, for the relation `is the father of`, we might see the fragment "he is the father of two children" far more often than "he is the father of twenty children." $P^{Right}_{\texttt{is the father of}}$ would therefore have a relatively low probability for $n = 20$. As one would expect, the relation `visited` appears more often with "twenty," and the relation `married` never does. Their P^{Right} distributions are comparatively higher and lower, respectively than the one for `is the father of` at $n = 20$.

In practice, we create histograms of the extracted counts for both our E and F extractions, and our probability distributions are really distributions over the buckets in these histograms, rather than over all possible set sizes. To help combat sparse counts for large numeric values, we use buckets of exponentially increasing width for larger numeric values. Thus between $n = 0$ and 10, buckets have size 1, between 10 and 100 they have size 10, and so on.

We also create distributions in the same way for relations together with their extracted argument classes. Since counts for these extractions tend to be much more sparse, we interpolate these distributions with the distribution for just the relation, and with the distribution for the relation and just one class. We use equal weights for all interpolated distributions.

5 A Probabilistic Model for Quantifier Scope Disambiguation

QSD requires reasoning about different possible states of the world. This involves logical reasoning, since the direct and indirect readings differ in the number of objects that exist in models satisfying each reading, and the number of relationships between those objects. QSD also involves probabilistic reasoning, since none of the extracted knowledge is certain. We leverage recent work on Markov Logic Networks (MLNs) (Richardson and Domingos, 2006) to incorporate both types of reasoning into our technique for QSD. We next briefly review MLNs, before describing our model and

[1] An example of an exception to this rule from our data set is the sentence "It is worn by millions of women." Here, "it" refers to a class of items such as a brand, and thus may refer to a different item for each of the "millions of women."

methods for training it.

5.1 Markov Logic Networks

Syntactically, an MLN consists of a set of first-order logical formulas $\mathbf{F}$ and a real-valued weight w_F for each $F \in \mathbf{F}$. Semantically, an MLN defines a probability distribution over possible *groundings* of the logical formulas. That is, if U denotes the set of all objects in the universe, and $\mathbf{G}$ denotes the set of all possible ways to ground every $F \in \mathbf{F}$ (*i.e.*, substitute an element from U for every variable in F), then an MLN defines a distribution over truth assignments to the grounded formulas $G \in \mathbf{G}$. Let $\mathcal{I}$ denote the set of all possible interpretations of $\mathbf{G}$ — that is, each $I \in \mathcal{I}$ assigns `true` or `false` to every $G \in \mathbf{G}$. The probability of a particular interpretation I according to the MLN is given by :

$$P(I) = \frac{1}{Z} \exp\left(\sum_{F \in \mathbf{F}} w_F \cdot n(F, I)\right)$$

$$Z = \sum_{I \in \mathcal{I}} \exp\left(\sum_{F \in \mathbf{F}} w_F \cdot n(F, I)\right)$$

where $n(F, I)$ gives the number of groundings of F that are true in interpretation I.

The equation above provides an expression for $P(I)$ when U, or at least the size of U, is known and fixed. When we are interpreting expressions like "every city" or "every doctor", however, we require extracted knowledge to inform the system of the correct number of "city" or "doctor" objects. Since our extractions are uncertain, they provide a distribution $P(|U| = n)$ for the size of a class. Using $P(|U|)$, we can still calculate $P(I)$, even without knowing the exact size of U:

$$P(I) = \sum_n P(|U| = n) P(I \mid |U| = n)$$

5.2 MLN Classifier for QSD

Let Q be a QSD problem, consisting of a relation Q_r, a class for the first argument of the relation Q_{c1}, a class for the second argument Q_{c2}, and quantifiiers Q_{q1}, Q_{q2} for each argument. We construct an MLN model for Q using the following logical formulas:

1) *Clustering:* We allow members of each class to belong to clusters denoted by γ, but each element can belong to no more than one cluster. This is represented by the following formula, which has infinite weight.

$$\forall_{x \in Q_{c1} \cup Q_{c2}, \gamma, \gamma'} x \in \gamma \wedge x \in \gamma' \Rightarrow \gamma = \gamma'$$

2) *Relation between clusters:* Every cluster of class 1 elements must participate in the relation Q_r with exactly one cluster of class 2 elements, and *vice versa*. We represent this participation in Q_r with a series of logical relations $R_{m,n}$, each of which indicates that a cluster of size m is participating in Q_r with a cluster of size n. We use a set of formulas for each setting of m and n, each having infinite weight.

$$\forall_{\gamma \subset Q_{c1}} \exists!_{\gamma' \subset Q_{c2}, m, n} \; R_{m,n}(\gamma, \gamma')$$
$$\forall_{\gamma' \subset Q_{c2}} \exists!_{\gamma \subset Q_{c1}, m, n} \; R_{m,n}(\gamma, \gamma')$$
$$\forall_{\gamma, \gamma'} \; R_{m,n}(\gamma, \gamma') \Rightarrow |\gamma| = m \wedge |\gamma'| = n$$

3) *Prefer relations between clusters of the appropriate size:* We include a set of formulas with finite weight that express the preference for a particular relation to have arguments of a certain size. There is a separate formula for each setting of m and n, with a separate weight $w_{m,n}$ for each.

$$\forall_{\gamma, \gamma'} R_{m,n}(\gamma, \gamma')$$

This formula does most of the work of our classifier. For a given relation, such as the `lives in(Person, City)` relation, we can set the weights $w_{m,n}$ so that the model prefers worlds where each person lives in just one place. For instance, we can set the weight $w_{1,1}$ relatively high, so that the model is more likely to make clusters of size 1, which then participate in the $R_{1,1}$ relation.

We describe how we choose the $w_{m,n}$ weights below, but first we explain how to incorporate the quantifiers Q_{q1} and Q_{q2} into the model. Unfortunately, every natural language quantifier has different semantics (Barwise and Cooper, 1981), and thus they affect our model in different ways. Here, we restrict our attention to the two common quantifiers "a" and "every", but note that the MLN framework is a powerful tool for incorporating the logical semantics and statistical preferences of other quantifiers.

For the quantifier "a", we require that the relation have no argument clusters with size more than 1 for that class. Thus if Q_{q1} = "a", we restrict $R_{m,n}$ to $R_{1,n}$, and *vice versa* if Q_{q2} = "a." Furthermore, we require that at least one element of the class belong to a cluster: $\exists_{x,\gamma} x \in \gamma$ has infinite weight. For "every," we require that every element of the class that "every" modifies to be part

of some cluster. To effect this change, we simply put an infinite weight on the formula $\forall_x \exists_\gamma x \in \gamma$.

Our MLN model is general in the sense that for any QSD problem Q, it can determine probabilities for any possible world corresponding to a reading of Q. For our purposes, we are primarily interested in the direct and indirect readings of any Q involving "a" and "every." To predict the correct reading for a given Q, we simply check to see which has the higher probability according to our MLN model.

5.3 Parameter Estimation

Our MLN model for QSD requires settings for the $w_{m,n}$ parameters for each QSD problem Q. The standard approach to this problem would be to estimate these parameters from labeled training data. We reject the standard supervised framework, however, because each distinct relation Q_r requires different settings of the parameters, and therefore a standard supervised approach would require manually labeled training data for every relation Q_r.

A second approach that is made possible by our extraction technique is to set the parameters using the extracted distributions. We tried this approach by setting $w_{1,n} = \log P_{Q_r}^{Right}(n)$ and $w_{m,1} = \log P_{Q_r}^{Left}(m)$; since we only consider sentences containing the quantifier "a", one of m and n will always be 1. Unfortunately, in our experiments we found that this setting for the parameters often gave far too little weight for large values of m and n, and as a consequence, the classifier would systematically judge one reading to be more likely than another.

To counteract this problem, we take a hybrid approach to parameter estimation, informed by both labeled training data and the extracted distributions. Crucially, our approach, which we call ZIPF FLATTENING, has only two parameters that need to be trained using a supervised approach, and these parameters do not depend on the relation R. Thus, the approach minimizes the amount of training data we need to a practical level.

ZIPF FLATTENING works by correcting the P_R distributions to give higher weight to larger values of m and n. First, we estimate a Zipf distribution from the raw extracted counts for each argument of relation R. To fit a Zipf curve, we use least-squares linear regression on the log-log plot of the extracted counts to find parameters z_R and c_R such that

$$\begin{aligned} \log(count) &= z_R \cdot \log(argSize) + c_R \\ \Rightarrow count &= e^{c_R} \cdot argSize^{z_R} \end{aligned}$$

We can perform this part automatically, using only the extraction data and no manually labeled training data, for every relation. However, the fitted Zipf distribution needs to be corrected for the systematic bias in the extracted counts. To do this, we introduce two parameters, α_1 and α_2, that we use to scale back the sharp falloff in the Zipf distribution. Our *flattened* distribution has the form:

$$count = e^{\alpha_1 c_R} \cdot argSize^{\alpha_2 z_R}$$

When α_2 is less than 1, the resulting curve has a less steep slope, and greater weight is placed on the large values of m and n, as desired. Our last step is to interpolate the P_R^{Right} and P_R^{Left} distributions with the flattened Zipf distribution to come up with corrected distributions for the right and left argument sizes of R. We use equal weights on the two distributions to interpolate. Note that if the original counts from the extraction system include counts for only one argument size, then it is impossible to estimate a Zipf distribution, and we simply fall back on the extracted distribution. We do not include counts for an argument size of zero in this process.

To estimate the parameters α_i, we collect a training set of QSD problems Q, labeled with the correct reading for each (direct or indirect), and run the extractor for the relations Q_r appearing in the training set. We then perform a gradient descent search to find optimal settings for the α_i on the training data.

6 Experiments

We report on two sets of experiments. The first tests our extraction technique on its own, and the second tests the accuracy of our complete QSD system, including the extraction mechanisms and the prediction model, on a quantifier scope disambiguation task.

6.1 Function Detection Experiment

Function detection is an important task in its own right, and has been used in several previous applications (Ritter et al., 2008; Yates and Etzioni, 2009; Popescu, 2007). To turn our extraction system into a classifier for functions vs. non-functions, we simply checked whether there were

	Num	Precision	Recall	F1
Functions	54	.79	.76	.77
Non-functions	74	.83	.85	.84

Table 3: **Precision and recall for detecting functions using the numeric extraction technique.**

any extractions for R with $F_{n2} > 1$. If so, we predicted that the R was nonfunctional, and otherwise we predicted it was functional.

We used the Web1Tgram Corpus of n-grams provided by Google, Inc to extract classes, relations, and counts. This corpus contains counts for 2- through 5-grams that appear on the Web pages indexed by Google. Counts are included in this data set for all n-grams that appeared at least 40 times in their text. We ran our extraction techniques on the 3-, 4- and 5-grams. To create a test set, we sampled a set of 200 relations from our extractions, removed any relations that consisted of punctuations, stopwords, or other non-relational items. We then manually labeled the remainder as functions or non-functions.

Table 3 shows our results. A baseline system that simply predicts the majority class (non-functions) on this data set would achieve an accuracy of 56%, well below the 81% accuracy of our classifier. Many of the relations in our test set, like `built(Person, House)` and `is riding(Person,Animal)`, do not ordinarily have named-entity extractions for both arguments, and would therefore not be amenable to previous function detection approaches.

Some of our technique's errors highlight interesting difficulties with function detection. For instance, while we labeled the `is capital of` relation as a function, our technique predicted that it was not. It turns out that the country of Bolivia has two capitals, and the South Asian region of Jammu and Kashmir also has two capitals. Both of these facts are prominent enough on the Web to cause our system to detect a small probability for $P^{Right}_{capital\ of}(2)$. Thus any label for this relation is somewhat unsatisfying: it is almost entirely functional, but not strictly so. By generalizing the problem to one of determining a distribution for the size of the argument, we can handle these border cases in a useful way for QSD, as discussed below.

6.2 Preliminary QSD Experiments

We test our complete QSD system on two important tasks. In the first, the system is presented with a series of QSD problems Q in which the first quantifier Q_{q1} is always "a," and the second (Q_{q2}) is always "every." Each example is manually labeled to indicate whether a direct or indirect reading of the sentence is preferred, and the system is charged with predicting the preferred reading. In the second task, each Q has "every" as the first quantifier, and "a" as the second quantifier. Since indirect readings are very rarely preferred for active-voice sentences of this form,we charge the system with making a different type of prediction: determine whether the indirect reading is plausible or not. The system assumes that every sentence has a plausible direct reading, but by determining whether the indirect reading is plausible, it can determine whether the sentence is ambiguous between the two readings.

We created data sets for these tasks by sampling our 5grams for examples containing the relations in our function experiment. From this set, we selected phrases that involved named classes for the arguments to the relation. When a class was missing, we either manually supplied one, or discarded the example. We then constructed two examples from each combination of relation and argument classes: one example in which the first argument is constrained by the quantifier "a" and the second by "every," and a second example in which the quantifiers are reversed. Finally, we manually labeled every example with a preference for direct or indirect reading (in the case of "a/every" examples) or with a plausibility judgment for the indirect reading (in the case of "every/a" examples). Our final test sets included 46 labeled examples for each task. Further experiments involving multiple annotators, as in the experiments of Kurtzman and MacDonald (1993), are of course desirable, but note that even their experiments included just 32 labeled examples.

Table 4 shows our results for the first QSD task, and Table 5 shows our results for the second one. In each case, we compare our supervised Corrected MLN model against an Uncorrected MLN model that uses no supervised data, and simply takes its weights straight from our extracted distributions. The supervised model uses a training corpus of 10 manually labeled examples for each task, five from each class. We also compare against a majority class baseline. Note that the Corrected

System	Acc.	Direct P	Direct R	Indirect P	Indirect R
All-Direct BL	.53	.53	1.0	0.0	0.0
Uncorrected MLN	.58	.78	.30	.53	.90
Corrected MLN	**.74**	.77	.74	.71	.75

Table 4: **Our trained MLN outperforms two other systems at predicting whether sentences of the form "A/some <class 1> <relation> every <class 2>" should have direct or indirect readings.** We measure accuracy over the whole dataset, as well as precision and recall for the two subsets labeled with direct and indirect readings, respectively.

System	Acc.	Plausible P	Plausible R	Implaus. P	Implaus. R
All-Plausible BL	.67	.67	1.0	0.0	0.0
Uncorrected MLN	.49	.89	.28	.38	.93
Corrected MLN	**.72**	.76	.86	.60	.43

Table 5: **Our trained MLN outperforms two other systems at predicting whether sentences of the form "Every <class 1> <relation> a/some <class 2>" have a plausible indirect reading or not.** We measure accuracy over the whole dataset, as well as precision and recall for the two subsets labeled with plausible and implausible indirect readings.

MLN model has balanced recall numbers for the two classes in both of our tasks, compared with the Uncorrected MLN. This indicates that our ZIPF FLATTENING technique is accurately learning better weights to remove the systematic bias in the Uncorrected MLN.

Our results demonstrate the utility of our extracted distributions for these difficult tasks. Although the extracted data prevents us from determining that `is capital of` should be classified as a function, since almost all of the probability mass in P^{Right} is still on $n \in \{0, 1\}$. Thus, the probability for the direct reading of a sentence like "Some city is the capital of every country" is still very low. Likewise, even though our system (correctly) determines that the relation `is a parent of` is non-functional, it does not therefore group it with other non-functional relations like `visited`. The distribution $P^{Right}_{\texttt{is parent of}}(n)$ is skewed to much smaller numbers for n than is the distribution for `visited`, and thus the indirect reading for "A person is the parent of every child" is much more likely than the indirect reading of "A person visited every country."

The biggest hurdle for better performance is noise in our extraction technique. Polysemous relations sometimes have large counts for large argument sizes in one sense, but not another. Using argument classes to disambiguate relations can help, but extractions for relations in combination with argument classes are much more sparse. Improved extraction techniques could directly impact performance on the QSD task.

7 Conclusion and Future Work

We have demonstrated targeted methods for extracting world knowledge that is necessary for making quantifier scope disambiguation decisions. We have also demonstrated a novel, minimally-supervised, statistical relational model in the Markov Logic Network framework for making QSD decisions based on extracted pragmatics.

While our preliminary results for QSD are promising, there are clearly many areas for improvement. We will need to handle more kinds of quantifiers in our MLN model. Our current system is biased towards using purely pragmatic knowledge, but a complete system should also integrate syntactic and lexical constraints and preferences. Also, discourses can introduce knowledge that directly affects QSD problems, such as constraints on the size of a particular set that is discussed in the discourse. Integrating our technique for QSD with discourse processing is a major challenge that we hope to address.

Abstract

Most existing systems for Chinese Semantic Role Labeling (SRL) make use of full syntactic parses. In this paper, we evaluate SRL methods that take partial parses as inputs. We first extend the study on Chinese shallow parsing presented in (Chen et al., 2006) by raising a set of additional features. On the basis of our shallow parser, we implement SRL systems which cast SRL as the classification of syntactic chunks with IOB2 representation for semantic roles (i.e. semantic chunks). Two labeling strategies are presented: 1) directly tagging semantic chunks in one-stage, and 2) identifying argument boundaries as a chunking task and labeling their semantic types as a classification task. For both methods, we present encouraging results, achieving significant improvements over the best reported SRL performance in the literature. Additionally, we put forward a rule-based algorithm to automatically acquire Chinese verb formation, which is empirically shown to enhance SRL.

1 Introduction

In the last few years, there has been an increasing interest in Semantic Role Labeling (SRL) on several languages, which consists of recognizing arguments involved by predicates of a given sentence and labeling their semantic types. Nearly all previous Chinese SRL research took full syntactic parsing as a necessary pre-processing step, such as (Sun and Jurafsky, 2004; Xue, 2008; Ding and Chang, 2008). Many features are extracted to encode the complex syntactic information. In English SRL research, there have been some attempts at relaxing the necessity of using full syntactic parses; better understanding of SRL with shallow parsing is achieved by CoNLL-2004 shared task (Carreras and Màrquez, 2004). However, it is still unknown how these methods perform on other languages, such as Chinese.

To date, the best SRL performance reported on the Chinese Proposition Bank (CPB) corresponds to a F-measure is 92.0, when using the hand-crafted parse trees from Chinese Penn Treebank (CTB). This performance drops to 71.9 when a real parser is used instead[1] (Xue, 2008). Comparatively, the best English SRL results reported drops from 91.2 (Pradhan et al., 2008) to 80.56 (Surdeanu et al., 2007). These results suggest that as still in its infancy stage, Chinese full parsing acts as a central bottleneck that severely limits our ability to solve Chinese SRL. On the contrary, Chinese shallow parsing has gained a promising result (Chen et al., 2006); hence it is an alternative choice for Chinese SRL.

This paper addresses the Chinese SRL problem on the basis of shallow syntactic information at the level of phrase chunks. We first extend the study on Chinese chunking presented in (Chen et al., 2006) by raising a set of additional features. The new set of features yield improvement over the strong chunking system described in (Chen et al., 2006). On the basis of our shallow parser, we implement lightweight systems which solve SRL as a sequence labeling problem. This is accomplished by casting SRL as the classification of syntactic chunks (e.g. NP-chunk) into one of semantic labels with IOB2 representation (**?**). With respect to the labeling strategy, we distinguish two different approaches. The first one directly recognizes semantic roles by an IOB-type sequence tagging. The second approach divides the problem into two independent subtasks: 1) Argument Identification (AI) and 2) Semantic Role Classification (SRC).

[1] This F-measure is evaluated on the basis of hand-crafted word segmentation and POS tagging.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1475–1483,
Singapore, 6-7 August 2009.

A Chinese word consists of one or more characters, and each character, in most cases, is a morpheme. The problem of how the words are constructed from morphemes, known as word formation, is very important for a majority of Chinese language processing tasks. To capture Chinese verb formation information, we introduce a rule-based algorithm with a number of heuristics. Experimental results indicate that word formation features can help both shallow parsing and SRL.

We present encouraging SRL results on CPB[2]. The best F-measure performance (74.12) with gold segmentation and POS tagging can be achieved by the first method. This result yield significant improvement over the best reported SRL performance (71.9) in the literature (Xue, 2008). The best recall performance (71.50) can be achieved by the second method. This result is also much higher than the best reported recall (65.6) in (Xue, 2008).

2 Related Work

Previous work on Chinese SRL mainly focused on how to implement SRL methods which are successful on English, such as (Sun and Jurafsky, 2004; Xue and Palmer, 2005; Xue, 2008; Ding and Chang, 2008). Sun and Jurafsky (2004) did the preliminary work on Chinese SRL without any large semantically annotated corpus of Chinese. Their experiments were evaluated only on ten specified verbs with a small collection of Chinese sentences. This work made the first attempt on Chinese SRL and produced promising results. After the CPB was built, (Xue and Palmer, 2005) and (Xue, 2008) have produced more complete and systematic research on Chinese SRL. Ding and Chang (2008) divided SRC into two sub-tasks in sequence. Under the hierarchical architecture, each argument should first be determined whether it is a core argument or an adjunct, and then be classified into fine-grained categories. Chen et al. (2008) introduced an application of transductive SVM in Chinese SRL. Because their experiments took hand-crafted syntactic trees as input, how transductive SVMs perform in Chinese SRL in realistic situations is still unknown.

Most existing systems for automatic Chinese SRL make use of a full syntactic parse of the sentence in order to define argument boundaries and to extract relevant information for training classifiers to disambiguate between role labels. On the contrary, in English SRL research, there have been some attempts at relaxing the necessity of using syntactic information derived from full parse trees. For example, Hacioglu and Ward (2003) considered SRL as a chunking task; Pradhan et al. (2005) introduced a new procedure to incorporate SRL results predicted respectively on full and shallow syntactic parses. Previous work on English suggests that even good labeling performance has been achieved by full parse based SRL systems, partial parse based SRL systems can still enhance their performance. Though better understanding of SRL with shallow parsing on English is achieved by CoNLL-2004 shared task (Carreras and Màrquez, 2004), little is known about how these SRL methods perform on Chinese.

3 Chinese Shallow Parsing

There have been some research on Chinese shallow parsing, and a variety of chunk definitions have been proposed. However, most of these studies did not provide sufficient detail. In our system, we use chunk definition presented in (Chen et al., 2006), which provided a chunk extraction tool. The tool to extract chunks from CTB was developed by modifying the English tool used in CoNLL-2000 shared task, Chunklink[3], and is publicly available at http://www.nlplab.cn/chenwl/chunking.html. The definition of syntactic chunks is illustrated in Line *CH* in Figure 1. For example, "保险公司/the insurance company", consisting of two nouns, is a noun phrase.

With IOB2 representation (Ramshaw and Marcus, 1995), the problem of Chinese chunking can be regarded as a sequence labeling task. In this paper, we first implement the chunking method described in (Chen et al., 2006) as a strong baseline. To conveniently illustrate, we denote a word in focus with a fixed window $w_{-2}w_{-1}ww_{+1}w_{+2}$, where w is current token. The baseline features includes:

- Uni-gram word/POS tag feature: w_{-2}, w_{-1}, w, w_{+1}, w_{+2};
- Bi-gram word/POS tag feature: $w_{-2}\_w_{-1}$, w_{-1}_w, w_w_{+1}, $w_{+1}\_w_{+2}$;

[2]Our system is available at http://code.google.com/p/csrler/

Until now, the insurance company has provided insurance services for the Sanxia Project.

Figure 1: An example from Chinese PropBank.

That means 18 features are used to represent a given token. For instance, the bi-gram Word features at 5th word position ("公司/company") in Figure 1 are "，_保险", "保险_公司", "公司_已", "已_为".

To improve shallow parsing, we raised an additional set of features. We will discuss these features in section 5.

4 SRL with Shallow Parsing

The CPB is a project to add predicate-argument relations to the syntactic trees of the CTB. Similar to English PropBank, the semantic arguments of a predicate are labeled with a contiguous sequence of integers, in the form of AN (i.e. Arg$N$); the adjuncts are annotated as such with the label AM (i.e. ArgM) followed by a secondary tag that represents the semantic classification of the adjunct. The assignment of argument labels is illustrated in Figure 1, where the predicate is the verb "提供/provide". For example, the noun phrase "保险公司/the insurance company" is labeled as *A0*, meaning that it is the *proto-Agent* of 提供; the preposition phrase "截止目前/until now" is labeled as *AM-TMP*, indicating a temporal component.

4.1 System Architecture

SRL is a complex task which has to be decomposed into a number of simpler decisions and tagging schemes in order to be addressed by learning techniques. Regarding the labeling strategy, we can distinguish at least two different strategies. The first one consists of performing role identification directly as IOB-type sequence tagging. The second approach consists of dividing the problem into two independent subtasks.

[4]The semantic chunk labels here are *B-AM-TMP* and *I-AM-TMP*. Limited to the document length, we cannot put all detailed chunk labels in one line in Figure 1.

4.1.1 One-stage Strategy

In the one-stage strategy, on the basis of syntactic chunks, we define semantic chunks which do not overlap nor embed using IOB2 representation. Syntactic chunks outside a chunk receive the tag O. For syntactic chunks forming a chunk of type *A**, the first chunk receives the *B-A** tag (Begin), and the remaining ones receive the tag *I-A** (Inside). Then a SRL system can work directly by using sequence tagging techinique. Since the semantic annotation in the PropBank corpus does not have any embedded structure, there is no loss of information in this representation. The line *M1* in Figure 1 illustrates this semantic chunk definition.

4.1.2 Two-stage Strategy

In the two-stage architecture, we divide Chinese SRL into two subtasks: 1) semantic chunking for AI, in which the argument boundaries are predicted, and 2) classification for SRC, in which the already recognized arguments are assigned role labels. In the first stage, we define semantic chunks *B-A* which means begin of an argument and *I-A* which means inside of an argument. In the second stage, we solve SRC problem as a multi-class classification. The lines *M2-AI* and *M2-SRC* in Figure 1 illustrate this two-stage architecture. For example, the noun phrase "保险公司/the insurance company" is *proto-Agent*, and thus should be labeled as *B-A* in the AI chunking phase, and then be tagged as *A0*. The phrase "为三峡工程/for the Sanxia Project" consists of three chunks, which should be labeled as *B-A*, *I-A*, and *I-A* respectively in the AI chunking phase, then these three chunks as a whole argument should be recognized as *A2*.

4.1.3 Chunk-by-Chunk

There is also another semantic chunk definition, where the basic components of a semantic chunk are words rather than syntactic chunks. A good election for this problem is chunk-by-chunk pro-

cessing instead of word-by-word. The motivation is twofold: 1) phrase boundaries are almost always consistent with argument boundaries; 2) chunk-by-chunk processing is computationally less expensive and allows systems to explore a relatively larger context. This paper performs a chunk-by-chunk processing, but admitting a processing by words within the target verb chunks.

4.2 Features

Most of the feature templates are "standard", which have been used in previous SRL research. We give a brief description of "standard" features, but explain our new features in detail.[5]

4.2.1 Features for Semantic Chunking

In the semantic chunking tasks, i.e. the one-stage method and the first step in the two-stage method, we use the same set of features. The features are extracted from three types of elements: syntactic chunks, target verbs, links between chunks and target verbs. They are formed making use of words, POS tags and chunks of the sentence. Xue (2008) put forward a rough verb classification where verb classes are automatically derived from the frame files, which are verb lexicon for the CPB annotation. This kind of verb class information has been shown very useful for Chinese SRL. Our system also includes this feature. In our experiments, we represent a verb in two dimensions: 1) number of arguments, and 2) number of framesets. For example, a verb may belong to the class "C1C2," which means that this verb has two framesets, with the first frameset having one argument and the second having two arguments.

To conveniently illustrate, we denote a token chunk with a fixed context $w_{i-1}[_{c_k} w_i ... w_h ... w_j]w_{j+1}$, where w_h is the head word of this chunk c_k. The complete list of features is listed here.

Extraction on Syntactic Chunks

Chunk type: c_k.

Length: the number of words in a chunk.

Head word/POS tag. The rules described in (Sun and Jurafsky, 2004) are used to extract head word.

IOB chunk tag of head word: chunk tag of head word with IOB2 representation (e.g. B-NP, I-NP).

Chunk words/POS tags context. Chunk context includes one word before and one word after: w_{i-1} and w_{j+1}.

POS tag chain: sequential containers of each word's POS tag: $w_{i\_...\_}w_j$. For example, this feature for "保险服务" is "NN_NN".

Position: the position of the phrase with respect to the predicate. It has three values as *before*, *after* and *here*.

Extraction on Target Verbs Given a target verb w_v and its context, we extract the following features.

Predicate, its POS tag, and its verb class.

Predicate IOB chunk tag context: the chain of IOB2 chunk tags centered at the predicate within a window of size -2/+2.

Predicate POS tag context: the POS tags of the words that immediately precede and follow the predicate.

Number of predicates: the number of predicates in the sentence.

Extraction on Links To capture syntactic properties of links between the chunks and the verbs, we use the following features.

Path: a flat path is defined as a chain of base phrases between the token and the predicate. At both ends, the chain is terminated with the POS tags of the predicate and the headword of the token.

Distance: we have two notions of distance. The first is the distance of the token from the predicate as a number of base phrases, and the second is the same distance as the number of VP chunks.

Combining Features We also combine above features as some new features.

Conjunctions of position and head word, target verb, and verb class, including: $position\_w_h$, $position\_w_v$, $position\_w_h\_w_v$, $position\_class$, and $position\_w_h\_class$.

Conjunctions of position and POS tag of head word, target verb, and verb class, including: $position\_w_h\_w_v$, $position\_w_h$, and $position\_w_h\_class$.

4.2.2 Features for SRC

In the SRC stage of the two-stage method, different from previous work, our system only uses word-based features, i.e. features extracted from words and POS tags, to represent a given argument. Experiments show that a good semantic

[5]The source code of our system also provides lots of comments for implementation of all features.

role classifier can be trained by using only word-based features. To gather all argument position information predicted in AI stage, we design a coarse frame feature, which is a sequential collection of arguments. So far, we do not know the detailed semantic type of each argument, and we use *XP* as each item in the frame. To distinguish the argument in focus, we use a special symbol to indicate the corresponding frame item. For instance, the Frame feature for argument 保险服务 is *XP+XP+XP+XP+V+!XP*, where *!XP* means that it is the argument in focus.

Denote 1) a given argument $w_{i-2}w_{i-1}[w_iw_{i+1}...w_{j-1}w_j]w_{j+1}w_{j+2}$, and 2) a given predicate w_v. The features for SRC are listed as follows.

Words/POS tags context of arguments: the contents and POS tags of the following words: w_i, w_{i-1}, w_{i-2}, w_{i+1}, w_{i+2}, w_j, w_{j+1}, w_{j-1}, w_{j-2}, w_{j+1}, w_{j+2}; the POS tags of the following words: w_{i+1}, w_{i+2}, w_{j+1}, w_{j+2}.

Token Position.

Predicate, its POS, and its verb class.

Coarse Frame.

Combining features: conjunctions of boundary words, including $w_{i-1}\_w_{j+1}$ and $w_{i-2}\_w_{j+2}$; conjunction of POS tags of boundary words, including $w_{i-1}\_w_{j+1}$ and $w_{i-2}\_w_{j+2}$; conjunction of token position, boundary words, and predicate word, including $position\_w_i\_w_j$, $w_i\_w_j\_w_v$; $position\_w_i\_w_j\_w_v$; conjunction of token position, boundary words' POS tags, and predicate word, also including $position\_w_i\_w_j$, $w_i\_w_j\_w_v$; $position\_w_i\_w_j\_w_v$; conjunction of predicate and frame; conjunction of target verb class and frame; conjunction of boundary words' POS tags, and predicate word.

5 Automatic Chinese Verb Formation Analyzing

5.1 Introduction to Chinese Word Formation

Chinese words consist of one or more characters, and each character, in most cases, is a morpheme which is the smallest meaningful unit of the language. According to the number of morphemes, the words can be grouped into two sets, simple words (consisting of one morpheme) and compound words (consisting of two morphemes or more). There are 9 kinds of word formation in Chinese compound words, and table 1 shows the detail with examples. Note that, *attributive-head* and *complementarity* are not for Chinese verbs.

Types	Examples
reduplication	看看(look) 想想(think)
affixation	激化(intensify) 觉着(feel)
subject-verb	耳闻(hear) 口述(dictate)
verb-object	戒烟(quit smoking) 理发(haircut)
verb-complement	通知(inform) 栽培(plant)
verb-result	超出(exceed) 煮沸(boil)
adverbial-head	隐居(retreat) 误用(misuse)
coordinate	爱惜(cherish) 追逐(chase)
attributive-head*	谣言(rumor) 医院(hospital)
complementarity*	纸张(paper) 马匹(horse)

Table 1: Example Words with Formation

The internal structure of a word constraints its external grammatical behavior, and the formation of a verb can provide very important information for Chinese SRL. Take "超出/exceed" as an example, the two characters are both verbal morphemes, and the character "超" means "pass" and the character "出" with the meaning of "over" shows the complement of the action of "超". In this word, "出" is usually collocated with an object, and hence a *Patient* role should comes after the verb "超出". Note that, the verb "超", however, is unlikely to have an object. Take "理发/haircut" as another example, the first character "理" is a verbal morpheme with the meaning of "cut" and the second character "发" is a nominal morpheme with the meaning of "hair". In this word, "发" acts as the object of "理", and the word "理发" is unlikely to have an *Patient* any more in the sentential context.

5.2 Verb Formation Analyzing Method

To automatically analyze verb formation, we introduce a rule-based algorithm. Pseudo code in Algorithm 1 illustrates our algorithm. This algorithm takes three string (one or more Chinese characters) sets as *lexicon* knowledge:

- adverbial suffix set $\mathcal{A}$: strings in $\mathcal{A}$ are usually realized as the modifier in a *adverbial-head* type word, e.g. 不/not, 别/not, 总/always, 并/both, 共/all.

- object head set $\mathcal{O}$: strings in $\mathcal{O}$ are usually realized as the head in a *verb-object* type word, e.g. 变/change, 获/get, 谈/talk, 发/send.

Algorithm 1: Verb Formation Analyzing.

Data: adverbial suffix set $\mathcal{A}$, object head set $\mathcal{O}$, complement suffix set $\mathcal{C}$
input : word $W = c_1...c_n$ and its POS P
output: head character h, adverbial character a, complement character c, object character o

begin
  $h = c = a = o = null$;
  if $n = 4$ **and** $c_1 = c_3$ **and** $c_2 = c_4$ **then**
    return *Verb formation of* $W' = c_1c_3$;
  else if $n = 3$ **and** $c_2 = c_3$ **then**
    $h = c_1, c = c_2$;
  else if $n = 2$ **and** $c_1 = c_2$ **then**
    $h = c_1$;
  else if $n = 1$ **then**
    $h = c_1$;
  else if $c_n \in \mathcal{C}$ **and** $c_{n-1}c_n \in \mathcal{C}$ **and** P=*"VV"* **then**
    $h = c_1, c = c_n/c_{n-1}c_n$;
  else if $c_1 \in \mathcal{A}$ **then**
    $a = c_1, h = c_2...c_n$;
  else if $c_1 \in \mathcal{O}$ **and** P=*"VV"* **then**
    $h = c_1, o = c_2...c_n$;
end

- complement suffix set $\mathcal{C}$: strings in $\mathcal{C}$ are usually realized as complement in a verb-complement type word: e.g. 出/out, 入/in, 完/finish, 来/come, 不到/not.

Note that, to date there is no word formation annotation corpus, so direct evaluation of our rule-based algorithm is impossible. This paper makes task-oriented evaluation which measures improvements in SRL.

5.3 Using Word Formation Information to improve Shallow Parsing

The majority of Chinese nouns are of type *attributive-head*. This means that for most nouns the last character provides very important information indicating the head of the noun. For example, the word formations of "桃树/peach", "柳树/willow" and "黄杨树/boxtree" (three different kinds of trees), are *attributive-head* and they have the same head word "树/tree". While for verbs, the majority are of three types: *verb-object*, *coordinate* and *adverbial-head*. For example, words "加大/enlarge", "加剧/make more drastic" and "加快/accelerate" have the same *head* "加/add". The *head* morpheme is very useful in alleviating the data sparseness in word level. However, for any given word, it is very hard to accurately find the head. In the shallow paring experiments, we use a very simple rule to get a *pseudo* head character: 1) extracting the last word for a noun, and 2) extracting the first word for a verb. The new features include:

Pattern 1: conjunction of pseudo head of w_{i-1} and POS tags of w_{i-1} and w_i.

Pattern 2: conjunction of pseudo head of w_i and POS tags of w_{i-1} and w_i.

Pattern 3: conjunction of length/POS tags of w_{i-1}, w_i, w_{i+1}.

5.4 Using Verb Formation Information to improve SRL

We use some new verb formation features to improve our SRL system. The new features are listed as follows. The first four are used in semantic chunking task, and all are used in SRC task.

First/last characters.

Word length.

Conjunction of word length and first/last character.

Conjunction of token position and first/last character.

The head string of a verb (e.g. "理" in "理发").

The adverbial string of a verb (e.g. "误" in "误用").

The complement string of a verb (e.g. "出" in "超出").

The object string of a verb (e.g. "发" in "理发").

6 Results and Discussion

6.1 Experimental Setting

6.1.1 Data

Experiments in previous work are mainly based on CPB and CTB, but the experimental data preparing procedure does not seem consistent. For example, the sum of each semantic role reported in (Ding and Chang, 2008) is extremely smaller than the corresponding occurrence statistics in original data files in CPB. In this paper, we modify CoNLL-2005 shared task software[6] to process CPB and CTB. In our experiments, we use the CPB 1.0 and CTB 5.0. The data is divided into three parts: files from chtb_081 to chtb_899 are used as training set; files from chtb_041 to

[6]http://www.lsi.upc.edu/∼srlconll/soft.html

chtb_080 as development set; files from chtb_001 to chtb_040, and chtb_900 to chtb_931 as test set. The data setting is the same as (Xue, 2008). The results were evaluated for precision, recall and F-measure numbers using the srl-eval.pl script provided by CoNLL-2005 shared task.

6.1.2 Classifier

For both syntactic and semantic chunking, we used TinySVM along with YamCha[7] (Kudo and Matsumoto, 2000; Kudo and Matsumoto, 2001). In the chunking experiments, all SVM classifiers were realized with a polynomial kernel of degree 2. Pair-wise strategy is used to solve multi-class classification problem. For the SRC experiments, we use a linear SVM classifier, along with One-Vs-All approach for multi-class classification. SVM_{lin}[8], a fast linear SVM solvers, is used for supervised learning. l_2-SVM-MFN (modified finite newton) method is used to solve the optimization problem (Keerthi and DeCoste, 2005).

6.2 Shallow Parsing Performance

	P(%)	R(%)	$F_{\beta=1}$
Baseline	93.54	93.00	93.27
Ours	93.83	93.39	93.61

Table 2: Shallow parsing performance

Table 2 summarizes the overall shallow parsing performance on test set. The first line shows the performance of baseline. Comparing the best system performance 94.13 F-measure of CoNLL 2000 shared task (Syntactic Chunking on English), we can see Chinese shallow parsing has reached a comparable result, tough the comparison of numeric performance is not very fair, because of different languages, different chunk definition, different training data sizes, etc.. The second line *Ours* shows the performance when new features are added, from which we can see the word formation based features can help shallow parsing.

Table 3 shows the detailed performance of noun phrase (NP) and verb phrase (VP), which make up most of phrase chunks in Chinese. Our new features help NP more, whereas the effect of new features for VP is not significant. That is in part because most VP chunk recognition error is caused by long dependency, where word formation features do not work. Take the sentences below for example:

	P(%)	R(%)	$F_{\beta=1}$
NP(Baseline)	90.84	90.05	90.44
NP(Ours)	91.42	90.78	91.10
VP(Baseline)	94.44	94.55	94.50
VP(Ours)	94.65	94.74	94.69

Table 3: Performance of NP-chunk and VP-chunk

1. [$_{VP}$ 因此获得胜利]。 (Therefore (we) achieve victory.)
2. [$_{ADVP}$ 因此] [$_{VP}$ 大量出现] 的是以前不曾遇到的。 (Therefore the major changes have not been met before.)

The contexts of the word "因此/therefore" in the two sentences are similar, where "因此" is followed by verbal components. In the second sentence, the word "因此/therefore" will be correctly recognized as an adverbial phrase unless classifier knows the following component is a clause. Unfortunately, word formation features cannot supply this kind of information.

6.3 SRL Performance

	P(%)	R(%)	A(%)	$F_{\beta=1}$
(Xue, 2008)	79.5	65.6	–	71.9
M1−	79.02	69.12	–	73.74
M1+	79.25	69.61	–	74.12
M2−/AI	80.34	75.11	–	77.63
M2+/AI	80.01	75.15	–	77.51
M2−/SRC	–	–	92.57	–
M2+wf/SRC	–	–	93.25	–
M2+/SRC	–	–	93.42	–
M2−AI+SRC	76.48	71.50	–	73.90

Table 4: Overall SRL performance of different methods

Table 4 lists the overall SRL performance numbers on test set using different methods mentioned earlier; these results are based on features computed from gold standard segmentation and POS tagging, but automatic recognized chunks, which is parsed by our improved shallow parsing system. For the AI and the whole SRL tasks, we report the precision (P), recall (R) and the $F_{\beta=1}$-measure scores, and for the SRC task we report the classification accuracy (A). The first line *(Xue,*

[7] http://chasen.org/∼taku/index.html.en

[8] http://people.cs.uchicago.edu/∼vikass/svmlin.html

2008) shows the SRL performance reported in (Xue, 2008). To the authors' knowledge, this result is best SRL performance in the literature. Line 2 and 3 shows the performance of the one-stage systems: 1) Line *M1−* is the performance without word formation features; 2) Line *M1+* is the performance when verb formation features are added. Line 4 to 8 shows the performance of the two-stage systems: 1) Line *M2−/AI* and *M2+/AI* shows the performance of AI phase without and within word formation features respectively; 2) Line *M2−/SRC* shows the SRC performance with trivial word-based features (i.e. frame features and verb formation features are not used); 3) Line *M2+wf/SRC* is the improved SRC performance when coarse verb formation features are added; 4) Line *M2+/SRC* is the SRC performance with all features; 5) Line *M2−AI+SRC* shows the performance of SRL system, which uses baseline features to identify arguments, and use all features to classify arguments.

6.4 Discussion

The results summarized in Table 4 indicate that according to the-state-of-the-art in Chinese parsing, SRL systems based on shallow parsing outperforms the ones based on full parsing. Comparison between *one-stage strategy* and *two-stage strategy* indicates 1) that there is no significant difference in the F-measure; and 2) that *two-stage strategy* method can achieve higher recall while *one-stage strategy* method can achieve higher precision. Both the *one-stage strategy* and *two-stage strategy* methods yield significant improvements over the best reported SRL performance in the literature, especially in terms of recall performance. Comparison SRL performance with full parses and partial parses indicates that both models have strong and weak points. The full parse based method can implement high precision SRL systems, while the partial parse based methods can implement high recall SRL systems. This is further justification for combination strategies that combine these independent SRL models.

Generally, Table 4 shows that verb formation features can enhance Chinese SRL, especially for fine-grained role classification. The effect of word formation in formation in both shallow parsing and SRL suggests that automatic word formation analyzing is very important for Chinese language processing. The rule-based algorithm is just a preliminary study on this new topic, which requires more research effort.

Num of words	P (%)	R (%)	$F_{\beta=1}$
Length = 1	84.69%	75.48%	79.82
Length = 2	82.14%	74.21%	77.97
Length = 3	75.43%	63.98%	69.24
Length = 4	75.71%	65.63%	70.32
Length = 5	72.46%	64.38%	68.18
Length = 6	72.97%	66.21%	69.43
Length = 7	77.03%	67.65%	72.04
Length = 8	74.39%	57.28%	64.72
Length = 9	66.67%	51.16%	57.89
Length = 10	68.08%	58.28%	62.80
Length = 11+	67.40%	57.71%	62.18

Table 5: SRL performance with arguments of different length

Though our SRC module does not use any parsing information, our system can achieve 93.42% accuracy, comparing the best gold parse based result 94.68% in the literature. This result suggests that Chinese SRC system, even without parsing, can reach a considerable good performance. The main reason is that in Chinese, arguments with different semantic types have discriminative boundary words, which can be extracted without parsing. It is very clear that the main bottleneck for Chinese SRL is to accurately identify arguments rather than to disambiguate their detailed semantic types.

Table 5 summarizes the labeling performance for argument of different length. It is not surprising that arguments are more and more difficult to rightly recognize as the increase of their length. But the performance decline slows up when the length of arguments is larger than 10. In other words, some of the arguments that are composed of many words can still be rightly identified. The main reason for this point is that these arguments usually have clear collocation words locating at argument boundaries. Take the sentences below for example,

3. 包括[*A*1 ..... 等] (including ... etc.)

the object of the verb "包括/include" has a definite collocation word "等/etc.", and therefore this object is easy to be recognized as a *A1*.

7 Conclusion

In this paper, we discuss Chinese SRL on the basis of partial syntactic structure. Our systems advance the state-of-the-art in Chinese SRL. We first

extend the study on Chinese shallow parsing and implement a good shallow parser. On the basis of partial parses, SRL are formulated as a sequence labeling problem, performing IOB2 decisions on the syntactic chunks of the sentence. We exploit a wide variety of features based on words, POS tags, and partial syntax. Additionally, we discuss a language special problem, i.e. Chinese word formation. Experimental results show that coarse word formation information can help shallow parsing, especially for NP-chunk recognition. A rule-based algorithm is put forward to automatically acquire Chinese verb formation, which is empirically shown to enhance SRL.

Discovery of Term Variation in Japanese Web Search Queries

Hisami Suzuki, Xiao Li, and Jianfeng Gao
Microsoft Research, Redmond
One Microsoft Way, Redmond, WA 98052 USA
{hisamis,xiaol,jfgao}@microsoft.com

Abstract

In this paper we address the problem of identifying a broad range of term variations in Japanese web search queries, where these variations pose a particularly thorny problem due to the multiple character types employed in its writing system. Our method extends the techniques proposed for English spelling correction of web queries to handle a wider range of term variants including spelling mistakes, valid alternative spellings using multiple character types, transliterations and abbreviations. The core of our method is a statistical model built on the MART algorithm (Friedman, 2001). We show that both string and semantic similarity features contribute to identifying term variation in web search queries; specifically, the semantic similarity features used in our system are learned by mining user session and click-through logs, and are useful not only as model features but also in generating term variation candidates efficiently. The proposed method achieves 70% precision on the term variation identification task with the recall slightly higher than 60%, reducing the error rate of a naïve baseline by 38%.

1 Introduction

Identification of term variations is fundamental to many NLP applications: words (or more generally, terms) are the building blocks of NLP applications, and any robust application must be able to handle variations in the surface representation of terms, be it a spelling mistake, valid spelling variation, or abbreviation. In search applications, term variations can be used for query expansion, which generates additional query terms for better matching with the terms in the document set. Identifying term variations is also useful in other scenarios where semantic equivalence of terms is sought, as it represents a very special case of paraphrase.

This paper addresses the problem of identifying term variations in Japanese, specifically for the purpose of query expansion in web search, which appends additional terms to the original query string for better retrieval quality. Query expansion has been shown to be effective in improving web search results in English, where different methods of generating the expansion terms have been attempted, including relevance feedback (e.g., Salton and Buckley, 1990), correction of spelling errors (e.g., Cucerzan and Brill, 2004), stemming or lemmatization (e.g., Frakes, 1992), use of manually- (e.g., Aitchison and Gilchrist, 1987) or automatically- (e.g., Rasmussen 1992) constructed thesauri, and Latent Semantic Indexing (e.g., Deerwester et al, 1990). Though many of these methods can be applied to Japanese query expansion, there are unique problems posed by Japanese search queries, the most challenging of which is that valid alternative spellings of a word are extremely common due to the multiple script types employed in the language. For example, the word for 'protein' can be spelled as たんぱくしつ, タンパク質, 蛋白質, たん白質 and so on, all pronounced *tanpakushitsu* but using combinations of different script types. We give a detailed description of the problem posed by the Japanese writing system in Section 2. Though there has been previous work on addressing specific subsets of spelling alterations within and across character types in Japanese, there has not been any comprehensive solution for the purpose of query expansion.

Our approach to Japanese query expansion is unique in that we address the problem comprehensively: our method works independently of the character types used, and targets a wide range of term variations that are both orthographically and semantically similar, including spelling errors, valid alternative spellings, transliterations and abbreviations. As described in Section 4, we define the problem of term variation identifica-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1484–1492,
Singapore, 6-7 August 2009.

tion as a binary classification task, and build two types of classifiers according to the maximum entropy model (Berger et al., 1996) and the MART algorithm (Friedman, 2001), where all term similarity metrics are incorporated as features and are jointly optimized. Another important contribution of our approach is that we derive our semantic similarity models by mining user query logs, which has been explored for the purposes of collecting related words (e.g., Jones et al., 2006a), improving search results ranking (e.g., Craswell and Szummer, 2007) and learning query intention (e.g., Li et al., 2008), but not for the task of collecting term variations. We show that our semantic similarity models are not only effective in the term variation identification task, but also for generating candidates of term variations much more efficiently than the standard method whose candidate generation is based on edit distance metrics.

2 Term Variations in Japanese

In this section we give a summary of the Japanese writing system and the problem it poses for identifying term variations, and define the problem we want to solve in this paper.

2.1 The Japanese Writing System

There are four different character types that are used in Japanese text: *hiragana*, *katakana*, *kanji* and Roman alphabet. Hiragana and katakana are the two subtypes of *kana* characters, which are syllabic character sets, each with about 50 basic characters. There is a one-to-one correspondence between hiragana and katakana characters, and, as they are phonetic, they can be unambiguously converted into a sequence of Roman characters. For example, the word for 'mackerel' is spelled in hiragana as さば or in katakana as サバ, both of which can be transcribed in Roman characters as *saba*, which is how the word is pronounced. Kanji characters, on the other hand, are ideographic and therefore numerous – more than 5,000 are in common usage. One difficulty in handling Japanese kanji is that each character has multiple pronunciations, and the correct pronunciation is determined by the context in which the character is used. For instance, the character 行 is read as *kou* in the word 銀行 *ginkou* 'bank', *gyou* in 行 'column', and *i* or *okona* in 行った *itta* 'went' or *okonatta* 'done' depending on the context in which the word is used.[1] Proper name readings are particularly difficult to disambiguate, as their pronunciation cannot be inferred from the context (they tend to have the same grammatical function) or from the dictionary (they tend to be out-of-vocabulary). Therefore, in Japanese, computing a pronunciation-based edit distance metric is not straightforward, as it requires estimating the readings of kanji characters.

2.2 Term Variation by Character Type

Spelling variations are commonly observed both within and across character types in Japanese. Within a character type, the most prevalent is the variation observed in katakana words. Katakana is used to transliterate words from English and other foreign languages, and therefore reflects the variations in the sound adaptation from the source language. For example, the word 'spaghetti' is transliterated into six different forms (スパゲッティ *supagetti*, スパゲッティー *supagettii*, スパゲッテイ *supagettei*, スパゲティ *supageti*, スパゲティー *supagetii*, スパゲテイ *supagetei*) within a newspaper corpus (Masuyama et al., 2004).

Spelling variants are also prevalent across character types: in theory, a word can be spelled using any of the character types, as we have seen in the example for the word 'protein' in Section 1. Though there are certainly preferred character types for spelling each word, variations are still very common in Japanese text and search queries. Alterations are particularly common among hiragana, katakana and kanji (e.g. さば~サバ~ 鯖 *saba* 'mackerel'), and between katakana and Roman alphabet (e.g. フェデックス *fedekkusu* fedex). This latter case constitutes the problem of transliteration, which has been extensively studied in the context of machine translation (e.g. Knight and Graehl, 1998; Bilac and Tanaka, 2004; Brill et al., 2001).

2.3 Term Variation by Re-write Categories

Table 1 shows the re-write categories of related terms observed in web query logs, drawing on our own data analysis as well as on previous work such as Jones et al. (2006a) and Okazaki et al. (2008b). Categories 1 though 9 represent strictly synonymous relations; in addition, terms in Categories 1 through 5 are also similar orthographically or in pronunciation. Categories 10

[1] In a dictionary of 200K entries, we find that on average each kanji character has 2.5 readings, with three characters (直,生,空) with as many as 11 readings.

Categories	Example in English	Example in Japanese
1. Spelling mistake	aple ~ apple	グウグル *guuguru* ~ グーグル *gu-guru* 'google'
2. Spelling variant	color ~ colour	さば~サバ~鯖; スパゲティ~スパゲッティー (Cf. Sec.2.2)
3. Inflection	matrix ~ matrices	作る *tsukuru* 'make' ~ 作った *tsukutta* 'made'
4. Transliteration		フェデックス ~ fedex 'Fedex'
5. Abbreviation/ Acronym	macintosh ~ mac	世界銀行 *sekaiginkou* ~ 世銀 *segin* 'World Bank'; マクドナルド *makudonarudo* ~ マック *makku* 'McDonald's'
6. Alias	republican party ~ gop	フランス *furansu* ~ 仏 *futsu* 'France'
7. Translation	パキスタン大使館 *pakisutantaishikan* ~ Pakistan embassy	
8. Synonym	carcinoma ~ cancer	暦 *koyomi* ~ カレンダー *karendaa* 'calendar'
9. Abbreviation (user specific)	mini ~ mini cooper	クロネコヤマト *kuronekoyamato* ~ クロネコ *kuroneko* (name of a delivery service company)
10. Generalization	nike shoes ~ shoes	シビック 部品 *shibikku buhin* 'Civic parts' ~ 車 部品 *kuruma buhin* 'car parts'
11. Specification	ipod ~ ipod nano	東京駅 *toukyoueki* 'Tokyo station' ~ 東京駅時刻表 *toukyouekijikokuhyou* 'Tokyo station timetable'
12. Related	windows ~ microsoft	トヨタ *toyota* 'Toyota' ~ ホンダ *honda* 'Honda'

Table 1: Categories of Related Words Found in Web Search Logs

through 12, on the other hand, specify non-synonymous relations.

Different sets out of these categories can be useful for different purposes. For example, Jones et al (2006a; 2006b) target all of these categories, as their goal is to collect related terms as broadly as possible for the application of sponsored search, i.e., mapping search queries to a small corpus of advertiser listings. Okazaki et al. (2008b) define their task narrowly, to focusing on spelling variants and inflection, as they aim at building lexical resources for the specific domain of medical text.

For web search, a conservative definition of the task as dealing only with spelling errors has been successful for English; a more general definition using related words for query expansion has been a mixed blessing as it compromises retrieval precision. A comprehensive review on this topic is provided by Baeza-Yates and Ribeiro-Neto (1999). In this paper, therefore, we adopt a working definition of the term variation identification task as including Categories 1 through 5, i.e., those that are synonymous and also similar in spelling or in pronunciation.[2] This definition is reasonably narrow so as to make automatic discovery of term variation pairs realistic, while covering all common cases of term variation in Japanese, including spelling variants and transliterations. It is also appropriate for the purpose of query expansion: because term variation defined in this manner is based on spelling or pronunciation similarity, their meaning and function tend to be completely equivalent, as opposed to Categories 6 through 9, where synonymy is more context- or user-dependent. This will ensure that the search results by query expansion will avoid the problem of compromised precision.

3 Related Work

In information retrieval, the problem of vocabulary mismatch between the query and the terms in the document has been addressed in many ways, as mentioned in Section 1, achieving varying degrees of success in the retrieval task. In particular, our work is closely related to research in spelling correction for English web queries (e.g., Cucerzan and Brill, 2004; Ahmad and Kondrak, 2005; Li et al., 2006; Chen et al., 2007). Among these, Li et al. (2006) and Chen et al. (2007) incorporate both string and semantic similarity in their discriminative models of spelling correction, similarly to our approach. In Li et al. (2006), semantic similarity was computed as distributional similarity of the terms using query strings in the log as context. Chen et al. (2007) point out that this method suffers from the data sparseness problem in that the statistics for rarer terms are unreliable, and propose using web search results as extended contextual information. Their method, however, is expensive as it requires web search results for each query-candidate pair, and also because their candidate set, generated using an edit distance function and phonetic similarity from query log data, is impractically large and must be pruned by using a language model. Our approach differs from these methods in that we exploit user query logs to derive semantic knowledge of terms, which is

[2] In reality, Category 3 (Inflection) is extremely rare in Japanese web queries, because nouns do not inflect in Japanese, and most queries are nominals.

used both for the purpose of generating a candidate set efficiently and as features in the term variation identification model.

Acquiring semantic knowledge from a large quantity of web query logs has become popular in recent years. Some use only query strings and their counts for learning word similarity (e.g., Sekine and Suzuki, 2007; Komachi and Suzuki, 2008), while others use additional information, such as the user session information (i.e., a set of queries issued by the same user within a time frame, e.g., Jones et al., 2006a) or the URLs clicked as a result of the query (e.g., Craswell and Szummer, 2007; Li et al., 2008). This additional data serves as an approximation to the meaning of the query; we use both user session and click-through data for discovering term variations.

Our work also draws on some previous work on string transformation, including spelling normalization and transliteration. In addition to the simple Levenshtein distance, we also use generalized string-to-string edit distance (Brill and Moore, 2000), which we trained on aligned katakana-English word pairs in the same manner as Brill et al. (2001). As mentioned in Section 2.2, our work also tries to address the individual problems targeted by such component technologies as Japanese katakana variation, English-to-katakana transliteration and katakana-to-English back-transliteration in a unified framework.

4 Discriminative Model of Identifying Term Variation

Recent work in spelling correction (Ahmed and Kondrak, 2005; Li et al., 2006; Chen et al., 2007) and normalization (Okazaki et al., 2008b) formulates the task in a discriminative framework:

$$c^* = \text{argmax}_{c \in \text{gen}(q)} P(c|q)$$

This model consists of two components: gen(q) generates a list of candidates $C(q)$ for an input query q, which are then ranked by the ranking function $P(c|q)$. In previous work, gen(q) is typically generated by using an edit distance function or using a discriminative model trained for its own purpose (Okazaki et al., 2008b), often in combination with a pre-complied lexicon. In the current work, we generate the list of candidates by learning pairs of queries and their re-write candidates automatically from query session and click logs, which is far more robust and efficient than using edit distance functions. We describe our candidate generation method in detail in Section 5.1.

Unlike the spelling correction and normalization tasks, our goal is to *identify* term variations, i.e., to determine whether each query-candidate pair (q,c) constitutes a term variation or not. We formulate this problem as a binary classification task. There are various choices of classifiers for such a task: we chose to build two types of classifiers that make a binary decision based on the probability distribution $P(c|q)$ over a set of feature functions $f_i(q,c)$. In maximum entropy framework, this is defined as:

$$P(c|q) = \frac{\exp \sum_{i=1}^{K} \lambda_i f_i(c,q)}{\sum_c \exp \sum_{i=1}^{K} \lambda_i f_i(c,q)}$$

where $\lambda_1,\ldots, \lambda_k$ are the feature weights. The optimal set of feature weights λ^* is computed by maximizing the log-likelihood of the training data. We used stochastic gradient descent for training the model with a Gaussian prior.

The second classifier is built on MART (Friedman, 2001), which is a boosting algorithm. At each boosting iteration, MART builds a regression tree to model the functional gradient of the cost function (which is cross entropy in our case), evaluated on all training samples. MART has three main parameters: M, the total number of boosting iterations, L, the number of leaf nodes for each regression tree, and v, the learning rate. The optimal values of these parameters can be chosen based on performance on a validation set. In our experiments, we found that the performance of the algorithm is relatively insensitive to these parameters as long as they are in a reasonable range: given the training set of a few thousand samples or more, as in our experiments, M=100, L=15, and v=0.1 usually give good performance. Smaller trees and shrinkage may be used if the training data set is smaller.

The classifiers output a binary decision according to $P(c|q)$: positive when $P(c|q) > 0.5$ and negative otherwise.

5 Experiments

5.1 Candidate Generation

We used a set of Japanese query logs collected over one year period in 2007 and 2008. More specifically, we used two different extracts of log data for generating term variation candidate pairs:

Query session data. From raw query logs, we extracted pairs of queries q_1 and q_2 such that they are (i) issued by the same user; (ii) q_2 follows within 3 minutes of issuing q_1; and (iii) q_2 generated at least one click of a URL on the result

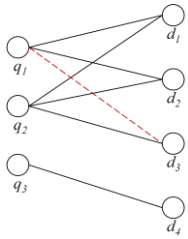

Figure 1. Random Walk Algorithm

page while q_1 did not result in any click. We then scored each query pair (q_1,q_2) in this subset using the log-likelihood ratio (LLR, Dunning, 1993) between q_1 and q_2, which measures the mutual dependence within the context of web search queries (Jones et al., 2006a). After applying an LLR threshold (LLR > 15) and a count cutoff (we used only the top 15 candidate q_2 according to the LLR value for each q_1), we obtained a list of 47,139,976 pairs for the 14,929,497 distinct q_1, on average generating 3.2 candidates per q_1[3]. We took this set as comprising query-candidate pairs for our model, along with the set extracted by click-through data mining explained below.

Click-through data. This data extract is based on the idea that if two queries led to the same URLs being repeatedly clicked, we can reasonably infer that the two queries are semantically related. This is similar to computing the distributional similarity of terms given the context in which they appear, where context is most often defined as the words co-occurring with the terms. Here, the clicked URLs serve as their context.

One challenge in using the URLs as contextual information is that the contextual representation in this format is very sparse, as user clicks are rare events. To learn query similarities from incomplete click-through data, we used the random walk algorithm similar to the one described in Craswell and Szummer (2007). Figure 1 illustrates the basic idea: initially, document d_3 has a click-through link consisting of query q_2 only; the random walk algorithm adds the link from d_3 to q_1, which has a similar click pattern as q_2. Formally, we construct a click graph which is a bipartite-graph representation of click-through data. We use $\{q_i\}_{i=1}^{m}$ to represent a set of query nodes and $\{d_j\}_{j=1}^{n}$ a set of document nodes. We further define an $m \times n$ matrix W in which element W_{ij} represents the click count associated with (q_i, d_j). This matrix can be normalized to be a query-to-document transition matrix, denoted by A, where $A_{ij} = p^{(1)}(d_j|q_i)$ is the probability that q_i transits to d_j in one step. Similarly, we can normalize the transpose of W to be a document-to-query transition matrix, denoted by B, where $B_{j,i} = p^{(1)}(q_i|d_j)$. It is easy to see that using A and B we can compute the probability of transiting from any node to any other node in k steps. In this work, we use a simple measure which is the probability that one query transits to another in two steps, and the corresponding probability matrix is given by AB.

We used this probability and ranked all pairs of queries in the same raw query logs as in the query session data described above to generate additional candidates for term variation pairs. 20,308,693 pairs were extracted after applying the count cutoff of 5, generating on average 6.8 candidates for 2,973,036 unique queries.

It is interesting to note that these two data extracts are quite complementary: of all the data generated, only 4.2% of the pairs were found in both the session and click-through data. We believe that this diversity is attributable to the nature of the extracts: the session data tends to collect the term pairs that are issued by the same user as a result of conscious re-writing effort, such as typing error corrections and query specifications (Categories 1 and 11 in Table 1), while the click-though data collects the terms issued by different users, possibly with different intentions, and tends to include many spelling variants, synonyms and queries with different specificity (Categories 2, 8, 10 and 11).

5.2 Features

We used the same set of features for the maximum entropy and MART models, which are given in Table 2. They are divided into three main types: string similarity features (1-16), semantic similarity features (17, 18), and character type features (19-39). Among the string similarity features, half of them are based on Levenshtein distance applied to surface forms (1-8), while the other half is based on Levenshtein and string-to-string edit distance metrics computed over the Romanized form of the query, reflecting its pronunciation. The conversion into Roman characters was done deterministically for kana characters using a simple mapping table. For Romanizing kanji characters, we used the function available from Windows IFELanguage API (version

[3] We consider each query as an unbreakable term in this paper, so term variation is equivalent to query variation.

String similarity features (16 real-valued features)
1. Lev distance on surface form
2. Lev distance on surface form normalized by *q1* length
3. Lev distance on surface form using character equivalence table
4. Lev distance on surface form normalized by *q1* length using character equivalence table

KataKanji, 31.KataRoman, 32. KataMixedNoKanji, 33. KataMixed, 34. KanjiRoman, 35. KanjiMixedNoKanji, 36. KanjiMixed, 37. RomanMixedNoKanji, 38. RomanMixed, 39. MixedNoKanjiMixed

Table 2: Classifier Features

2).[4] The character equivalence table mentioned in the features 3,4,7,8 is a table of 643 pairs of characters that are known to be equivalent, including kanji allography (same kanji in different graphical styles). The alpha-beta edit distance (11, 12, 15, 16) is the string-to-string edit distance proposed in Brill and Moore (2001), which we trained over about 60K parallel English-to-katakana Wikipedia title pairs, specifically to capture the edit operations between English and katakana words, which are different from the edit operations between two Japanese words. Semantic similarity features (17, 18) use the LLR score from the session data, and the click-though pair probability described in the subsection above. Finally, features 19-39 capture the script types of the query-candidate pair. We first defined six basic character types for each query or candidate: Hira (hiragana only), Kata (katakana only), Kanji (kanji only), Roman (Roman alphabet only), MixedNoKanji (includes more than one character sets but not kanji) and Mixed (includes more than one character sets with kanji). We then derived 21 binary features by concatenating these basic character type features for the combination of query and candidate strings. For example, if both the query and candidate are in hiragana, BothHira will be on; if the query is Mixed and the candidate is Roman, then RomanMixed will be on. Punctuation characters and Arabic numerals were treated as being transparent to character type assignment. The addition of these features is motivated by the assumption that appropriate types of edit distance operations might depend on different character types for the query-candidate pair.

Since the dynamic ranges of different features can be drastically different, we normalized each feature dimension to a normal variable with zero-mean and unit-variance. We then used the same normalized features for both the maximum entropy and the MART classifiers.

5.3 Training and Evaluation Data

In order to generate the training data for the binary classification task, we randomly sampled the query session (5,712 samples) and click-through data (6,228 samples), and manually labeled each pair as positive or negative: the positive label was assigned when the term pair fell into Categories 1 through 5 in Table 1; otherwise it was assigned a negative label. Only 364 (6.4%) and 244 (3.9%) of the samples were positive examples for the query session and click-through data respectively, which makes the baseline per-

[4] http://msdn.microsoft.com/en-us/library/ms970129.aspx. We took the one-best conversion result from the API. The conversion accuracy on a randomly sampled 100 kanji queries was 89.6%.

formance of the classifier quite high (always predict the negative label – the accuracy will be 95%). Note, however, that these data sets include term variation candidates much more efficiently than a candidate set generated by the standard method that uses an edit distance function with a threshold. For example, there is a query-candidate pair *q*=家風情報 *kafuujouhou* 'house-style information' *c*= 花 粉 情 報 *kafunjouhou* 'pollen information') in the session data extract, the first one of which is likely to be a misspelling of the second.[5] If we try to find candidates for the query 家風情報 using an edit distance function naively with a threshold of 2 from the queries in the log, we end up collecting a large amount of completely irrelevant set of candidates such as 台風情報 *taifuujouhou* 'typhoon information', 株情報 *kabu jouhou* 'stock information', 降雨情報 *kouu jouhou* 'rainfall information' and so on – as many as 372 candidates were found in the top one million most frequent queries in the query log from the same period; for rarer queries these numbers will only be worse. Computing the edit distance based on the pronunciation will not help here: the examples above are within the edit distance of 2 even in terms of Romanized strings.

Another advantage of generating the annotated data using the result of query log data mining is that the annotation process is less prone to subjectivity than creating the annotation from scratch. As Cucerzan and Brill (2004) point out, the process of manually creating a spelling correction candidate is seriously flawed as the intention of the original query is completely lost: for the query *gogle*, it is not clear out of context if the user meant *goggle*, *google*, or *gogle*. Using data mined from query logs solves this problem: an annotator can safely assume that if *gogle-goggle* appears in the candidate set, it is very likely to be a valid term variation intended by the user. This makes the annotation more robust and efficient: the inter-annotator agreement rate for 2,000 query pairs by two annotators was 95.7% on our data set, each annotator spending only about two hours to annotate 2,000 pairs.

5.4 Results and Discussion

In order to compare the performance of two classifiers, we first built maximum entropy and MART classifiers as described in Section 4 using all the features in Section 5.2. We run five experiments using different random split of training and test data: in each run, we used 10,000 samples for training and the remaining 1,940 samples for testing, and measured the performance of the two classifiers on the task of term variation identification in terms of the error rate i.e., 1–accuracy. The results, average over five runs, were 4.18 for the maximum entropy model, and 3.07 for the MART model. In all five runs, the MART model outperformed the maximum entropy classifier. This is not surprising given the superior performance of tree-boosting algorithms previously reported on similar classification tasks (e.g., Hastie et al., 2001). In our task where different types of features are likely to perform better when they are combined (such as semantic features and character types features), MART would be a better fit than linear classifiers because the decision trees generated by MART optimally combines features in the local sense. In what follows, we only discuss the results produced by MART for further experiments. Note that the baseline classifier, which always predicts the label to be negative, achieves 95.04% in accuracy (or 4.96% error rate), which sounds extremely high, but in fact this baseline classifier is useless for the purpose of collecting term variations, as it learns none of them by classifying all samples as negative.

Features	Error rate (%)
A. All features (1-39 in Table 2)	3.07
B. String features only (1-16)	3.49
C. Surface string features only (1-8)	4.9
D. No semantic feats (1-16,19-39)	3.28
E. No character type feats (1-18)	3.5

Table 3: Results of Features Ablation Experiments Using MART Model

For evaluating the contribution of different types of features in Section 5.2, we performed feature ablation experiments using MART. Table 3 shows the results in error rate by various MART classifiers using different combination of features. The results in this table are also averaged over five run with random training/test data split. From Table 3, we can see that the best performance was achieved by the model using all features (line A of the table), which reduces the baseline error rate (4.96%) by 38%. The improvement is statistically significant according to the McNemar test ($P < 0.05$). Models that use string edit distance features only (lines B and C) did not perform well: in particular, the model that uses surface edit distance features only

[5] 家風情報 does not make any sense in Japanese; on the other hand, information about cedar pollen is commonly sought after in spring due to widespread pollen allergy.

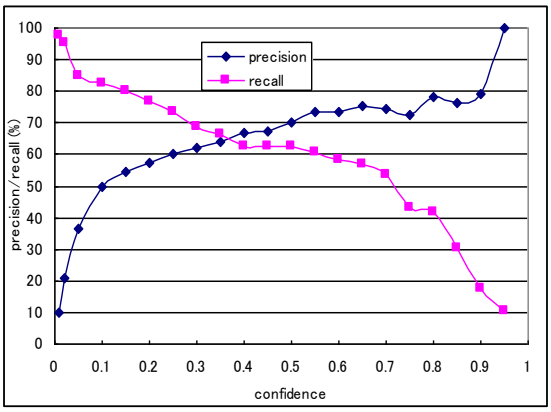

Figure 2: Precision/Recall Curve of MART

without considering the term pronunciation performed horribly (line C), which confirms the results reported by Jones et al. (2006b). However, unlike Jones et al. (2006b), we see a positive contribution of semantic features: the use of semantic features reduced the error rate from 3.28 (line D) to 3.07 (line A), which is statistically significant. This may be attributable to the nature of semantic information used in our experiments: we used the user session and click-though data to extract semantic knowledge, which may be semantically more specific than the probability of word substitution in a query collection as a whole, which is used by Jones et al. (2006b). Finally, the character type features also contributed to reducing the error rate (lines A and E). In particular, the observation that the addition of semantic features without the character type features (comparing lines B and E) did not improve the error rate indicates that the character type features are also important in bringing about the contribution of semantic features.

Figure 2 displays the test data precision/recall curve of one of the runs of MART that uses all features. The x-axis of the graph is the confidence score of classification $P(c|q)$, which was set to 0.5 for the results in Table 3. At this confidence, the model achieves 70% precision with the recall slightly higher than 60%. In the graph, we observe a familiar trade-off between precision and recall, which is useful for practical applications that may favor one over the other.

In order to find out where the weaknesses of our classifiers lie, we performed a manual error analysis on the same MART run whose results are shown in Figure 2. Most of the classification errors are false negatives, i.e., the model failed to predict a case of term variation as such. The most conspicuous error is the failure to capture abbreviations, such as failing to capture the alteration between 十条中学校 *juujoochuugakkou* 'Juujoo middle school' and 十条中 *juujoochuu*, which our edit distance-based features fail as the length difference between a term and its abbreviation is significant. Addition of more targeted features for this subclass of term variation (e.g., Okazaki et al., 2008a) is called for, and will be considered in future work. Mistakes in the Romanization of kanji characters were not always punished as the query and the candidate string may contain the same mistake, but when they occurred in either in the query or the candidate string (but not in both), the result was destructive: for example, we assigned a wrong Romanization on 水銀燈 as *suiginnakari* 'mercury lamp', as opposed to the correct *suiginntou*, which causes the failure to capture the alteration with 水銀痘 *suiginntou*, (a misspelling of 水銀燈). Using N-best (N>1) candidate pronunciations for kanji terms or using all possible pronunciations for kanji characters might reduce this type of error. Finally, the features of our models are the edit distance functions themselves, rather than the individual edit rules or operations. Using these individual operations as features in the classification task directly has been shown to perform well on spelling correction and normalization tasks (e.g., Brill and Moore, 2000; Okazaki et al., 2008b). Okazaki et al.'s (2008b) method of generating edit operations may not be viable for our purposes, as they assume that the original and candidate strings are very similar in their surface representation – they target only spelling variants and inflection in English. One interesting future avenue to consider is to use the edit distance functions in our current model to select a subset of query-candidate pairs that are similar in terms of these functions, separately for the surface and Romanized forms, and use this subset to align the character strings in these query-candidate pairs as described in Brill and Moore (2000), and add the edit operations derived in this manner to the term variation identification classifier as features.

6 Conclusion

In this paper we have addressed the problem of acquiring term variations in Japanese query logs for the purpose of query expansion. We generate term variation candidates efficiently by mining query log data, and our best classifier, based on the MART algorithm, can make use of both edit-distance-based and semantic features, and can identify term variation with the precision of 70% at the recall slightly higher than 60%. Our next

goal is to use and evaluate the term variation collected by the proposed method in an actual search scenario, as well as improving the performance of our classifier by using individual, character-dependent edit operations as features in classification.

Abstract

Argumentative Zoning (AZ) is an analysis of the argumentative and rhetorical structure of a scientific paper. It has been shown to be reliably used by independent human coders, and has proven useful for various information access tasks. Annotation experiments have however so far been restricted to one discipline, computational linguistics (CL). Here, we present a more informative AZ scheme with 15 categories in place of the original 7, and show that it can be applied to the life sciences as well as to CL. We use a domain expert to encode basic knowledge about the subject (such as terminology and domain specific rules for individual categories) as part of the annotation guidelines. Our results show that non-expert human coders can then use these guidelines to reliably annotate this scheme in two domains, chemistry and computational linguistics.

1 Introduction

Teufel et al. (1999) define the task of Argumentative Zoning (AZ) as a sentence-by-sentence classification with mutually exclusive categories from the annotation scheme given in Fig. 1. The reasoning behind the categories is inspired by the notion of a *knowledge claim* (Myers, 1992; Luukkonen, 1992): the act of writing a paper corresponds to an attempt of claiming ownership for a new piece of knowledge, which is to be integrated into the repository of scientific knowledge in the authors' field by the process of peer review and publication. In the cause of this process, the authors have to convince the reviewers that the knowledge claim of the paper is valid (Swales, 1990; Hyland, 1998). What AZ aims to model, then, are some of the relevant stages in this argument. We divide the paper into *zones*, OTHER, OWN and BACKGROUND. These are defined on the basis of who owns the knowledge claim in the corresponding segment. There are also two categories which are defined by their relationship to existing work, BASIS and CONTRAST. That means that parts of the AZ scheme are similar to citation function classification schemes from the area of citation content analysis (Garfield, 1965; Weinstock, 1971; Spiegel-Rüsing, 1977), and to automatic citation function classification (Nanba and Okumura, 1999; Garzone and Mercer, 2000; Teufel et al., 2006). The remaining categories, AIM and TEXTUAL, fulfil different rhetorical functions for the presentation of the paper. AIM points out the paper's main knowledge claim, a rhetorical move which may be repeated in the conclusion and the introduction. TEXTUAL explains the physical location of information, e.g., by giving a section overview or presenting a summary of a subsection. On the basis of human-annotated training material, AZ can be automatically classified using supervised machine learning.

Category	Description
AIM	Statement of research goal.
BACKGROUND	Description of generally accepted background knowledge.
BASIS	Existing KC provides basis for new KC.
CONTRAST	An existing KC is contrasted, compared, or presented as weak.
OTHER	Description of existing KC.
OWN	Description of any other aspect of new KC.
TEXTUAL	Indication of paper's textual structure.

Figure 1: AZ Annotation Scheme (Teufel et al. 1999).

Rhetorical information marking is useful for

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1493–1502,
Singapore, 6-7 August 2009.

many novel information access tasks. For instance, information retrieval can profit from rhetorical information in the form of paradigm shift statements (Chichester et al., 2005), as papers containing such statements have a high impact in an area. 75% of the "Faculty of 1000 Biology" papers (which are chosen by experts for their special importance) contain paradigm shift sentences (Agnes Sandor, personal communication).

AZ annotation allows the construction of multi- and single document summaries which concentrate on differences and similarities to related (cited) work. AZ can also be used for search in a data base of scientific articles, in particular for enhanced citation indexing. This has been previously explored in a task-based evaluation, were users were asked to list positive and negative citations they would expect in a paper, given a short extract (Teufel, 2001). In that task, AZ-based extracts outperformed other document surrogates.

Feltrim et al. (2005) present a writing support system which analyses students' drafts of summaries for their PhD theses, performs an AZ analysis on them and critiques the rhetorical structure of the students' draft on the basis of it.

The definition of the AZ categories is based on rhetorical principles and should be decidable, in principle, without specific domain knowledge about what is discussed in detail in the paper. We present here the first evidence that AZ categories can be reliably recognised across scientific disciplines, using chemistry and computational linguistics as our model disciplines for these experiments.

The categories just introduced are abstract and depend on the annotators' interpretation of a rhetorical argument. This means that there is no guarantee that several independent annotators would annotate similarly. It is therefore crucial that all annotations at a high level of interpretation are backed up by human annotation with more than one annotator. However, annotations of citation function classification typically use only the untested annotation of a single human annotator as gold standard, who is typically the designer of a scheme (Spiegel-Rüsing, 1977; Weinstock, 1971; Nanba and Okumura, 1999; Garzone and Mercer, 2000). Teufel et al. (2006) are the only exception who test their citation function scheme using modern corpus-linguistic annotation methodology.

A study of human agreement on AZ annotation exists (Teufel et al., 1999), but this uses articles from only one discipline, namely computational linguistics. In this paper, we use a similar methodology to Teufel et al., but with data from two disciplines. The preliminary conclusion from these experiments is that annotation with chemistry papers has resulted in higher agreement than annotation with computational linguistics papers.

We extend the AZ annotation scheme to make further distinctions, as will be discussed in section 2. We also created an environment in which domain knowledge that an annotator might have about the science in a paper is systematically disregarded. We will describe how this was done in section 3, and then present the annotation experiment itself in section 4.

2 Changes to the AZ Scheme

Argumentative Zoning II (AZ-II) is a new annotation scheme, which is an elaboration of the original AZ scheme. It is presented in Fig. 2. Our annotation guidelines are 111 sides of A4 and contain a decision tree, detailed description of the semantics of the 15 categories, 75 rules for pairwise distinction of the categories and copious examples from both chemistry and computational linguistics. During guideline development, 70 chemistry papers and 20 CL papers were used, which are distinct from the ones used for annotation. It took 3 months part-time-work to prepare the guidelines for CL, and substantially less time to adapt them for chemistry. We have made them available at `www.cl.cam.ac.uk/research/nl/sciborg`.

The differences between the original AZ and AZ-II are as follows:

- Category AIM remained the same.
- Category BACKGROUND was renamed CO_GRO, or common ground.
- Category OTHER was split into other people's work (OTHR) and the authors' own previous work (PREV_OWN).
- Category BASIS was split into usage (USE) and support (SUPPORT).
- Category CONTRAST was split into neutral comparison (CODI), contradiction (ANTISUPP), and a category combining research gaps with criticism (GAP_WEAK).
- Category OWN was split into description of method (OWN_MTHD), results (OWN_RES) and conclusions (OWN_CONC), and a category which specifies recoverable errors made by the authors (OWN_FAIL).

Category	Description	Category	Description
AIM	Statement of specific research goal, or hypothesis of current paper	OWN_CONC	Findings, conclusions (non-measurable) of own work
NOV_ADV	Novelty or advantage of own approach	CODI	Comparison, contrast, difference to other solution (neutral)
CO_GRO	No knowledge claim is raised (or knowledge claim not significant for the paper)	GAP_WEAK	Lack of solution in field, problem with other solutions
OTHR	Knowledge claim (significant for paper) held by somebody else. Neutral description	ANTISUPP	Clash with somebody else's results or theory; superiority of own work
PREV_OWN	Knowledge claim (significant) held by authors in a previous paper. Neutral description.	SUPPORT	Other work supports current work or is supported by current work
OWN_MTHD	New Knowledge claim, own work: methods	USE	Other work is used in own work
OWN_FAIL	A solution/method/experiment in the paper that did not work	FUT	Statements/suggestions about future work (own or general)
OWN_RES	Measurable/objective outcome of own work		

Figure 2: AZ-II Annotation Scheme.

- Category TEXTUAL was discontinued, because it is less informative than the other categories.
- Two new categories were introduced, NOV_ADV (advantages of the new knowledge claim) and FUT (declaration of limitations or future work).

Our AZ-II categories are more fine-grained than the original AZ categories. The reasons for this are twofold: To bring AZ closer to contemporary citation function schemes, and to incorporate distinctions recently found useful by other researchers. For instance, Chichester et al. (2005) argue that ANTISUPP is particularly important. The finer grain in AZ-II has been accomplished purely by splitting existing AZ categories; hence, the coarser AZ categories are recoverable (with the exception of the TEXTUAL category). Annotation examples are given in the appendix.

As in AZ, citations are an important but not necessarily decisive cue for a sentence to belong to a particular zone. The guidelines mention citations as one factor in deciding whether a knowledge claim holds, and citations occur in several examples, so it is likely that the presence of citations would have influenced annotators in their decision.

Of the changes, the distinction which is likely to have the greatest impact on the annotation is the split of OWN according to the stage of the authors' problem solving process – into methods, results, conclusion or local failure. In most life sciences, descriptions of research as a problem solving process are a dominant phenomenon, whereby problem-solving descriptions can be of differing length and embeddedness. For instance, in synthetic chemistry, the starting compound for the main synthesis in the paper may first have to be synthesised itself (if it is not commercially available, for instance). In that case, arriving at the compound is an intermediate, smaller problem-solving process which enables the larger problem-solving process that represents the new KC.

The original AZ scheme didn't mark the distinction, possibly because it is not as easily observable in CL as it is in the life sciences, and because problem-solving stages were not part of the main analytic interest of AZ, which focused on how scientific argumentation is related to descriptions of own and other work. Also, neither of the traditional AZ applications (summarisation or citation indexing) had any direct use for the subdivided categories. But in the life sciences, there are applications which would make use of such a subdivision. For instance, in chemistry there is a niche for search applications which guide searchers directly to the method and/or result sections in papers. Specifically, the OWN_FAIL category is motivated by the failure–and–recovery search. In text, OWN_FAILmarks cases where the authors helpfully mention in passing steps which were found not to work during a long synthetic procedure (often the 'total synthesis' of a compound which is found in nature). Such cases happen frequently, and are generally followed by a 'recovery' statement which explains how the problem can be avoided. Another possible application that calls for a subdivision is Feltrim et al.'s

(2005) rhetorical writing system for novice writers. It trains novices in writing rhetorically well-formed abstracts and therefore must have a way of distinguishing, for instance, between methods and results.

Note that several of the applications based on AZ and AZ-II in general rely on the rare categories much more than they rely on the more frequent categories. OWN_FAIL is an example of a rare but important category, and so is AIM, which is central to summarisation applications. The comparative and contrastive categories CODI ANTISUPP and GAP_WEAK, on the other hand, are particularly useful to citation-based search applications.

Other AZ-like schemes for scientific discourse created for the biomedical domain (Mizuta and Collier, 2004) and for computer science (Feltrim et al., 2005) also made the decision to subdivide OWN, in similar ways to how we propose here. The current work, however, is the first experimental proof that humans can make this distinction – and the others encoded in AZ-II – reliably, and in two quite distinct disciplines.

3 Discipline-Independent Non-Expert Annotation

An important principle of AZ is that its categories can be decided without domain knowledge. This rule is anchored in the guidelines: when choosing a category, no reasoning about the scientific facts is allowed. The avoidance of domain-knowledge has its motivation in a strategy for a hypothetical automatic text-understanding system for unrestricted texts. Given the state of the art in text processing and knowledge representation, text understanding systems should in our opinion use general, rhetorical, and logical aspects of the text, rather than attempting to recognise or represent the scientific knowledge contained in the text. What the human annotation – the gold standard – should then do is to simulate the best possible output that such a system could theoretically create.

Annotators may use only general, rhetorical or linguistic knowledge; knowledge which is shared by all proficient speakers of a language. The guidelines spell out what is meant by these general principles. For instance, one can use lexical and syntactic parallelism in a text to infer that the authors were setting up a comparison between themselves and some other approach.

There is, however, a problem with annotator expertise and with the exact implementation of the "no domain knowledge" principle. This problem does not become apparent until one starts working with disciplines where at least some of the annotators or guideline developers are not domain experts (chemistry, in our case). Domain experts naturally use scientific knowledge and inference when they make annotation decisions. It would be unrealistic to expect them to be able to disregard their domain knowledge simply because they were *instructed* to do so. Additionally, when all annotators/scheme developers are domain experts, it is hard to even notice the cases where they "accidentally" use domain knowledge during annotation. We therefore artificially created a situation where all annotators are "semi-informed non-experts", which forces them to comply with the principle, namely by the following rules:

Justification: Annotators have to justify all annotation decisions by pointing to some text-based evidence, and by giving the section heading in the guidelines that describes the particular reason for assigning the category. General discipline-specific knowledge an annotator may happen to have is excluded as justification. Annotators' justifications have to be typed into the annotation tool and are open to challenge during the training phase. Much of the allowable justification comes in the form of general and linguistic principles, e.g., an explicit cue phrase, the title, or the structural similarity of textual strings. For instance, annotators are allowed to infer that process-VPs in the title are likely to be the contribution (knowledge of the actual concrete contribution of a paper is a requirement for annotation of AIM).

Discipline-specific Generics: The guidelines contain a section with high-level facts about the general research practices in the discipline. These generics constitute the only *scientific* knowledge which is acceptable as a justification, and are aimed to help non-expert annotators recognise how a paper might relate to already established scientific knowledge, so that they will be able to avoid common mistakes about the knowledge claim status of a certain fact. For instance, the better they are able to distinguish what is commonly known from what is newly claimed by the authors, the more consistent their annotation will be.

Annotation with expert-trained non-expert annotators means that a domain expert must be available initially, during the development of the anno-

tation scheme and the guidelines, either as a co-developer or as an informant. The domain expert's job is to describe scientific knowledge in that domain in a general way, in as far as it is necessary for the scheme's distinctions, and to write the domain-specific rules for the individual categories, including the choice of example sentences. This means that the guidelines are split into a domain-general and a domain-specific part.

The discipline-specific generics in chemistry come in the form of a "chemistry primer", a 10-page collection of high-level scientific domain knowledge. It contains: a glossary of words a non-chemist would not have heard about or would not necessarily recognise as chemical terminology; a list of possible types of experiments performed in chemistry; a list of commonly used machinery; a list of non-obvious negative characterisations of experiments and compounds ("sluggish", "inert"); and a list of possible types of knowledge claims. For instance, in chemistry each chemical substance mentioned can have in principle a knowledge claim associated with its discovery or invention – with the exception of water, rock salt, the metals known in prehistory and a few others. If a compound or process is however considered to be so commonly used that it is in the "general domain" (e.g., "the Stern–Volmer equation" or "the Grignard reaction"), it is no longer associated with somebody's knowledge claim, and as a result its usage is not to be marked with category USE.

Descriptions of individual categories can have domain-specific subsections, as well as the general ones. For instance, if the text states that the authors could not replicate a published result, the guidelines describe the cases when this is the authors' fault (OWN_FAIL) in contrast to the cases where this is an indirect accusation of the previous experiment (ANTISUPP).

Another potentially unclear distinction is between results (OWN_RES) and conclusions (OWN_CONC). The difference is defined on the basis of how much reasoning is necessary to be able to make the statement concerned. If all the authors did was to read a measurement off an instrument, the label OWN_RES applies. Reasoning points to OWN_CONC; it is sometimes linguistically marked ("therefore", "we conclude", "this means that"), but in many cases, domain knowledge may be required to decide whether reasoning was necessary to make a certain statement. Possible OWN_RES statements, according to the chemistry primer, include: statements of simple numerical result; descriptions of graphs; descriptions of atoms' positions in three-dimensional space; statements of trends, unless a reason for these results is given; comparisons of results of more than one experiment, unless a reason for these results is given.

The chemistry primer also lists phenomena which in a typical experiment would be read off chemical machinery (e.g., "Stark effect"). This list gives the non-expert annotator an objective criterion to answer the question how likely it is that a certain statement by the authors was arrived at by inference. We also found that our list of phenomena which can be read off machinery, which was compiled from the first 30 papers, generalised well to the other 40 papers considered.

The chemistry primer is not an attempt to summarise all methods and experimentation types in chemistry; this would be impossible to do, certainly in a few pages. Rather, it tries to answer many of the high-level questions a non-expert would have to an expert, in the framework of AZ.

This methodology allows to hire expert and non-expert annotators and bring them in line with each other. We believe it could be expanded relatively easily into many other disciplines, using domain experts which create similar primers for genetics, experimental physics, cell biology, but re-using the bulk of the guidelines.

4 Annotation Experiments

The annotators were the co-developers of the annotation scheme and the authors of this paper. Whereas all three annotators have good background knowledge in CL, the largest difference between them concerns their expertise in chemistry: Annotator A is a PhD-level chemist, Annotator B has two years' of undergraduate training in chemistry and can therefore be considered a chemical semi-expert, and Annotator C has no specialised chemistry knowledge.

As agreement measure we choose the Kappa coefficient κ (Fleiss, 1971; Siegel and Castellan, 1988), the agreement measure predominantly used in natural language processing research (Carletta, 1996). κ corrects raw agreement $P(A)$ for agreement by chance $P(E)$:

$$\kappa = \frac{P(A)-P(E)}{1-P(E)}$$

No matter how many items or annotators, or how the categories are distributed, $\kappa = 0$ when there is no agreement other than what would be expected by chance, and $\kappa = 1$ when agreement is perfect. If two annotators agree *less* than expected by chance, κ can also be negative. Chance agreement $P(E)$ is defined as the level of agreement which would be reached by random annotation using the same distribution of categories as the real annotators. All work done here is reported in terms of Fleiss' κ. [1] κ is also designed to abstract over the number of annotators as its formula relies on the proportion of expected vs. observed *pairwise* agreements possible in a pool. That is, κ for k annotators will be an average of the values of κ taking all possible m-tuples of annotators from the annotator pool (with $m < k$). As a side effect of its definition of random agreement, κ treats agreement in a rare category as more surprising, and rewards such agreement more than an agreement in a frequent category. This is a desirable property, because we are more interested in the performance of the rare rhetorical categories than we are in the performance of the more frequent zone categories.

4.1 Data

For chemistry, 30 random-sampled papers from journals published between 2004 and 2007 by the Royal Society of Chemistry were used for annotation[2]. The papers cover all areas of chemistry and some areas close to chemistry, such as climate modelling, process engineering, and a double-blind medical trial. The data used for the experiment contains a total of 3745 sentences.

For computational linguistics, 9 papers were annotated, with a total of 1629 sentences. The papers were published between 1998 and 2001 at ACL, EACL or EMNLP conferences, and were taken from the Computation and Language archive. Both chemistry and CL papers were automatically sentence-split, with manual correction of errors; acknowledgement sections were disregarded. A web-based annotation tool was used for guideline definition and for annotation.

Category	Chem	CL	Category	Chem	CL
OWN_MTHD	25.4	55.6	SUPPORT	1.5	0.7
OWN_RES	24.0	5.6	GAP_WEAK	1.1	1.0
OWN_CONC	15.1	10.7	FUT	1.0	1.4
OTHR	8.3	10.0	NOV_ADV	1.0	0.8
USE	7.9	2.7	CODI	0.8	1.2
CO_GRO	6.7	5.7	OWN_FAIL	0.8	0.1
PREV_OWN	3.4	1.7	ANTISUPP	0.5	0.6
AIM	2.3	1.8			

Figure 3: Frequency of AZ-II Categories (in %).

Our choice of which data sets to use was effected by the relative length of papers more than by the journal/conference distinction. Average article length between chemistry journal articles (3650 words/paper) and CL conference articles (4219 words/paper) is comparable, so conference articles in CL seem a much better choice for comparative work than journal publications, which are often very long in CL. Additionally, conferences have a high profile in CL, and we found the conference publications to be of high editorial quality. We are nevertheless interested in the structure of longer journal articles, and plan to investigate CL journals in the future.

The annotations were done using a web-based annotation tool. Every sentence is assigned a category. No communication between the annotators was allowed.

4.2 Results

The inter-annotator agreement for chemistry was κ = 0.71 (N=3745,n=15,k=3). For CL, the inter-annotator agreement was κ = 0.65 (N=1629,n=15,k=3). For comparison, the inter-annotator agreement for the original, CL-specific AZ with 7 categories was κ = 0.71 (N=3420,n=7,k=3). Given the subjective nature of the task and the fact that AZ-II introduces additional distinctions, the AZ-II agreement can be considered acceptable for CL and relatively high for chemistry. Additionally, chemistry annotation used one non-expert annotator, who had no chemistry-specific domain knowledge apart from that in the chemistry primer.

The distribution of categories for the two disciplines is given in Fig. 3. As expected, there is a large discrepancy in frequency between the (rare) rhetorical categories and the (much more frequent) zone categories OWN_MTHD, OWN_RES,

[1] Artstein and Poesio (2008) observe that there are several version of κ which differ in how $P(E)$ is calculated. In particular, Fleiss' (1971) κ calculates $P(E)$ as the average observed distribution of all annotators, whereas Cohen's (1960) κ calculates $P(E)$ only on the basis of the other annotator(s).

[2] 100 papers across a spread of disciplines from the January 2004 issues of the RSC were selected blindly (but with an attempt to cover most areas of chemistry). 30 out of these were random sampled for annotation; the rest were used for annotation development.

OWN_CONC, OTHR and CO_GRO. For supervised learning, too few examples of any category can be a problem. There are methods which attempt to reduce the annotation effort by using a trained classifier to suggest possible cases to a human. However, the classifier can only find examples similar to the ones that have already been manually classified, when the real problem is a recall-problem, i.e., the challenge is to find more new examples in the multitude of possible sentences. To solve this in a fundamentally sound way, there seems to be no other way than to annotate more texts, at the cost of more human effort.

If we consider the differences across disciplines, the most striking ones concern the distribution of OWN_MTHD, which is more than twice as common in CL (56% v. 25%), and OWN_RES, which is far more common in chemistry overall (24% v 5.6%). Usage of other people's knowledge claims or materials also seems to be more common in chemistry, or at least more explicitly expressed (7.9% vs 2.7%). With respect to the shorter, rarer categories, there is a marked difference in OWN_FAIL (0.1% in CL, but 0.8% in chemistry[3] and SUPPORT, which is more common in chemistry (1.5% vs 0.7%). However, this effect is not present for ANTISUPP (contradiction of results), the "reverse" category to SUPPORT, (0.6% in CL vs 0.5% in chemistry).

As far as the chemistry annotation is concerned, it is interesting to find out whether Annotator A was influenced during annotation by domain knowledge which Annotator C did not have, and Annotator B had to a lower degree[4]. We therefore calculated pairwise agreement, which was $\kappa_{\mathrm{AC}} = 0.66$, $\kappa_{\mathrm{BC}} = 0.73$ and $\kappa_{\mathrm{AB}} = 0.73$ (all: N=3745,n=15,k=2). That means that the largest disagreements were between the non-expert (C) and the expert (A), though the differences are modest. This might point to the fact that Annotators A and B might have used a certain amount of domain-knowledge which the chemistry primer in the guidelines does not yet, but should, cover.

In an attempt to determine how well categories are defined, we first consider the binary distinction between zone categories (OWN_MTHD, OWN_RES, OWN_CONC, OWN_FAIL, OTHR, PREV_OWN and CO_GRO) and rhetorical categories (the other 8). This shows an inter-annotator agreement of κ_{binary} = 0.78 (N=3745, n=2, k=3) for chemistry and κ_{binary} = 0.65 (N=1629, n=2, k=3) for CL, indicating that annotators find it relatively easy (chemistry) or at least not more difficult than the overall distinction (CL) to distinguish these two types of categories. We next perform Krippendorff's (1980) category distinctions (Fig. 4). Here, all categories apart from the one diagnosed are collapsed, and what is reported is the difference of inter-annotator agreement when compared to the overall distinctiveness (κ=0.71 for chemistry, κ=0.65 for CL). Where the difference is positive, the annotators could distinguish the given category better than they could distinguish all categories, and where they are negative, correspondingly worse.[5]

The results confirm that categories USE, AIM, OWN_MTHD, OWN_RES and FUT are particularly well distinguished in both disciplines. This is a positive result, as these categories are important for several types of searches. In these cases the guidelines seem to fully suffice for their description, but then again good performance of AIM, FUT and USE is not that surprising, as they are signalled clearly by linguistic and non-linguistic cues. However, there are three categories with particularly low distinguishability in both disciplines: ANTISUPP, OWN_FAIL and PREV_OWN. As ANTISUPP and OWN_FAIL are crucial for the envisaged downstream tasks, the problems with their definition should be identified and fixed. We are in the process of systematically troubleshooting the guidelines for those categories.

The table also shows that category definition has discipline-specific problems. For instance, we believe that the fact that distinctiveness for OWN_FAIL is so bad for CL must be due to the fact that we only encountered very few potential OWN_FAIL cases in this domain. The definition of the categories SUPPORT and NOV_ADV also seem to be substantially more confusing for CL than for chemistry. However, CODI is a category which shows average distinctiveness for CL, but much worse distinctiveness for chemistry. We believe this is due to the fact that comparisons of

[3]These are not large differences in absolute terms – 55 items identified as OWN_FAIL by at least one annotator in chemistry, vs. 7 such items in CL, the relative difference is large and confirms that in chemistry papers, particularly descriptions of synthesis procedures, OWN_FAIL cases appear relatively frequently.

[4]This question does not arise in the case of CL, as all annotators can be considered experts in this respect.

[5]All κ values for chemistry were measured with N=3745, n=2, k=3; for CL with N=1629, n=2, k=3.

methods and approaches are more common in CL and are clearly expressed, whereas in chemistry the objects that are involved in comparisons are more varied and at a lower grade of abstraction (e.g., compounds, properties of compounds, coefficients, etc.), which obviously has a negative effect on the distinctiveness of this category.

Category	Chem	CL	**Category**	Chem	CL
USE	+0.12	+0.00	NOV_ADV	-0.07	-0.23
AIM	+0.09	+0.08	OWN_CONC	-0.08	-0.13

SUPPORT	-0.04	-0.12	CODI	-0.36	+0.00
OTHR	-0.06	+0.07			

Figure 4: Krippendorff's Diagnostics for Category Distinction (κ, relative to Overall Distinctiveness).

We also provide a direct comparison of our annotation results with those from the original AZ scheme. Comparisons between two similar annotation schemes can be made by collapsing those categories in each scheme which are not distinguished in the other scheme. Such a comparison can of course only ever approximate the smallest common denominator between two schemes.

The AZ-II categories were collapsed into a set of six categories that closely resemble AZ categories, as described in section 2 (with OWN simulated by the union of OWN_FAIL, OWN_MTHD, OWN_RES, OWN_CONC, FUT, and NOV_ADV). This created a 6-category AZ annotation.

As TEXTUAL is not marked up in AZ-II, the original AZ annotation was also collapsed, by incorporating TEXTUAL examples into OWN. The two 6-pronged AZ-annotations are now more directly comparable. Inter-annotator agreement for the collapsed AZ-II showed κ = 0.75 (N=3745, n=6, k=3). This compares favourably to the collapsed AZ's agreement of κ = 0.71 (N=3420, n=6, k=3); but when comparing the raw numerical results one should consider that different data from different disciplines is used (chemistry in AZ-II, CL in AZ).

These results should be interpreted as a positive result for the domain-independence of AZ, and also for the feasibility of using trained non-experts as annotators. The additional work that went into the guidelines has produced annotation of a high consistency, even though AZ-II provides more distinctions (15 categories vs. 7 in AZ).

There is also the faint possibility that discourse annotation of chemistry is intrinsically easier than discourse annotation of CL, *because* it is a more established discipline and not despite of it. For instance, it is likely that the problem-solving categories OWN_FAIL, OWN_MTHD, OWN_RES and OWN_CONC are easier to describe in a discipline with an established methodology (such as chemistry), than they are in a younger, developing discipline such as computational linguistics.

5 Conclusion

Argumentative Zoning is an analysis of the rhetorical progression of the scientific argument in a paper. In this paper, we have made the following contributions to this analysis:

- We have presented a more informative scheme, which additionally recognises the structure of an experiment in terms of problem solving (method – results – conclusions) and makes more fine-grained distinctions in some of the sentiment-inspired relational categories (e.g., criticism and comparisons to other approaches).
- We introduced an annotation methodology which attempts to systematically exclude the use of annotators' extraneous domain knowledge from the annotation.
- We have experimentally shown that human coders can independently annotate this new AZ scheme in two distinct disciplines. Our results show inter-annotator agreements of κ=0.65 and κ=0.71 for computational linguistics and chemistry, respectively.

Overall, the outcome of this work indicates that the phenomena described in AZ can be defined in a domain-independent way. The experiment also tested how realistic the "expert-trained non-expert" approach to domain-knowledge free annotation is. The fact that the agreement between three annotators (an expert, a semi-expert, and a non-expert) is acceptable overall vindicate our task definition as domain-knowledge free (using the tools of justification and domain-specific generic knowledge). However, the agreements involving the semi-expert are higher than the agreement between expert and non-expert. This probably means that the chemistry generics were not fully adequate to ensure that the non-expert understood enough of the chemistry to achieve the highest-possible agreement.

The automation of AZ-annotation is underway. This requires adaptation of the high-level features used in AZ (Teufel and Moens, 2002) to chemistry. We are also preparing an annotation experiment with naive annotators. Another research avenue is the expansion of the guidelines to other disciplines such as bio-medicine, and to longer journal articles, e.g., in computational linguistics.

Character-level Analysis of Semi-Structured Documents for Set Expansion

Richard C. Wang

William W. Cohen
Machine Learning Department
Carnegie Mellon University
wcohen@cs.cmu.edu

Abstract

Set expansion refers to expanding a partial set of "seed" objects into a more complete set. One system that does set expansion is SEAL (Set Expander for Any Language), which expands entities automatically by utilizing resources from the Web in a language-independent fashion. In this paper, we illustrated in detail the construction of character-level wrappers for set expansion implemented in SEAL. We also evaluated several kinds of wrappers for set expansion and showed that character-based wrappers perform better than HTML-based wrappers. In addition, we demonstrated a technique that extends SEAL to learn binary relational concepts (e.g., "x is the mayor of the city y") from only two seeds. We also show that the extended SEAL has good performance on our evaluation datasets, which includes English and Chinese, thus demonstrating language-independence.

1 Introduction

SEAL[1] (Set Expander for Any Language) is a set expansions system that accepts input elements (seeds) of some target set S and automatically finds other probable elements of S in semi-structured documents such as web pages. SEAL is a research system that has shown good performance in previously published results (Wang and Cohen, 2007). By using only three seeds and top one hundred documents returned by Google, SEAL achieved 90% in mean average precision (MAP), averaged over 36 datasets from three languages: English, Chinese, and Japanese. Unlike other published research work (Etzioni et al., 2005), SEAL focuses on finding small closed sets of items (e.g., Disney movies) rather than large and more open sets (e.g., scientists).

In this paper, we explore the impact on performance of one of the innovations in SEAL, specifically, the use of character-level techniques to detect candidate regular structures, or *wrappers*, in web pages. Although some early systems for web-page analysis induce rules at character-level (e.g., such as WIEN (Kushmerick et al., 1997) and DIPRE (Brin, 1998)), most recent approaches for set expansion have used either tokenized and/or parsed free-text (Carlson et al., 2009; Talukdar et al., 2006; Snow et al., 2006; Pantel and Pennacchiotti, 2006), or have incorporated heuristics for exploiting HTML structures that are likely to encode lists and tables (Nadeau et al., 2006; Etzioni et al., 2005).

In this paper, we experimentally evaluate SEAL's performance under two settings: 1) using the character-level page analysis techniques of the original SEAL, and 2) using page analysis techniques constrained to identify only HTML-related wrappers. Our conjecture is that the less constrained character-level methods will produce more candidate wrappers than HTML-based techniques. We also conjecture that a larger number of candidate wrappers will lead to better performance overall, due to SEAL's robust methods for ranking candidate wrappers.

The experiments in this paper largely validate this conjecture. We show that the HTML-restricted version of SEAL performs less well, losing 13 points in MAP on a dozen Chinese-language benchmark problems, 8 points in MAP on a dozen English-language problems, and 2 points in MAP on a dozen Japanese-language problems.

SEAL currently only handles unary relationships (e.g., "x" is a mayor). In this paper, we show that SEAL's character-level analysis techniques can, like HTML-based methods, be read-

[1] http://rcwang.com/seal

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1503–1512,
Singapore, 6-7 August 2009.

ily extended to handle binary relationships. We then demonstrate that this extension of SEAL can learn binary concepts (e.g., "x is the mayor of the city y") from a small number of seeds, and show that, as with unary relationships, MAP performance is 26 points lower when wrappers are restricted to be HTML-related. Furthermore, we also illustrate that the learning of binary concepts can be bootstrapped to improve its performance.

Section 2.1 explains how SEAL constructs wrappers and rank candidate items for unary relations. Section 3 describes the experiments and results for unary relations. Section 4 presents the method for extending SEAL to handle binary relationships, as well as their experimental results. Related work is discussed in Section 5, and the paper concludes in Section 6.

2 SEAL

2.1 Identifying Wrappers for Unary Relations

When SEAL performs set expansion, it accepts a small number of *seeds* from the user (e.g., "Ford", "Nissan", and "Toyota"). It then uses a web search engine to retrieve some documents that contain these instances, and then analyzes these documents to find *candidate wrappers* (i.e., regular structures on a page that contain the seed instances). Strings that are extracted by a candidate wrapper (but are not equivalent to any seed) are called *candidate instances*. SEAL then statistically ranks the candidate instances (and wrappers), using the techniques outlined below, and outputs a ranked list of instances to the user.

One key step in this process is identifying candidate wrappers. In SEAL, a candidate wrapper is defined by a pair of left and right character strings, ℓ and r. A wrapper "extracts" items from a particular document by locating all strings in the document that are bracketed by the wrapper's left and right strings, but do not contain either of the two strings. In SEAL, wrappers are always learned from, and applied to, a single document.

Table 1 illustrates some candidate wrappers learned by SEAL. (Here, a wrapper is written as ℓ`[...]`r, with the `[...]` to be filled by an extracted string.) Notice that the instances extracted by wrappers can and do appear in surprising places, such as embedded in URLs or in HTML tag attributes. Our experience with these character-based wrappers lead us to conjecture that existing heuristics for identifying structure in HTML are fundamentally limited, in that many potentially useful structures will not be identified by analyzing HTML structure only.

SEAL uses these rules to find wrappers. Each candidate wrapper ℓ, r is a maximally long pair of strings that bracket at least one occurrence of every seed in a document: in other words, for each pair ℓ, r, the set of strings C extracted by ℓ, r has the properties that:

1. For every seed s, there exists some $c \in C$ that is equivalent to s; and
2. There are no strings ℓ', r' that satisfy property (1) above such that ℓ is a proper suffix of ℓ' and r is a proper prefix of r'.

SEAL's wrappers can be found quite efficiently. The algorithm we use has been described previously (Wang and Cohen, 2007), but will be explained again here for completeness. As an example, below shows a mock document, written in an unknown mark-up language, that has the seeds: Ford, Nissan, and Toyota located (and boldfaced). There are two other car makers hidden inside this document (can you spot them?). In this section, we will show you how to automatically construct wrappers that reveal them.

```

Given a set of seeds and a semi-structured document, the wrapper construction algorithm starts by locating all strings equivalent to a seed in the document; these strings are called *seed instances* below. (In SEAL, we always use case-insensitive string matching, so a string is "equivalent to" any case variant of itself.) The algorithm then inserts all the instances into a list and assigns a unique id to each of them by its index in the list (i.e., the id of an instance is its position in the list.)

For every seed instance in the document, its immediate left character string (starting from the first character of the document) and right character string (ending at the last character of the document) are extracted and inserted into a *left-context* trie and a *right-context* trie respectively, where the left context is inserted in reversed character order. (Here, we implemented a compact trie called

Table 1: Examples of wrappers constructed from web pages given the seeds: Ford, Nissan, Toyota.

Patricia trie where every node stores a substring.) Every node in the left-context trie maintains a list of ids for keeping track of the seed instances that follow the string associated with that node. Same thing applies to the right-context trie symmetrically. Figure 1 shows the two context tries and the list of seed instances when provided the mock document with the seeds: Ford, Nissan, and Toyota.

Provided that the left and right context tries are populated with all the contextual strings of every seed instance, the algorithm then finds maximally long contextual strings that bracket at least one seed instance of every seed. The pseudo-code for finding these strings for building wrappers is illustrated in Table 2, where $Seeds$ is the set of input seeds and ℓ is the minimum length of the strings. We observed that longer strings produce higher precision but lower recall. This is an interesting parameter that is worth exploring, but for this paper, we consider and use only a minimum length of one throughout the experiments. The basic idea behind the pseudo-code is to first find all the longest possible strings from one trie given some constraints, then for every such string s, find the longest possible string s' from another trie such that s and s' bracket at least one occurrence of every given seed in a document.

The wrappers constructed as well as the items extracted given the mock document and the example seeds are shown below. Notice that Audi and Acura are uncovered (did you spot them?).

Wrapper:	`xKH[...]xkr`
Content:	**audi**, ford, nissan, toyota
Wrapper:	`KxH[...]xjH`
Content:	**acura**, ford, nissan, toyota

Wrappers MakeWrappers(Trie ℓ, Trie r)
Return Wraps(l, r) $\cup$ Wraps(r, l)

Wrappers Wraps(Trie t_1, Trie t_2)
For each $n_1 \in$ TopNodes(t_1, ℓ)
For each $n_2 \in$ BottomNodes(t_2, n_1)
For each $n_1 \in$ BottomNodes(t_1, n_2)
Construct a new Wrapper(Text(n_1), Text(n_2))
Return a union of all wrappers constructed

Nodes BottomNodes(Trie t_1, Node n')
Find node $n \in t_1$ such that:
(1) NumCommonSeeds(n, n') == $|Seeds|$, and
(2) All children nodes of n (if exist) fail on (1)
Return a union of all nodes found

Nodes TopNodes(Trie t, int ℓ)
Find node $n \in t$ such that:
(1) Text(n).$length \geq \ell$, and
(2) Parent node of n (if exist) fails on (1)
Return a union of all nodes found

String Text(Node n)
Return the textual string represented by the path from root to n in the trie containing n

---

Integer NumCommonSeeds(Node n_1, Node n_2)
For each index $i \in$ Intersect(n_1, n_2):
Find the seed at index i of seed instance list
Return the size of the union of all seeds found

Integers Intersect(Node n_1, Node n_2)
Return $n_1.indexes \cap n_2.indexes$

Table 2: Pseudo-code for constructing wrappers.

Table 1 shows examples of wrappers constructed from real web documents. We have also observed items extracted from plain text (.txt), comma/tab-separated text (.csv/.tsv), latex (.tex), and even Word documents (.doc) of which the wrappers have binary character strings. These observations support our claim that the algorithm is independent of mark-up language. In our experimental results, we will show that it is independent of human language as well.

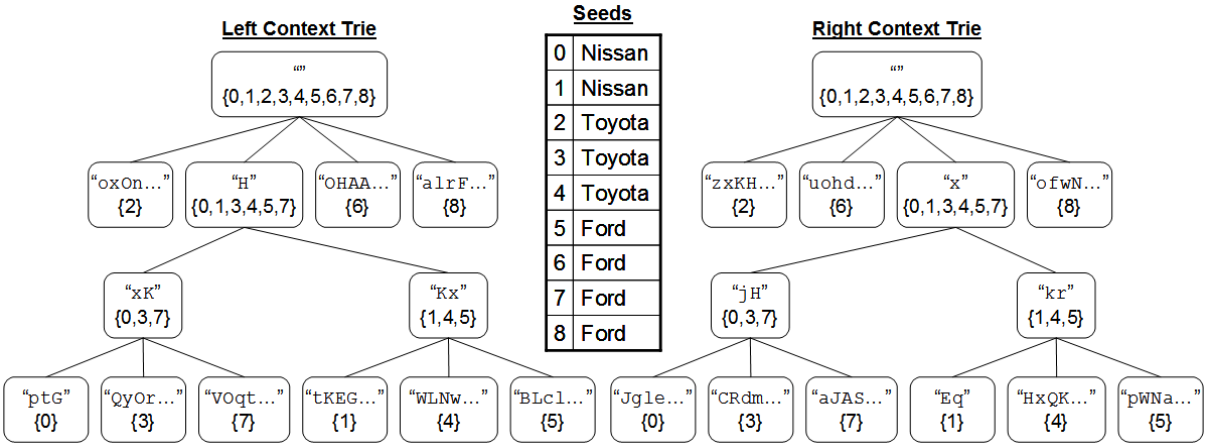

Figure 1: The context tries and the seed instance list constructed given the mock document presented in Section 2.1 and the seeds: Ford, Nissan and Toyota.

2.2 Ranking Wrappers and Candidate Instances

In previous work (Wang and Cohen, 2007), we presented a graph-walk based technique that is effective for ranking sets and wrappers. This model encapsulates the relations between documents, wrappers, and extracted instances (entity mentions). Similarly, our graph also consists of a set of nodes and a set of labeled directed edges. Figure 2 shows an example graph where each node d_i represents a document, w_i a wrapper, and m_i an extracted entity mention. A directed edge connects a node d_i to a w_i if d_i contains w_i, a w_i to a m_i if w_i extracts m_i, and a d_i to a m_i if d_i contains m_i. Although not shown in the figure, every edge from node x to y actually has an inverse relation edge from node y to x (e.g., m_i is extracted by w_i) to ensure that the graph is cyclic.

We will use letters such as x, y, and z to denote nodes, and $x \xrightarrow{r} y$ to denote an edge from x to y with labeled relation r. Each node represents an object (document, wrapper, or mention), and each edge $x \xrightarrow{r} y$ asserts that a binary relation $r(x, y)$ holds. We want to find entity mention nodes that are *similar* to the seed nodes. We define the similarity between two nodes by random walk with restart (Tong et al., 2006). In this algorithm, to walk away from a source node x, one first chooses an edge relation r; then given r, one picks a target node y such that $x \xrightarrow{r} y$. When given a source node x, we assume that the probability of picking an edge relation r is uniformly distributed among the set of all r, where there exist a target node y such that $x \xrightarrow{r} y$. More specifically,

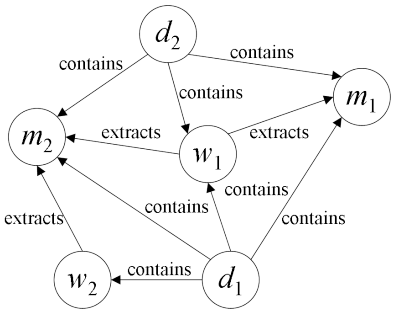

Figure 2: Example graph built by Random Walk.

$$P(r|x) = \frac{1}{|r : \exists y \; x \xrightarrow{r} y|} \tag{1}$$

We also assume that once an edge relation r is chosen, a target node y is picked uniformly from the set of all y such that $x \xrightarrow{r} y$. More specifically,

$$P(y|r, x) = \frac{1}{|y : x \xrightarrow{r} y|} \tag{2}$$

In order to perform random walk, we will build a transition matrix M where each entry at (x, y) represents the probability of traveling one step from a source node x to a target node y, or more specifically,

$$M_{xy} = \sum_r P(r|x)P(y|r, x) \tag{3}$$

We will also define a state vector $\vec{v}_t$ which represents the probability at each node after iterating through the entire graph t times, where one iteration means to walk one step away from every node. The state vector at $t + 1$ iteration is defined as:

$$\vec{v}_{t+1} = \lambda \vec{v}_0 + (1 - \lambda) M \vec{v}_t \tag{4}$$

Since we want to start our walk from the seeds, we initialize v_0 to have probabilities uniformly distributed over the seed nodes. In each step of our walk, there is a small probability λ of teleporting back to the seed nodes, which prevents us from walking too far away from the seeds. We iterate our graph until the state vector converges, and rank the extracted mentions by their probabilities in the final state vector. We use a constant λ of 0.01 in the experiments below.

2.3 Bootstrapping Candidate Instances

Bootstrapping refers to iterative unsupervised set expansion. This process requires minimal supervision, but is very sensitive to the system's performance because errors can easily propagate from one iteration to another. As shown in previous work (Wang and Cohen, 2008), carefully designed seeding strategies can minimize the propagated errors. Below, we show the pseudo-code for our bootstrapping strategy.

$stats \leftarrow \emptyset, used \leftarrow inputs$
for i = 1 to M **do**
  $m = min(3, |used|)$
  $seeds \leftarrow select_m(used) \cup top(list)$
  $stats \leftarrow expand(seeds, stats)$
  $list \leftarrow rank(stats)$
  $used \leftarrow used \cup seeds$
end for

where M is the total number of iterations, $inputs$ are the two initial input seeds, $select_m(S)$ randomly selects m different seeds from the set S, $used$ is a set that contains previously expanded seeds, $top(list)$ returns an item that has the highest rank in $list$, $expand(seeds, stats)$ expands the selected $seeds$ using $stats$ and outputs accumulated statistics, and $rank(stats)$ applies Random Walk described in Section 2.2 on the accumulated $stats$ to produce a $list$ of items. This strategy dumps the highest-ranked item into the $used$ bucket after every iteration. It starts by expanding two input seeds. For the second iteration, it expands three seeds: two *used* plus one from last iteration. For every successive iteration, it expands four seeds: three randomly selected $used$ ones plus one from last iteration.

3 Experiments with Unary Relations

We would like to determine whether character-based or HTML-based wrappers are more suited for the task of set expansion. In order to do that, we introduce five types of wrappers, as illustrated in Table 3. The first type is the character-based wrapper that does not have any restriction on the alphabets of its characters. Starting from the second type, the allowable alphabets in a wrapper become more restrictive. The fifth type requires that an item must be tightly bracketed by two complete HTML tags in order to be extracted.

#	L. Context `[...]` R. Context	Eng	Jap	Chi	Avg
1	`.+[...].+`	87.6	96.9	95.4	93.3
2	`.*[<>].*[...].*[<>].*`	85.7	96.8	90.7	91.1
3	`.*>[...]<.*`	85.7	96.7	90.7	91.0
4	`.*<.+?>.*[...].*<.+?>.*`	80.1	95.8	83.7	86.5
5	`.*<.+?>[...]<.+?>.*`	79.6	94.9	82.4	85.6

Table 3: The performance (MAP) of various types of wrappers on semi-structured web pages.

All pure HTML-based wrappers are type 5, possibly with additional restrictions imposed (Nadeau et al., 2006; Etzioni et al., 2005). SEAL currently does not use an HTML parser (or any other kinds of parser), so restrictions cannot be easily imposed. As far as we know, there isn't an agreement on what restrictions make the most sense or work the best. Therefore, we evaluate performance for varying wrapper constraints from type 1 (most general) to type 5 (most strict) in our experiments.

For set expansion, we use the same evaluation set as in (Wang and Cohen, 2007) which contains 36 manually constructed lists across three different languages: English, Chinese, and Japanese (12 lists per language). Each list contains all instances of a particular semantic class in a certain language, and each instance contains a set of synonyms (e.g., USA, America).

Since the output of our system is a ranked list of extracted instances, we choose mean average precision (MAP) as our evaluation metric. MAP is commonly used in the field of Information Retrieval for evaluating ranked lists because it is sensitive to the entire ranking and it contains both recall and precision-oriented aspects. The MAP for multiple ranked lists is simply the mean value of average precisions calculated separately for each ranked list. We define the average precision of a single ranked list as:

$$AvgPrec(L) = \frac{\sum_{r=1}^{|L|} \text{Prec}(r) \times \text{isFresh}(r)}{\text{Total \# of Correct Instances}}$$

where L is a ranked list of extracted instances, r is the rank ranging from 1 to $|L|$, Prec(r) is the precision at rank r, or the percentage of correct synonyms above rank r (inclusively). isFresh(r) is a binary function for ensuring that, if a list contains multiple synonyms of the same instance (or instance pair), we do not evaluate that instance (or instance pair) more than once. More specifically, the function returns 1 if a) the synonym at r is correct, and b) it is the highest-ranked synonym of its instance in the list; it returns 0 otherwise.

We evaluate the performance of each type of wrapper by conducting set expansion on the 36 datasets across three languages. For each dataset, we randomly select two seeds, expand them by bootstrapping ten iterations (where each iteration retrieves at most 200 web pages only), and evaluate the final result. We repeat this process three times for every dataset and report the average MAP for English, Japanese, and Chinese in Table 3. As illustrated, the more restrictive a wrapper is, the worse it performs. As a result, this indicates that further restrictions on wrappers of type 5 will not improve performance.

4 Set Expansion for Binary Relations

4.1 Identifying Wrappers for Binary Relations

We extend the wrapper construction algorithm described in Section 2.1 to support relational set expansion. The major difference is that we introduce a third type of context called the *middle* context that occurs between the left and right contexts of a wrapper for separating any two items. We execute the same algorithm as before, except that a seed instance in the algorithm is now a seed instance pair bracketing some middle context (i.e., "$s_1 \cdot middle \cdot s_2$").

Given some seed pairs (e.g., Ford and USA), the algorithm first locates the seeds in some given documents. For every pair of seeds located, it extracts their left, middle, and right contexts. The left and right contexts are inserted into their corresponding tries, while the middle context is inserted into a list. Every middle context is assigned a flag indicating whether the two instances bracketing it were found in the same or reversed order as the input seed pairs. Every entry in the seed instance list described previously now stores a pair of instances as one single string (e.g. "Ford/USA"). An id stored in a node now matches the index of a pair of instances as well as a middle context.

Shown below is a mock example document of which the seed pairs: Ford and USA, Nissan and Japan, Toyota and Japan are located (and boldfaced).

GtpKxH**nIsSaN**oKp**jaPaN**xjHJgleTuoLpBlcLBxKH
forDEFc**uSA**xkrpWNapnIkAAHO**FoRd**awHDa**USa**uoh
deQsKxHaCuRAoKpJapANxjHdIjWnOxo**TOyOTa**Vaq
jApaNzxKHAUdIEFcgErmANyxkrOyQKxH**ToYotA**oK
p**JApaN**xjHCRdmtqOVKxH**foRd**oKp**usA**xjHaJASzEi
nSfrla**FoRD**LMmp**uSa**ofwNLWxKH**tOYota**EFc**jAPan**
xkrHxQKzrHpoKdGEKtxKH**NisSan**EFc**JApAn**xkrEq

After performing the abovementioned procedures on this mock document, we now have context tries that are much more complicated than those illustrated in Figure 1, as well as a list of middle contexts similar to the one shown below:

id	Seed Pairs	r	Middle Context
0	Nissan/Japan	No	oKp
1	Nissan/Japan	No	EFc
2	Nissan/Japan	Yes	xkrHxQKzrHpoKd...
4	Toyota/Japan	No	oKp
6	Toyota/Japan	Yes	xjHdIjWnOxo
9	Ford/USA	No	EFc
13	Ford/USA	Yes	xkrpWNapnIkAAHO

where r indicates if the two instances bracketing the middle context were found in the reversed order as the input seed pairs. In order to find the maximally long contextual strings, the "Intersect" function in the set expansion pseudo-code presented in Table 2 needs to be replaced with the following:

Integers Intersect(Node n_1, Node n_2)
  Define $S = n_1.indexes \cap n_2.indexes$
  Return the largest subset s of S such that:
    Every index $\in s$ corresponds to same middle context

which returns those seed pairs that are bracketed by the strings associated with the two input nodes with the same middle context. A wrapper for relational set expansion, or *relational wrapper*, is defined by the left, middle, and right contextual strings. The relational wrappers constructed from the mock document given the example seed pairs are shown below. Notice that Audi/Germany and Acura/Japan are discovered.

Wrapper:	xKH[.1.]EFc[.2.]xkr
Content:	**audi/germany**, ford/usa, nissan/japan, toyota/japan
Wrapper:	KxH[.1.]oKp[.2.]xjH
Content:	**acura/japan**, ford/usa, nissan/japan, toyota/japan

4.2 Experiments with Binary Relations

For binary relations, we performed the same experiment as with unary relations described in Section 3. A relational wrapper is of type t if the wrapper's left and right context match t's constraint for left and right respectively, and also that the wrapper's middle context match both constraints.

For choosing the evaluation datasets for relational set expansion, we surveyed and obtained a dozen relationships, from which we randomly selected five of them and present in Table 4. Each dataset was then manually constructed. For the last two datasets, since there are too many items, we tried our best to make the lists as exhaustive as possible.

To evaluate relational wrappers, we performed relational set expansion on randomly selected seeds from the five relational datasets. For every dataset, we select two seeds randomly and bootstrap the relational set expansion ten times. The results after the first iteration are shown in Table 5 and after the tenth iteration in Table 6. When computing precision at 100 for each resulting list, we kept only the top-most-ranked synonym of every instance and remove all other synonyms from the list; this ensures that every instance is unique. Notice that for the "Car Maker" dataset, there exists no wrappers of types 2 to 5; thus resulting in zero performance for those wrapper types. In each table, the results indicate that character-based wrappers perform the best, while those HTML-based wrappers that require tight HTML bracketing of items (type 3 and 5) perform the worse.

In addition, the results illustrate that bootstrapping is effective for expanding relational pairs of items. As illustrated in Table 6, the result of finding translation pairs of NBA team names is perfect, and it is almost perfect for finding pairs of U.S. states/territories and governors, as well as Taiwanese cities and mayors. In finding pairs of acronyms and full names of federal agencies, the precision at top 100 is nearly perfect (97%). The results for finding pairs of car makers and countries is good as well, with a high precision of 90%. For the last two datasets, we believe that MAP could be improved by increasing the number of bootstrapping iterations. Table 7 shows some example wrappers constructed and instances extracted for wrappers of type 1.

5 Related Work

In recent years, many research has been done on extracting relations from free text (e.g., (Pantel and Pennacchiotti, 2006; Agichtein and Gravano, 2000; Snow et al., 2006)); however, almost all of them require some language-dependent parsers or taggers for English, which restrict the language of their extractions to English only (or languages that have these parsers). There has also been work done on extracting relations from HTML-structured tables (e.g., (Etzioni et al., 2005; Nadeau et al., 2006; Cafarella et al., 2008)); however, they all incorporated heuristics for exploiting HTML structures; thus, they cannot handle documents written in other mark-up languages.

Extracting relations at character-level from semi-structured documents has been proposed (e.g., (Kushmerick et al., 1997),(Brin, 1998)). In particular, Brin's approach (DIPRE) is the most similar to ours in terms of expanding relational items. One difference is that it requires maximally-long contextual strings to bracket *all* seed occurrences. This technique has been experimentally illustrated to perform worse than SEAL's approach on unary relations (Wang and Cohen, 2007). Brin presented five seed pairs of author names and book titles that he used in the experiment (unfortunately, he did not provide detailed results). We input the top two seed pairs listed in his paper into the relational SEAL, performed ten bootstrapping iterations (took about 3 minutes), and obtained 26,000 author name/book title pairs of which the precision at 100 is perfect (100%).

6 Conclusions

In this paper, we have described in detail an algorithm for constructing document-specific wrappers automatically for set expansion. In the experimental results, we have illustrated that character-based wrappers are better suited than HTML-based wrappers for the task of set expansion. We also presented a method that utilizes an additional middle context for constructing relational wrappers. We also showed that our relational set expansion approach is language-independent; it can be applied to non-English and even cross-lingual seeds and documents. Furthermore, we have illustrated that bootstrapping improves the performance of relational set expansion. In the future, we will explore automatic mining of binary concepts given only the relation (e.g., "mayor of").

Classifying Relations for Biomedical Named Entity Disambiguation

Abstract

Named entity disambiguation concerns linking a potentially ambiguous mention of named entity in text to an unambiguous identifier in a standard database. One approach to this task is supervised classification. However, the availability of training data is often limited, and the available data sets tend to be imbalanced and, in some cases, heterogeneous. We propose a new method that distinguishes a named entity by finding the informative keywords in its surrounding context, and then trains a model to predict whether each keyword indicates the semantic class of the entity. While maintaining a comparable performance to supervised classification, this method avoids using expensive manually annotated data for each new domain, and thus achieves better portability.

1 Introduction

While technology on named entity recognition (NER) matures, many researchers in the field of information extraction (IE) gradually shifted their focus to more complex tasks such as named entity disambiguation and relation extraction. Both tasks are particularly important for biomedical text mining, which concerns automatically extracting facts from the exponentially growing biomedical literature (Hunter and Cohen, 2006). One type of facts is relations between biomedical named entities, such as disease-drug relation, gene-disease relation, protein-protein interaction (PPI), etc. To automatically extract these facts, advanced natural language processing techniques such as parsing have been adopted to analyse the syntactic and semantic structure of text. The idea is that linguistic structures between the interacting biological entities may have common characteristics that can be exploited by similarity measures or machine learning algorithms. For example, Erkan et al. (2007) used the shortest path between two genes according to edit distance in a dependency tree to define a kernel function for extracting gene interactions. Miwa et al. (2008) comparably evaluated a number of kernels for incorporating syntactic features, including the bag-of-word kernel, the subset tree kernel (Moschitti, 2006) and the graph kernel (Airola et al., 2008), and they concluded that combining all kernels achieved better results than using any individual one. Miyao et al. (2008) used syntactic paths as one of the features to train a support vector machines (SVM) model for PPIs and also discussed how different parsers and output representations affected the end results.

Another crucial IE task is named entity disambiguation, which concerns grounding mentions of named entities in text to unambiguous *concepts* as defined in some standard dictionary or database. For instance, given a search term *Python*, users may like to see the results grouped into the following categories: *a type of snake*, *a programming language*, or *a film* (Bunescu and Paşca, 2006). One approach to such lexical disambiguation tasks is supervised classification. However, such techniques suffer from the knowledge acquisition bottleneck, meaning that manually annotating training data is costly and can never satisfy the need by the machine learning algorithms. In addition, supervised techniques may not yield reliable results when the distributions of the semantic classes are different in the training and test datasets (Agirre and Martinez, 2004; Koeling et al., 2005). For example, on the task of word sense disambiguation, a model trained on a dataset where the predominant sense of the word *star* is "heavenly body", may not work well on text mainly composed of entertainment news. Such problems are also major concerns when developing a system to disambiguate biomedical named entities (e.g., protein,

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1513–1522,
Singapore, 6-7 August 2009.

gene, and disease), for which some researchers rely on hand-crafted rules in addition to a small amount of training data (Morgan and Hirschman, 2007; Hakenberg et al., 2008).

This paper proposes a new disambiguation method that, instead of classifying each individual occurrence of an entity, it classifies pair-wise relations between the entity mention in question and the "*cue words*" in its adjacent context, where each cue word is assumed to bear a semantic class. We then select the cue word that has a positive relation with the entity, and pass its semantic tag to it. While an individual entity mention may belong to a large number of semantic classes, a relation can only take one of two values: positive or negative, hence transforming a complex multi-classification problem into a less complicated binary classification task. The remainder of the paper is organised as follows: Section 2 proposes the disambiguation method and Section 3 introduces the task of disambiguating the model organisms of biomedical named entities. Section 4 describes in detail our proposed method and also a number of baseline systems for comparison purposes. Section 5 shows the evaluation results and discusses the advantages and drawback of our system, and we finally conclude in Section 6.

2 Disambiguation as Relation Classification

The named entity disambiguation task is defined as follows: given a mention of a named entity in text, we automatically assign a semantic tag d to it, where $d \in D$, and D is a pre-compiled dictionary with $|D|$ entries. When $|D|$ is small, the problem can be approached by supervised classification. For example, to determine whether an occurrence of an entity is a protein, a gene or an RNA, Hatzivassiloglou et al. (2001) compared performance of 3 supervised classification methods and reported results near the human agreement rate. Nevertheless, when $|D|$ is large (e.g., > 100), the performance of classification may decrease, especially when the distribution of d in training dataset differs from that in the test set. In other words, when $|D|$ is large, named entity disambiguation becomes a multi-class classification task on heterogeneous and imbalanced datasets, which is challenging for a machine learning model to learn to discriminate enough between the semantic classes (Japkowicz, 2000).

We propose an alternative method for named entity disambiguation. Intuitively, in the surrounding context of an ambiguous entity, one can often find "cue words" that are informative indicators of the entity's semantic category. These cue words are provided by authors to remind readers the semantic identity of a named entity. For example, in an article about protein p53, phrase "human protein p53" may be mentioned, where both *human* and *protein* contain semantic information regarding p53: *human* indicates the model organism of p53, and *protein* suggests the type of this entity. Such cue words may occur infrequently in the training data, making it difficult for machine learning classifiers to capture.

Our method exploits this observation. Given a sentence, let E be the set of 'target' entities (e.g., *p53*) and W of the 'cue' words (e.g., *human*) that co-occur in a sentence, we define a relation as a pair $r = \langle e, w \rangle$, where $e \in E$ and $w \in W$, and r is a positive relation if e belongs to the semantic class indicated by w, and is a negative one if not. Then we can disambiguate e by accomplishing the following steps: 1) identify W and build a set of relations $R = \{\langle e, w_i \rangle | w_i \in W, i = 1, 2, .., n\}$, where n is the size of W; and 2) classify every $r \in R$ and assign the semantic tag of w_j to e such that $r_j = \langle e, w_j \rangle$ is positive. The first task can be tackled by a dictionary lookup, or by an NER system, if manually annotated data is available. The second is essentially a binary relation classification task, and in this work, we use an SVM model exploiting bag-of-word and syntactic features.

3 Species Disambiguation

We show the performance of the proposed method on a task of resolving one major source of ambiguity in protein and gene entities: model organisms. Model organisms are species studied to understand particular biological phenomena. Biological experiments are often conducted on one species, with the expectation that the discoveries will provide insight into the workings of others, including humans, which are more difficult to study directly. From viruses, prokaryotes, to plants and animals, there are dozens of organisms commonly used in biological studies, such as *E. coli*, *Drosophila*, *Homo sapiens*, and hundreds more are frequently mentioned in biological research papers. In biomedical articles, entities of different species are commonly referred to us-

ing the same name, causing great ambiguity. For example, searching a protein sequence database, RefSeq[1] with query "*tumor protein p53*" resulted in over 100 proteins, as the name is shared by many organisms.

The importance of distinguishing model organisms has been recognised by the community of biomedical text mining. Chen et al. (2005) collected gene names from various source databases and calculated intra- and inter-species ambiguities. Overall, only 25 (0.02%) official symbols were ambiguous within the organisms. However, when official symbols from 21 organisms were combined, the ambiguity increased substantially to $21,279$ (14.2%) symbols. Hakenberg et al. (2008) showed that species disambiguation is one of the most important steps for term normalisation and identification, which concerns automatically associating mentions of biomedical entities in text to unique database identifiers (Morgan et al., 2008). Also, the task of extracting PPIs in the recent BioCreative Challenge II workshop (Hirschman et al., 2007) requires protein pairs to be recognised and normalised, which inevitably involves species disambiguation.

More specifically, given a text, in which mentions of biomedical named entities are annotated, a species disambiguation system automatically assigns a *species identifier*, as in a standard database of model organisms, to every entity mention. The types of biomedical named entities concerned in this study are protein, gene, protein complex and mRNA/cDNA, and we used identifiers from the NCBI Taxonomy of model organisms.[2] The work focuses on species disambiguation and assumes that the entities are already identified. In practice, an automated named entity recogniser (e.g., ABNER (Settles, 2005)) should be used before applying the systems.

4 Approaches

This section describes a number of approaches to species disambiguation, highlighting the relation classification method proposed in Section 2.

4.1 Heuristics Baselines

The cue words for species are words denoting names of model organisms (e.g., *mouse* as in phrase "mouse p53"). Another clue is the presence of the species-indicating prefixes in gene and protein names. For instance, prefix 'h' in entity "hSos-1" suggests that it is a *human* protein. Throughout this paper, we refer to such cue words (e.g., *mouse*, *hSos-1*) as "species words". Note that a species "word" may contain multiple tokens (e.g., *E. Coli*).

We encoded this knowledge in a rule-based species tagging system (Wang and Grover, 2008). The system takes a 2-step approach. First, it marks up species words in the document using a species-word detection program,[3] which searches every word in a dictionary of model organisms and assigns a species ID to the word if a match is found. The dictionary was built using the NCBI taxonomy[4] and the UniProt controlled vocabulary of species,[5] and in total it contains 420,224 species words for 324,157 species IDs. When species words are identified, we disambiguate an entity mention using *one of* the following rules:

1. *previous species word*: If the word preceding an entity is a species word, assign the species ID indicated by that word to the entity.

2. *species word in the same sentence*: If a species word and an entity appear in the same sentence, assign its species ID to the entity. When more than one species word co-occurs in the sentence, priority is given to the species word to the entity's left with the smallest distance. If all species words occur to the right of the entity, take the nearest one.

3. *majority vote*: assign the most frequently occurring species ID in the document to all entity mentions.

It is expected that the first rule would produce good precision. However, it can only disambiguate the fraction of entities that happen to have a species word to their *immediate* left. The second rule relaxes the first by allowing an entity to take the species indicated by its nearest species word in the same sentence, which should increase recall but decrease precision. Statistics from our dataset (see Section 5.1) show that only 5.68% entities can potentially be resolved by rule 1 and 22.16% by rule 2, while the *majority* rule can tackle every entity mention in the dataset.

[1] http://www.ncbi.nlm.nih.gov/RefSeq

[2] http://www.ncbi.nlm.nih.gov/sites/entrez?db=taxonomy

[3] The species word detector identifies the cue words and was used in all the systems studied in this paper. We could not properly evaluate the detector due to the lack of manually annotated data. Its performance, however, would not affect the comparative evaluation results, and improvement to species word detection should increase the performance of these disambiguation systems.

4.2 Supervised Classification

The disambiguation problem can be approached as a classification task. Given an entity mention and its surrounding context, a machine learning model classifies the entity into one of the classes, where each class corresponds to a species ID. We carried out experiments with two classification methods: multi-class classification and one-class classification, where a maximum entropy model[6] was used for the former and SVM-light[7] for the latter. In one-class classification, we trained a series of binary SVM classifiers, each constructing a separating hyperplane that maximises the margin between the instances of one specific species (i.e., the target class) and a set of randomly selected instances of other species (i.e., the outlier class). We used equal numbers of instances for both classes in training. The following types of features were used in both multi-class and one-class experiments, where the values of n were set empirically by cross-validation on the training data:

- *leftContext* The n word lemmas to the left of the entity ($n = 200$).
- *rightContext* The n word lemmas to the right of the entity ($n = 200$).
- *leftSpeciesIDs* The n species IDs to the left of the entity (with order, $n = 5$).
- *rightSpeciesIDs* The n species IDs to the right of the entity (with order, $n = 5$).
- *leftNouns* The n nouns to the left of the entity (with order, $n = 2$).
- *leftAdjs* The n adjectives to the left of the entity (with order, $n = 2$).
- *leftSpeciesWords* The n species word forms to the left of the entity ($n = 5$).
- *rightSpeciesWords* The n species word forms to the right of the entity ($n = 5$).
- *firstLetter* The first character of the entity itself (e.g., 'h' in *hP53*).
- *documentSpeciesIDs* All species IDs that occur in the document in question.
- *useStopWords* filter out function words.
- *useStopPattern* filter out words consisting only of digits and punctuation characters.

Feature selection was also carried out for the one-class classification experiments. We compared two feature selection methods that reportedly work well on the task of text classification: information gain (IG) (Yang and Pedersen, 1997) and Bi-Normal separation (BNS) (Forman, 2003). IG measures the decrease in entropy when the feature is given vs. absent, and is defined as: $IG(Y|X) = H(Y) - H(Y|X)$ where $H(Y)$ is the uncertainty about the value of Y (i.e., Y's entropy), and $H(Y|X)$ is Y's conditional entropy given X. The BNS is defined as: $|F^{-1}(x) - F^{-1}(y)|$, where F^{-1} is the standard Normal distribution's inverse cumulative probability function, namely, *z-score*; x is the ratio between the number of positive cases containing the feature in question, and the total number of positive cases; and y is the ratio between the number of negative cases containing the feature, and the total number of negative cases.

We computed a weight for each feature and then ranked the features according to their weight, with respect to each feature selection method. The top 10% features were used in training. Given a test instance, the one-class classification method first counts the species words in the document that the instance appears in, and then applies in sequence the binary models of each occurring species, starting from the most frequent one. For example, if a document contains 5 occurrences of *human* and 3 *mouse*, we first apply the *human* species model to judge whether an entity mention is of *human* species, and only if not, the *mouse* model was applied. The most-frequent species in the document was used as backup when none of the binary models gives positive answers.

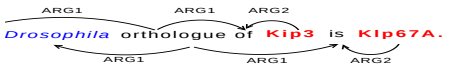

Figure 1: Predicate argument structure (PAS).

4.3 Relation Classification

4.3.1 Overview

As for the proposed relation classification method, in the training phase, we first selected the sentences in which an entity mention and a species word co-occur, and constructed pair-wise entity-species relations. We then assigned each relation a binary label: a relation is positive if the species ID inferred from the species word matches the gold-standard species annotation on the entity, and is negative otherwise. For example, for the sentence shown in Figure 1, where *Drosophila* is a species word, and Kip3 and Klp67A are proteins, relation ⟨Kip3, *Drosophila*⟩ is a negative instance and the

[6] http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html

[7] http://svmlight.joachims.org/

pair ⟨Klp67A, *Drosophila*⟩ is a positive one.[8]

For each relation, a vector of features were extracted. We followed the PPI extraction method described in (Miyao et al., 2008), where two types of features were used for a SVM classifier. The first was bag-of-word features, i.e., the words before, between and after the pair of entities, where the words were lemmatised. We added an additional feature of the distance between the entity and the cue word. The other type was syntactic features obtained from parsers. For bag-of-word features, a linear kernel was used, and for syntactic ones, a subset tree kernel (Moschitti, 2006) was adopted. The syntactic features were represented in a flat tree format. Figure 2 shows such a feature for the negative instance ⟨Kip3, *Drosophila*⟩ from Figure 1. Note that all species words (e.g., *Drosophila*) were normalised to "SPECIESWORD", and entities (e.g., Kip3) to "ENTITY", which not only reduces the noise in the feature set, but also makes the model more species-generic. From the training dataset (see Section 5.1), $25,413$ relations were extracted, of which 63.3% were positive.

```
(ENJU(noun_arg1(SPECIESWORD orthologue))
(prep_arg12(of orthologue))
(prep_arg12(of ENTITY)))
```

Figure 2: A syntactic feature obtained from the ENJU parser.

To identify the species of an entity in unseen text, we first parsed the sentence, and then listed all pairs of species words and entities as relations. Having extracted the bag-of-word and syntactic features from the instance, the trained model was applied to judge whether each species-entity relation was positive. The entity mention in a positive relation would be tagged with the ID indicated by the species word, while the mentions in negative relations would be left untagged. The next section describes in detail how we extracted the syntactic features from text.

4.3.2 Syntactic Features

Given a sentence, a natural language parser automatically recognises its syntactic structure and outputs a parse tree, in which nodes represent words or syntactic constituents. A path between a pair of nodes can be interpreted as a syntactic relation between sentence units, which was proved useful to infer biological relations (e.g., Airola et al., 2008; Miwa et al., 2008).

Parser	Input	Output
C&C	POS-tagged	GR
ENJU	POS-tagged	PAS
ENJU-Genia	POS-tagged	PAS
Minipar	Sentence-detected	Minipar
RASP	Tokenised	GR
Stanford	POS-tagged	SD
Stanford-Genia	POS-tagged	SD

Table 1: Parsers and their input and output format

We experimented with the following parsers (summarised in Table 1):

- **Dependency parsers** identify one word as the head of a sentence and all other words are either a dependent of that word, or else dependent on some other word that connects to the headword through a sequence of dependencies. We used Minipar (Lin, 1998) and RASP (Briscoe et al., 2006) for the experiments;
- **Constituent-structured parsers** split a sentence into syntactic constituents such as *noun phrases* or *verb phrases*. We used the Stanford parser (Klein and Manning, 2003), and also a variant of the Stanford parser (i.e., Stanford-Genia), which was trained on the GENIA treebank (Tateisi et al., 2005) for biomedical text;
- **Deep parsers** aim to compute in-depth syntactic and semantic structures based on syntactic theories such as HPSG (Pollard and Sag, 1994) and CCG (Steedman, 2000). We used the C&C parser (Clark and Curran, 2007), ENJU (Miyao and Tsujii, 2008), and a variant of ENJU (Hara et al., 2007) adapted for the biomedical domain (i.e., ENJU-Genia);

There were a number of practical issues to consider when using parsers for this task. Firstly, before parsing, the text needs to be linguistically pre-processed, and the quality of this process has a significant impact on parsers' performance. The pre-processing steps include sentence boundary detection, tokenisation and part-of-speech (POS) tagging, all of which can be tricky especially when applied to biomedical text (Grover et al., 2003). To avoid the noise that can be introduced in the pre-processing steps and to concentrate on evaluating the performance of the parsers, we used the same pre-processing tools (Alex et al., 2008a)[9] whenever possible. The middle column in Table 1 shows how the input text was linguistically pre-processed with respect to each parser. A POS-tagged text implies that it was also sentence boundary detected and tokenised Except for

[8] *Orthologues* are genes/proteins in different species but have similar sequences. In this example it implies that Klp67A is a *Drosophila* protein but Kip3 is not.

[9] These particular tools were chosen because they were adopted to pre-process the ITI-TXM dataset, which we used in our study.

RASP and Minipar, all parsers took POS-tagged text as input. RASP requires POS tags and punctuation labels that were derived from the CLAWS-7 tagset,[10] whereas our dataset uses POS labels from the Penn Treebank tagset (Marcus et al., 1994). As RASP does not recognise the Penn tagset, we used its build-in POS tagger. Minipar, on the other hand, does not support input of tokenised or POS-tagged text, and therefore took split sentences as input.

Secondly, the output representations of the parsers are different and we preferred a format that depicts relations between words instead of syntactic constituents. In total, 4 representations were used: grammatical relation (GR) (Briscoe et al., 2006), Stanford typed dependency (SD) (de Marneffe et al., 2006), Minipar's own representation (Lin, 1998), and ENJU's predicate-argument structure (PAS). All the above representations define relations of words in triples, where a dependency triple (i.e., GR, SD and Minipar) consists of head, dependent and relation, and a PAS triple contains predicate, argument, and relation. Figure 1 shows a sentence parsed by ENJU in PAS representation. The right-most column in Table 1 lists the output representation of each parser. A syntactic path between an entity and a species word was represented by a sequence of triples, each following the order of head-dependent or predicate-argument. These paths were used as syntactic features for the SVM classifier.

4.4 Spreading Strategies

Except for the *majority vote* rule, the approaches described in Sections 4.1 and 4.3 were expected to yield low recall, because they can only detect intra-sentential relations, and therefore only be applied to the entities having at least one species word appearing in the same sentence.

Since our aim is to disambiguate as many entity mentions as possible, we would like to "spread" the decisions from the disambiguated mentions to their "relatives" in the same document. We define an entity mention $\bar{e}$ as another mention e's relative under either of the following conditions: a) if $\bar{e}$ has the same surface form with e; or, b) if $\bar{e}$ is an abbreviation or an antecedent of e, where abbreviation/antecedent pairs were detected using the algorithm described in (Schwartz and Hearst, 2003). Given the set of disambiguated mentions, we then "spread" their species IDs to their relatives in the same document. After this process, the mentions that do not have any disambiguated relatives would still be missed by the system. In such cases, we used a "default" species, as determined by the rule of *majority vote* (see Section 4.1).

5 Evaluation

5.1 Data and Ontology

The species disambiguation experiments were conducted using the ITI-TXM corpus (Alex et al., 2008b), a collection of *full-length* biomedical research articles manually annotated with linguistic and biomedical information for developing automatic information extraction systems. The corpus contains two datasets covering slightly different domains: enriched protein-protein interaction (EPPI) and tissue expression (TE). Whenever possible, protein, protein complex, gene, and mRNA/cDNA entities were tagged with NCBI Taxonomy IDs, denoting their species, and it was the species annotation that this study used.

The EPPI and TE datasets have different distributions of species. The entities in EPPI belong to 118 species with *human* being the most frequent at 51.98%. In TE, the entities are across 67 species and *mouse* is the most frequent at 44.67%.[11] The inter-annotator agreement of species annotation on EPPI and TE are 86.45% and 95.11%, respectively.

The species disambiguation systems were developed on the training portions of the EPPI and TE corpora, each containing 221 articles, and evaluated on a dataset combining the development test (DEVTEST) datasets of EPPI and TE, containing 58 and 48 articles, respectively. The combined training dataset contains $96,992$ entity mentions belonging to 138 model organisms, while the DEVTEST dataset contains $23,118$ entities of 54 species. The diversity of model organisms in this corpus highlights the fact that a primary consideration when developing a species disambiguation system is its ability to distinguish a wide range of species with minimal additional manual effort.

5.2 Results

5.2.1 Evaluation Metrics

The evaluation was carried out on the DEVTEST dataset, and the systems are compared using av-

[10] http://ucrel.lancs.ac.uk/claws7tags.html

[11] These figures were obtained from the training split of the datasets.

	micro-avg.	macro-avg.
Maxent	70.48 / 70.48 / 70.48	10.07 / 10.00 / 9.85
SVM	62.24 / 59.35 / 60.76	14.70 / 17.11 / 15.01
SVM (IG)	65.20 / 61.06 / 63.06	14.90 / 19.53 / 16.09
SVM (BNS)	43.61 / 42.63 / 43.11	11.99 / 10.05 / 9.34

Table 2: Evaluation results of the classification systems on DEVTEST (precision/recall/F1-score, in %)

eraged precision, recall and F1 scores over all species. In more detail, for each model organism that appears in the DEVTEST dataset, we collect two lists of entity mentions of that species: one from the gold-standard DEVTEST dataset, and the other from the output of a disambiguation system. Then the list of system output is compared against the gold-standard list to obtain precision, recall and F1 score. For each system, the scores obtained from all species are averaged using micro-average and macro-average. The micro-average is the mean of the summation of contingency metrics for all model organisms, so that scores of the more frequent species influence the mean more than those of less frequent ones. The macro-average is the mean of precision, recall, or F1 over all labels, thus attributing equal weights to each species, and measuring a system's adaptability across different model organisms.

5.2.2 Evaluation Results

First of all, Table 2 shows the results of the classification methods described in Section 4.2. The multi-classification system using a maximum entropy model (Maxent) yielded the highest overall micro-averaged F1. Among the SVM-based systems, the one using IG feature selection achieved better performance. In particular, it outperformed the Maxent model in term of macro-averages. The performance of the SVM model with BNS feature selection is disappointing, perhaps because the occurrences of a feature in each instance are not normally distributed. As the Maxent system obtained better results, it was used to compare with other disambiguation systems.

Table 3 shows the results of a number of methods described in the previous sections. The methods are categorised into 4 groups: rule-based baseline systems, a Maxent classification model, relation-classification methods, and a hybrid system. The difference between the relation classification systems is the features adopted. Rel-Context was trained on only bag-of-word and distance features, whereas each other system also used syntactic features provided by a specific parser. For example, the Rel-RASP system identifies an entity's species by finding positive relations between the entity and its neighbouring species words, using features including bag-of-word, distance, and dependency paths generated by RASP. The hybrid system (Hbrd) ran the Rel-ENJU-Genia system on top of the outcome of Maxent. When a conflict occurs, the species ID is chosen by Rel-ENJU-Genia. The idea is that the relation classification system is more accurate than Maxent when it is applicable, and hence would improve precision on disambiguating the species with few or no training instances.

Without spreading (shown in the "NO SPRD" columns of Table 3), most of the rule-based and relation classification systems only work on a subset of DEVTEST, resulting in low recall: Rule-Sp works on the small proportion of entities (5.68%) with a preceding species word, while the other systems only work on the collection of sentences containing at least one species word and one entity, which covers 4.60% sentences and 22.16% entity mentions. Rule-Majority, Maxent, and Hbrd, on the other hand, apply to all entity mentions, and therefore they are only compared against the others when spreading was applied.

The results shown in the "NO SPRD" columns can be viewed as a comparative evaluation of the usefulness of the syntactic features supplied by the parsers on this particular task. The rule-based systems set high baselines: Rule-Sp produced good precision and Rule-SpSent achieved the highest micro-averaged F1, thanks to its high coverage, which is also an upperbound of recall for the relation classification systems. Nevertheless, it is encouraging that the relation classification systems obtained higher precision than Rule-SpSent, which is important, considering the decisions will be transfered to the untagged entity mentions across the document. Indeed, as shown in the SPRD columns in Table 3, most relation classification systems outperformed the Rule-SpSent baseline when spreading was used. The scores of the systems using different parser outputs only vary slightly. Rel-Context, on the other hand, surpassed others in terms of micro-averaged precision, while sacrificing micro-averaged recall and macro-averaged scores.

Next, the SPRD columns in Table 3 show the results when the spreading rules were applied, which

METHOD	NO SPRD (micro-avg)	NO SPRD (macro-avg)	SPRD (micro-avg)	SPRD (macro-avg)
Rule-Majority	N/A	N/A	66.14 / 61.99 / 64.00	16.76 / 21.75 / 18.08
Rule-Sp	88.96 / 5.02 / 9.51	33.77 / 8.55 / 10.18	66.96 / 63.41 / 65.13	28.25 / 30.65 / 27.00
Rule-SpSent	80.82 / 16.88 / 27.93	43.16 / 28.85 / 24.73	67.34 / 63.22 / 65.21	22.65 / 26.42 / 23.10

Table 3: Evaluation results of the species disambiguation systems on DEVTEST (precision/recall/F1-score, in %)

effectively improved recall (see Section 5.2.3 for discussion on statistical significance tests on the results). The Maxent system achieved very good micro-averaged precision, but low macro-averaged scores. In fact, as shown in Table 4, Maxent can only disambiguate 7 species (out of a total of 54) that have relatively large amount of training instances,[12] and failed completely on other species. This suggests that Maxent may not be able to generate good micro-averaged scores when applied to a dataset where the dominant species are different from those in the training set. On the other hand, the relation-classification approaches have a clear advantage over Maxent as measured by macro-averaged scores. As shown in Table 4, Rel-ENJU-Genia worked well on most of the species, displaying its good adaptability, while achieving comparable micro-averaged F1 to Maxent. Overall, Hbrd, which combines the strengths of relation classification and the Maxent classification model, obtained the highest points as measured by every metric.

Species Name	Pct	Mxt	Rel	Hbrd
H. sapiens	50.13%	76.25	65.33	79.51
M. musculus	13.99%	66.41	58.29	68.27
X. tropicalis	7.35%	64.80	77.72	71.39
D. melanogaster	6.34%	93.17	78.46	95.15
S. cerevisiae	4.79%	90.12	83.32	87.68

Table 4: The micro-averaged F1 scores (%) of Maxent (Mxt), Rel-ENJU-Genia with spreading (Rel), and Hbrd with respect to each of the most frequent 12 species in DEVTEST.

5.2.3 Statistical Significance

To see whether our methods significantly improved the baseline systems, we performed randomisation tests (Noreen, 1989; Yeh, 2000) on some of the results shown in Table 3. The intuition of randomisation test is as follows: when comparing two systems (e.g., A and B), we erase the labels "output of A" or "output of B" from all observations. The null hypothesis is that there is no difference between A and B, and thus any response produced by one of the systems could have as likely come from the other. We shuffle these responses R times, reassign each response to A or B and see how likely such a shuffle produces a difference in the metric of interest that is at least as large as the difference observed when using A and B on the test data. Let r denote the number of times that such a difference occurred, then as $R \rightarrow \infty$, $\frac{r+1}{R+1}$ approaches the significance level. In our case, the metrics tested were micro- and macro-averaged precision, recall and F1.

Following this procedure, we tested whether the improvements made by a relation classification based system (i.e., Rel-ENJU-Genia with SPRD) and the hybrid system (i.e., Hbrd) over the baseline systems were statistically significant. We carried out approximate randomisation with 10,000 shuffles and the test results are shown in Table 5. The numerical figures in the cells are differences in precision, recall and F1 between a pair of systems. The significance levels (i.e., p-values) are indicated by superscript marks, whose corresponding values are displayed in Table 6. For exam-

[12] The following 7 species occur most frequently in the training set: H. sapiens (43.25%), M. musculus (27.05%), R. norvegicus (5.35%), S. cerevisiae (3.98%), X. tropicalis (3.56%), D. melanogaster (3.33%) and C. elegans (0.94%).

		Rule-Majority	Rule-Sp	Rule-SpSent	Maxent
Rel	micro-avg	2.77*/3.46*/3.13*	1.95*/2.04*/2.00*	1.57*/2.22*/1.92*	-1.57* / -5.02* / -3.35*
	macro-avg	15.24*/13.12*/12.13*	3.75[a]/4.21[a]/3.20[a]	9.35*/8.44*/7.10*	21.92*/24.87*/20.35*
Hbrd	micro-avg	8.01*/11.27*/9.70*	7.19*/9.85*/8.57*	6.81*/10.04* /8.49*	3.67*/2.78*/2.82[b]
	macro-avg	27.22*/15.72[c]/13.72[d]	15.73*/6.82[e]/4.80[f]	21.33*/11.05[g] / 8.70[h]	33.91[i]/27.47*/21.95*

Table 5: Results of paired randomisation tests on whether Rel-ENJU-Genia with SPRD (Rel) and Hbrd significantly improved the baseline systems. The numerical figures in the cells show the differences between the two systems as measured by precision/recall/F1 in percentage. The superscript marks indicate the significance levels and are explained in Table 6.

ple, the difference in micro-averaged precision between Rel-ENJU-Genia and Rule-Majority on the test data was 2.77%, and in 10,000 approximate randomisation trials, there was zero times[13] that Rel-ENJU-Genia's micro-averaged precision is greater than Rule-Majority's by at least 2.77% ($p < 0.0001$).

MARK	VALUE	MARK	VALUE
*	$p < 0.0001$	a	$p < 0.06$
b	$p < 0.002$	c	$p < 0.0003$
d	$p < 0.0002$	e	$p < 0.03$
f	$p < 0.05$	g	$p < 0.003$
h	$p < 0.005$	i	$p < 0.07$

Table 6: p-values.

The test results confirmed that, the improvements made by Hbrd are statistically significant with at least 95% confidence as measured by all metrics except for macro-averaged precision. The relation classification approach achieved significantly lower performance than Maxent in terms of micro-averaged scores (hence the "-" sign in the corresponding cell in Table 5), but in all other cases it can reject the null hypothesis with very high confidence (i.e., $p < 0.0001$).

6 Conclusions and Future Work

This paper proposes a method that tackles a complex disambiguation problem by breaking it into two cascaded simpler tasks of cue word discovery and binary relation classification. We evaluated the method on the task of disambiguating the model organisms of biomedical named entities, along with a number of other approaches. As measured by micro-averaged F1 score, a supervised classification approach (Maxent) yielded the second best result. However, it can only disambiguate a small number of species that have abundant training instances. With spreading rules, a relation classification system (Rel-ENJU-Genia) trained on word and syntactic features from ENJU-Genia also obtained good micro-averaged F1, while surpassing Maxent significantly in terms of macro-averaged scores. Combining these two systems achieved the best overall performance. Nevertheless, we combined the two methods in a rather crude way, leaving ample room for exploring better strategies in the future.

One drawback of the relation classification systems is that they can not cover all entity mentions but only the ones with informative keywords co-occurring in the same sentence. We overcame the drawback by using spreading rules. For some applications, however, it may be sufficient to make predictions exclusively for cases where the systems are applicable. Also, the predictions with high confidence can be used as seed training material for automatically harvesting more training data.

[13]The numbers of times are not shown in Table5 for brevity.

Abstract

Bootstrapping is the process of improving the performance of a trained classifier by iteratively adding data that is labeled by the classifier itself to the training set, and retraining the classifier. It is often used in situations where labeled training data is scarce but unlabeled data is abundant. In this paper, we consider the problem of domain adaptation: the situation where training data may not be scarce, but belongs to a different domain from the target application domain. As the distribution of unlabeled data is different from the training data, standard bootstrapping often has difficulty selecting informative data to add to the training set. We propose an effective domain adaptive bootstrapping algorithm that selects unlabeled target domain data that are *informative about the target domain* and *easy to automatically label correctly*. We call these instances *bridges*, as they are used to bridge the source domain to the target domain. We show that the method outperforms supervised, transductive and bootstrapping algorithms on the named entity recognition task.

1 Introduction

Most recent researches on natural language processing (NLP) problems are based on machine learning algorithms. High performance can often be achieved if the system is trained and tested on data from the same domain. However, the performance of NLP systems often degrades badly when the test data is drawn from a source that is different from the labeled data used to train the system. For named entity recognition (NER), for example, Ciaramita and Altun (2005) reported that a system trained on a labeled Reuters corpus achieved an F-measure of 91% on a Reuters test set, but only 64% on a Wall Street Journal test set.

The task of adapting a system trained on one domain (called the *source* domain) to a new domain (called the *target* domain) is called domain adaptation. In domain adaptation, it is generally assumed that we have labeled data in the source domain while labeled data may or may not be available in the target domain. Previous work in domain adaptation can be classified into two categories: [S+T+], where a small, labeled target domain data is available, e.g. (Blitzer et al., 2006; Jiang and Zhai, 2007; Daumé III, 2007; Finkel and Manning, 2009), or [S+T-], where no labeled target domain data is available, e.g. (Blitzer et al., 2006; Jiang and Zhai, 2007). In both cases, and especially for [S+T-], domain adaptation can leverage on large amounts of unlabeled data in the target domain. In practice, it is often unreasonable to expect labeled data for every new domain that we come across, such as blogs, emails, a different newspaper agency, or simply articles from a different topic or period in time. Thus although [S+T+] is easier to handle, [S+T-] is of higher practical importance.

In this paper, we propose a domain adaptive bootstrapping (DAB) approach to tackle the domain adaptation problem under the setting [S+T-]. Bootstrapping is an iterative process that uses a trained classifier to label and select unlabeled instances to add to the training set for retraining the classifier. It is often used when labeled training data is scarce but unlabeled data is abundant. In contrast, for domain adaptation problems, we may have a lot of training data but the target application domain has a different data distribution. Standard bootstrapping usually selects instances that are most confidently labeled from the unlabeled data. In domain adaptation situations, usually the most confidently labeled instances are the ones that are most similar to the source domain in-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1523–1532,
Singapore, 6-7 August 2009.

stances - these instances tend to contain very little information about the target domain. For domain adaptive bootstrapping, we propose a selection criterion that selects instances that are informative and easy to automatically label correctly. In addition, we propose a criterion for stopping the process of bootstrapping before it adds uninformative and incorrectly labeled instances that can reduce performance.

Our approach leverages on instances in the target domain called *bridges*. These instances contain domain-independent features, as well as features specific to the target domain. As they contain domain-independent features, they can be classified correctly by classifiers trained on the source domain labeled data. We argue that these instances act as a bridge between the source and the target domain. We show that, on the NER task, DAB outperforms supervised, transductive and standard bootstrapping algorithms, as well as a bootstrapping variant, called *balanced* bootstrapping (Jiang and Zhai, 2007), that has recently been proposed for domain adaptation.

2 Related work

One general class of approaches to domain adaptation is to consider that the instances from the source and the target domain are drawn from different distributions. Bickel et al. (Bickel et al., 2007) discriminatively learns a scaling factor for source domain training data, so as to adapt the source domain data distribution to resemble the target domain data distribution, under the [S+T-] setting. Daume III and Marcu (Daumé III and Marcu, 2006) considers that the data distribution is a mixture distribution over general, source domain and target domain data. They learn the underlying mixture distribution using the conditional expectation maximization algorithm, under the [S+T+] setting. Jiang and Zhai (2007) proposed an instance re-weighting framework that handles both the [S+T+] and [S+T-] settings. For [S+T-], the resulting algorithm is a *balanced* bootstrapping algorithm, which was shown to outperform the *standard* bootstrapping algorithm. In this paper, we assume the [S+T-] settings, and we show that the approach proposed in this paper, domain adaptive bootstrapping (DAB), outperforms the balanced bootstrapping algorithm on NER.

Another class of approaches to domain adaptation is feature-based. Daume III (Daumé III, 2007) divided features into three classes: domain-independent features, source-domain features and target-domain features. He assumed the existence of training data in the target-domain (under the setting [S+T+]), so that the three classes of features can be jointly trained using source and target domain labeled data. This cannot be done in the setting [S+T-], where no training data is available in the target domain. Using a different approach, Blitzer et al. (2006) induces correspondences between feature spaces in different domains, by detecting pivot features. Pivot features are features that occur frequently and behave similarly in different domains. Pivot features are used to put domain-specific features in correspondence. In this paper, instead of pivot features, we attempt to leverage on pivot instances that we call *bridges*, which are instances that bridge the source and target domain. This will be illustrated in Section 3.

It is generally recognized that adding informative and correctly labeled instances is more useful for learning. Active learning queries the user for labels of most informative or relevant instances. Active learning, which has been applied to the problem of NER in (Shen et al., 2004), is used in situations where a large amount of unlabeled data exists and data labeling is expensive. It has also been applied to the problem of domain adaptation for word sense disambiguation in (Chan and Ng, 2007). However, active learning requires human intervention. Here, we want to achieve the same goal without human intervention.

3 Bootstrapping for domain adaptation

We first define the notations used for domain adaptation in the [S+T-] setting. A set of training data $D_S = \{x_i, y_i\}_{1 \leq i \leq |D_S|}$ is given in the source domain, where the notation $|X|$ denotes the size of a set X. Each instance x_i in D_S has been manually annotated with a label, y_i, from a given set of labels Y. The objective of domain adaptation is to label a set of unlabeled data, $D_T = \{x_i\}_{1 \leq i \leq |D_T|}$ with labels from Y. A machine learning algorithm will take a labeled data set (for e.g. D_S) and outputs a *classifier*, which can then be used to classify unlabeled data, i.e. assign labels to unlabeled instances.

A special class of machine learning algorithms, called *transductive* learning algorithms, is able to take the unlabeled data D_T into account during the learning process (see e.g. (Joachims, 1999)).

However, such algorithms do not take into account the shift in domain of the test data. Jiang and Zhai (2007) recently proposed an instance re-weighting framework to take domain shift into account. For [S+T-], the resulting algorithm is a *balanced* bootstrapping algorithm, which we describe below.

3.1 Standard and balanced bootstrapping

We define a general bootstrapping algorithm in Algorithm 1. The algorithm can be applied to any machine learning algorithm that allows training instances to be weighted, and that gives confidence scores for the labels when used to classify test data. The bootstrapping procedure iteratively improves the performance of a classifier SC_t over a number of iterations. In Algorithm 1, we have left a number of parameters unspecified. These parameters are (1) the *selection-criterion* for instances to be added to the training data, (2) the *termination-criterion* for the bootstrapping process, and (3) the weights (w^S, w^T) given to the labeled and bootstrapped training sets.

Standard bootstrapping: (Jiang and Zhai, 2007) the *selection-criterion* is based on selecting the top k most-confidently labeled instances in R_t. The weight w_t^S is equal to w_t^T. The value of k is a parameter for the bootstrapping algorithm.

Balanced bootstrapping: (Jiang and Zhai, 2007) the *selection-criterion* is still based on selecting the top k most-confidently labeled instances in R_t. Balanced bootstrapping was formulated for domain adaptation, and hence they set the weights to satisfy the ratio $\frac{w_t^S}{w_t^T} = \frac{|T_t|}{|D_S|}$. This allows the small amount of target data added, T_t, to have an equal weight to the large source domain training set D_S.

In this paper, we formulate a selection-criterion and a termination-criterion which are better than those used in standard and balanced bootstrapping. Regarding the selection-criterion, standard and balanced bootstrapping both select instances which are confidently labeled by SC_t to be used for training SC_{t+1}, in the hope of avoiding using wrongly labeled data in bootstrapping. However, instances that are already confidently labeled by SC_t may not contain sufficient information which is not in D_S, and using them to train SC_{t+1} may result in SC_{t+1} performing similarly to SC_t. This motivates us to select samples which are both *informative* and *easy to automatically label correctly*. Regarding the *termination-criterion*, which is not mentioned in the paper (Jiang and Zhai, 2007), we assume that bootstrapping is simply run for either a single iteration, or a small and fixed number of iterations. However, it is known that such simple criterion may result in stopping too early or too late, leading to sub-optimal performance. We propose a more effective termination-criterion here.

Algorithm 1 Bootstrapping algorithm

Input: labeled data D_S, test data D_T and a machine learning algorithm.
Output: the predicted labels of the set D_T.
Set $T_0 = \emptyset$, $R_0 = D_T$, and $t = 0$
Repeat

1. learn a classifier SC_t with (D_S, T_t) with weights (w_t^S, w_t^T)
2. label the set R_t with SC_t
3. select $S_t \subseteq R_t$ based on *selection-criterion*
4. $T_{t+1} = T_t \cup S_t$, and $R_{t+1} = R_t \setminus S_t$.

Until *termination-criterion*
Output the predicted labels of D_T by SC_t.

3.2 Domain adaptive bootstrapping (DAB)

Our selection-criterion relies on the observation that in domain adaptation, instances (from the source or the target domain) can be divided into three types according to their information content: *generalists* are instances that contain only domain-independent information and are present in all domains; *specialists* are instances containing only domain-specific information and are present only in their respective domains; *bridges* are instances containing both domain-independent and domain-specific information, also present only in their respective domains but are useful as a "bridge" between the source and the target domains.

The implication of the above observation is that when choosing unlabeled target domain data for bootstrapping, we should exploit the *bridges*, because the *generalists* are not likely to contain much information not in D_S due to their domain-independence, and the *specialists* are difficult to be labeled correctly due to their domain-specificity. In contrast, the *bridges* are informative and easier to label correctly. Choosing confidently classified instances for bootstrapping, as in standard bootstrapping and balanced bootstrapping, is simple, but results in choosing mostly *generalists*, and is too conservative. We design a scoring function

on instances, which has high value when the instance is informative and sufficiently likely to be correctly labeled in order to identify correctly labeled *bridges*.

Intuitively, informativeness of an instance can be measured by the prediction results of the ideal classifier IS for the source domain and the ideal classifier IT for the target domain. If IS and IT are both probabilistic classifiers, IS should return a noninformative distribution while IT should return an informative one. The ideal classifier for the source domain is approximated with a *source classifier* SC trained on D_S, while the ideal classifier for the target domain is approximated by training a classifier, TC, on target domain instances labeled by the source classifier.

We also try to ensure that instances that are selected are correctly classified. As the label used is provided by the target classifier, we estimate the precision of the target classification. The final ranking function is constructed by combining this estimate with the informativeness of the instance.

We show the algorithm for the instance selection in Algorithm 2. The notations used follow those used in Algorithm 1. For simplicity, we assume that $w_t^S = w_t^T = 1$ for all t. We expect TC to be a reasonable classifier on D_T due to the presence of *generalists* and *bridges*. Note that the target classifier is constructed by randomly splitting D_T into two partitions, training a classifier on each partition and using the prediction of the trained classifier on the partition it is not trained on. This is because classifiers tend to fit the data that they have been trained on too well making the probability estimates on their training data unreliable. Also, a random partition is used to ensure that the data in each partition is representative of D_u.

3.3 The scoring function: $score(p^{(s)}, p^{(t)})$

The scoring function $score(p^{(s)}, p^{(t)})$ in Algorithm 2 is simply implemented as the product of two components: a measure of the informativeness and the probability that SC's label is correct. We show how the intuitive ideas (described above) behind these two components are formalized.

Informativeness of a distribution p on a set of discrete labels Y is measured by its entropy $h(p)$ defined by

$$h(p) = -\sum_{y \in Y} p(y) \log p(y).$$

Algorithm 2 Algorithm for selecting instances for bootstrapping at iteration t

Input: Labeled source domain data D_S, target domain training data T_t, remaining data R_t, the classifier SC_t trained on $D_S \cup T_t$, and a scoring function $score(p^{(s)}, p^{(t)})$

Output: k instances for bootstrapping.

1. Label R_t with SC_t, and to each instance $x_i \in R_t$, SC_t outputs a distribution $p_i^{(s)}(y_i)$ over its labels.
2. Randomly split R_t into two partitions, R_t^0 and R_t^1 with their labels assigned by SC_t.
3. Train each target classifier, TC_t^x with the data R_t^x, for $x = \{0, 1\}$.
4. Label $R_t^{(1-x)}$ with the classifier TC_t^x, which to each instance $x_i \in R_t$, outputs a distribution $p_i^{(t)}(y_i)$ over its labels.
5. Score each instance from $x_i \in R_t$ with the function $score(p_i^{(s)}, p_i^{(t)})$.
6. Select top k instances from R_t with the highest scores.

$h(p)$ is nonnegative; $h(p) = 0$ if and only if p has probability 1 on one of the labels; $h(p)$ attains its maximum value when the distribution p is uniform over all labels. Hence, an instance is classified with high confidence when the distribution over its labels has low entropy.

We measure the informativeness of an instance using $h(p^{(s)}) - h(p^{(t)})$, where $p^{(s)}$ and $p^{(t)}$ are as in Algorithm 2. We argue that a larger value of this expression implies that the instance is more likely to be a *bridge* instance. This expression has a high value when the source classifier is uncertain, and the target classifier is certain. Uncertain classification by the source classifier indicates that the instance is unlikely to be a *generalist*. Moreover, if the target classifier is certain on x_i, it means that instances similar to the instance x_i are consistently labeled with the same label by the source classifier SC_t, indicating that it is likely to be a *bridge* instance.

The probability that TC's label is correct cannot be estimated directly because we do not have labeled target domain data. Instead, we use the source domain to give an estimate. We do this with a simple pre-processing step: we split the data D_S into two partitions of equal size, train a classifier on each partition, and test each classifier on the

other partition. We then measure the resulting accuracy given each label:

$$\rho(y) = \frac{\text{\# correctly labeled instances of label } y}{\text{\# total instances of label } y}.$$

Summarizing the above discussion, the scoring function is as shown below.

$$score(p^{(s)}, p^{(t)}) = \rho(y^*) \left[h(p^{(s)}) - h(p^{(t)})\right],$$
$$\text{where } y^* = \arg\max_{y \in Y} p^{(s)}(y)$$

The scoring function has a high value when the information content of the example is high and the label has high precision.

3.4 The termination criterion

Intuitively, our algorithm terminates when there are not enough informative instances. Formally, we define the termination criterion as follows: we terminate the bootstrapping process when, there exists an instance x_i in the top k instances satisfying the following condition:

1. $h(p_i^{(s)}) < h(p_i^{(t)})$, or
2. $\max_{y \in Y} p_i^{(s)}(y) > \max_{y \in Y} p_i^{(t)}(y)$

The second case is used to check for instances where the classifier SC_t is more confident than the target classifiers TC_t^x, on their respective predicted labels. This shows that the instance x_i is more of a *generalist* than a *bridge*.

4 NER task and implementation

The algorithm described in Section 3 is not specific to any particular application. In this paper, we apply it to the problem of named entity recognition (NER). In this section, we describe the NER classifier and the features used in our experiments.

4.1 NER features

We used the features generated by the CRF package (Finkel et al., 2005). These features include the word string feature, the case feature for the current word, the context words for the current word and their cases, the presence in dictionaries for the current word, the position of the current word in the sentence, prefix and suffix of the current word as well as the case information of the multiple occurrences of the current word. We use the same set of features for all classifiers used in the bootstrapping process, and for all baselines used in the experimental section.

4.2 Machine learning algorithms

A base machine learning algorithm is required in bootstrapping approaches. We describe the two machine learning algorithms used in this paper. We chose these algorithms for their good performance on the NER task.

Maximum entropy classification (MaxEnt): The MaxEnt approach, or logistic regression, is one of the most competitive methods for named entity recognition (Tjong and Meulder, 2003). MaxEnt is a discriminative method that learns a distribution, $p(y_i|x_i)$, over the labels, y_i, given the vector of features, x_i. We used the implementation of MaxEnt classifier described in (Manning and Klein, 2003). For NER, each instance represents a single word token within a sentence, with the feature vector x_i derived from the sentence as described in the previous section. MaxEnt is not designed for sequence classification. To deal with sequences, each name-class (e.g. PERSON) is divided into sub-classes: first token (e.g. PERSON-begin), unique token (e.g. PERSON-unique), or subsequent tokens (e.g. PERSON-continue) in the name-class. To ensure that the results returned by MaxEnt is coherent, we define deterministic transition probabilities that disallow transitions such as one from PERSON-begin to LOCATION-continue. A Viterbi parse is used to find the *valid* sequence of name-classes with the highest probability.

Support vector machines (SVM): The basic idea behind SVM for binary classification problems is to consider the data points in their feature space, and to separate the two classes with a hyper-plane, by maximizing the shortest distance between the data points and the hyper-plane. If there exists no hyperplane that can split the two labels, the soft margin version of SVM will choose a hyperplane that splits the examples as cleanly as possible, while still maximizing the distance to the nearest cleanly split examples (Joachims, 2002). We used the SVM^{light} package for our experiments (Joachims, 2002). For the multi-label NER classification with N classes, we learn N SVM classifiers, and use a softmax function to obtain the distribution. Formally, denoting by $s(y)$ the confidence returned by the classifier for each label $y \in Y$, the probability of the label y_i is given by

$$p(y_i|x_i) = \frac{\exp(s(y_i))}{\sum_{y \in Y} \exp(s(y))}$$

Similarly to MaxEnt, we subdivide name-classes into begin, continue, and unique sub-classes, and use a Viterbi parse for the sequence of highest probability. The SVM^{light} package also implements a transductive version of the SVM algorithm. We also compare our approach with the transductive SVM (Joachims, 1999) in our experimental results.

5 Experimental results

In this paper, we use the annotated data provided by the Automatic Content Extraction (ACE) program. The ACE data set is annotated for an Entity Detection task, and the annotation consists of the labeling of entity names (e.g. *Powell*) and mentions for each entity (e.g. pronouns such as *he*). In this paper, we are interested in the problem of recognition of the proper names (the named entity recognition task), and hence use only entities labeled with the type *NAM* (LDC, 2005). Entities are classified into seven types: *Person* entities are humans mentioned in a document; *Organization* entities are limited to established associations of people; *Geo-political* entities are geographical areas defined by political and/or social groups; *Location* entities are geographical items like landmasses and bodies of water; *Facility* entities refer to buildings and real estate improvements; *Vehicle* entities are devices used for transportation; and *Weapon* entities are devices used for harming or destruction.

We compare performances of a few algorithms: MaxEnt classifier (MaxEnt); MaxEnt classifier with standard bootstrapping (MaxEnt-SB); balanced bootstrapping based on MaxEnt classifier (MaxEnt-BB); MaxEnt with DAB (MaxEnt-DAB); SVM classifier (SVM); transductive SVM classifier (SVM-Trans); and DAB based on SVM classifier (SVM-DAB). No regularization is used for MaxEnt classifiers. SVM classifiers use a value of 10 for parameter C (trade-off between training error and margin). Bootstrapping based algorithms are run for 30 iterations and 100 instances are selected in every iteration.

The evaluation measure used is the F-measure. F-measure is the harmonic mean of precision and recall, and is commonly used to evaluate NER systems. We use the scorer for CONLL 2003 shared task (Tjong and Meulder, 2003) where the F-measure is computed by averaging F-measures for name-classes, weighted by the number of occurrences.

Code	Source	Num docs

Table 1: The sources, and the number of documents in each source, in the ACE 2005 data set.

5.1 Cross-source transfer

The ACE 2005 data set consists of articles drawn from a variety of sources. We use the four categories shown in Table 1. Each category is considered to be a domain, and we consider each pair of categories as the source and the target domain in turn.

Figure 1 compares the performance of MaxEnt-SB, MaxEnt-BB and MaxEnt-DAB over multiple iterations. Figure 2 compares the performance of SVM, SVM-Trans and SVM-DAB. Each line in the figures represents the average F-measure across all the domains over many iterations. When the termination condition is met for one domain, its F-measure remains at the value of the final iteration.

Despite a large number of iterations, both standard and balanced bootstrapping fail to improve performance. Supervised learning performance on each domain is shown in Table 3 (by 2-fold cross-validation with random ordering) as a reference. In Table 5, we compare the F-measures obtained by different algorithms at the last iteration they were run. We will discuss more on this in Section 5.3.

5.2 Cross-topic transfer

This data set is constructed from 175 articles from the ACE 2005 corpus. The data set is used to evaluate transfer across topics. We manually classify the articles into 4 categories: military operations (MO), political relationship or politicians (POL), terrorism-related (TER), and those which are not in the above categories (OTH). A detailed breakdown of the number of documents in the each topic is given in Table 2.

Supervised learning performance on each domain is shown in Table 4 (by 2-fold cross-validation with random ordering) as a reference. Experimental results on cross-topic evaluation are shown in Table 6. Figure 3 compares the performance of MaxEnt-SB, MaxEnt-BB and MaxEnt-

5.3 Discussion

We show in our experiments that DAB outperforms standard and balanced bootstrapping, as well as the transductive SVM. We have also shown DAB to be robust across two state-of-the-art classifiers, MaxEnt and SVM. Balanced bootstrapping has been shown to be more effective for domain adaptation than standard bootstrapping (Jiang and Zhai, 2007) for named entity classification on a subset of the dataset used here. In contrast, we found that both methods perform poorly on domain adaptation for NER. In named entity classification, the names have already been segmented out and only need to be classified with the appropriate class. However, for NER, the names also

need to be separated from not-a-name instances. We find that the addition of not-a-name instances changes the problem - the not-a-names form most of the instances classified with high confidence. As a result, we find that both standard and balanced bootstrapping fail to improve performance: the selection of the most confident instances no longer provide sufficient new information to improve performance.

We also find that transductive SVM performs poorly on this task. This is because it assumes that the unlabeled data comes from the same distribution as the labeled data. In general, applying semi-supervised learning methods directly to [S+T-] type domain adaptation problems do not work and appropriate modifications need to be made to the methods.

The ACE 2005 data set also contains a set of ariticles from the *broadcast news* (BN) source which is written entirely in lower case. This makes NER much more difficult. However, when BN is the source domain, the capitalization information can be discovered by DAB. Figures 5 and 6 show the average performance when BN is used as the source domain and all other domains in Table 1 as the target domains.

The source domain classifier tends to have high precision and low recall, DAB results in an increase in recall, with a small decrease in precision.

Testing the significance of the F-measure is not trivial because the named entities wrongly labeled by two classifiers are not directly comparable. We tested the labeling disagreements instead, using a McNemar paired test. The significance test is performed on the improvement of MaxEnt-DAB over MaxEnt and SVM-DAB over SVM. In most of the domains for the cross-source transfer, the improvements are significant at a significance level of 0.05, using MaxEnt classifier. The exceptional train-test pairs are NW-WL and WL-BC. In the case of WL-BC, this means the slight decrement in performance is not statistically significant. Similar result is achieved for the cross-source transfer using SVM classifier. In the cross-topic transfer, the source domain and the target domain are not very different. When we have a large amount of training data and little testing data, the gain of DAB can be not statistically significant, as in the case when we train with MO and POL domains.

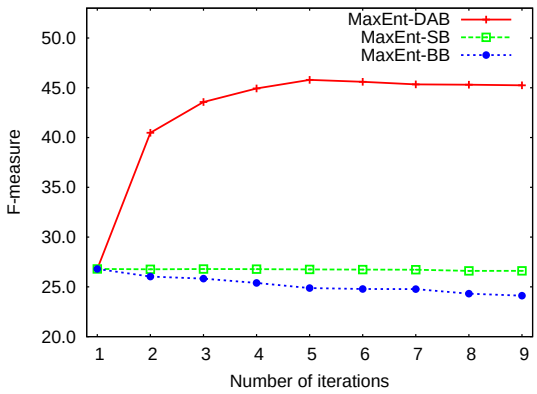

Figure 5: Performance on recovering capitalization using MaxEnt classifier.

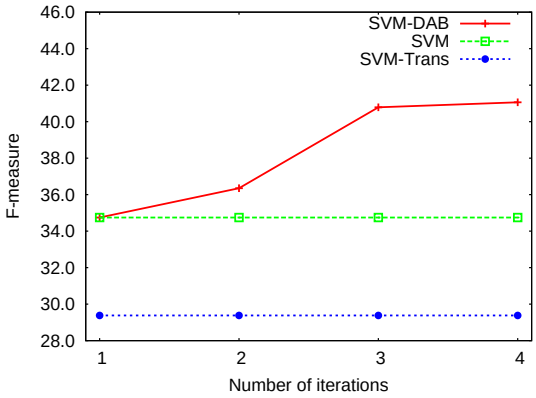

Figure 6: Performance on recovering capitalization using SVM classifier.

6 Conclusion

We proposed a bootstrapping approach for domain adaptation, and we applied it to the named entity recognition task. Our approach leverages on instances that serve as *bridges* between the source and target domain. Empirically, our method outperforms baseline approaches including supervised, transductive and standard bootstrapping approaches. It also outperforms balanced bootstrapping, an approach designed for domain adaptation (Jiang and Zhai, 2007).

Phrase Dependency Parsing for Opinion Mining

Yuanbin Wu, Qi Zhang, Xuanjing Huang, Lide Wu
Fudan University
School of Computer Science
{ybwu,qi_zhang,xjhuang,ldwu}@fudan.edu.cn

Abstract

In this paper, we present a novel approach for mining opinions from product reviews, where it converts opinion mining task to identify product features, expressions of opinions and relations between them. By taking advantage of the observation that a lot of product features are phrases, a concept of phrase dependency parsing is introduced, which extends traditional dependency parsing to phrase level. This concept is then implemented for extracting relations between product features and expressions of opinions. Experimental evaluations show that the mining task can benefit from phrase dependency parsing.

1 Introduction

As millions of users contribute rich information to the Internet everyday, an enormous number of product reviews are freely written in blog pages, Web forums and other consumer-generated mediums (CGMs). This vast richness of content becomes increasingly important information source for collecting and tracking customer opinions. Retrieving this information and analyzing this content are impossible tasks if they were to be manually done. However, advances in machine learning and natural language processing present us with a unique opportunity to automate the decoding of consumers' opinions from online reviews.

Previous works on mining opinions can be divided into two directions: sentiment classification and sentiment related information extraction. The former is a task of identifying positive and negative sentiments from a text which can be a passage, a sentence, a phrase and even a word (Somasundaran et al., 2008; Pang et al., 2002; Dave et al., 2003; Kim and Hovy, 2004; Takamura et al., 2005). The latter focuses on extracting the elements composing a sentiment text. The elements include source of opinions who expresses an opinion (Choi et al., 2005); target of opinions which is a receptor of an opinion (Popescu and Etzioni, 2005); opinion expression which delivers an opinion (Wilson et al., 2005b). Some researchers refer this information extraction task as opinion extraction or opinion mining. Comparing with the former one, opinion mining usually produces richer information.

In this paper, we define an opinion unit as a triple consisting of a product feature, an expression of opinion, and an emotional attitude(positive or negative). We use this definition as the basis for our opinion mining task. Since a product review may refer more than one product feature and express different opinions on each of them, the relation extraction is an important subtask of opinion mining. Consider the following sentences:

1. I highly [recommend]$^{(1)}$ the Canon SD500$^{(1)}$ to anybody looking for a compact camera that can take [good]$^{(2)}$ pictures$^{(2)}$.

2. This camera takes [amazing]$^{(3)}$ image qualities$^{(3)}$ and its size$^{(4)}$ [cannot be beat]$^{(4)}$.

The phrases underlined are the product features, marked with square brackets are opinion expressions. Product features and opinion expressions with identical superscript compose a relation. For the first sentence, an opinion relation exists between "*the Canon SD500*" and "*recommend*", but not between "*picture*" and "*recommend*". The example shows that more than one relation may appear in a sentence, and the correct relations are not simple Cartesian product of opinion expressions and product features.

Simple inspection of the data reveals that product features usually contain more than one word, such as "LCD screen", "image color", "Canon PowerShot SD500", and so on. An incomplete product feature will confuse the successive analysis. For example, in passage *"Image color is dis-*

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1533–1541,
Singapore, 6-7 August 2009.

appointed", the negative sentiment becomes obscure if only "*image*" or "*color*" is picked out.

Since a product feature could not be represented by a single word, dependency parsing might not be the best approach here unfortunately, which provides dependency relations only between words. Previous works on relation extraction usually use the head word to represent the whole phrase and extract features from the word level dependency tree. This solution is problematic because the information provided by the phrase itself can not be used by this kind of methods. And, experimental results show that relation extraction task can benefit from dependencies within a phrase.

To solve this issue, we introduce the concept of phrase dependency parsing and propose an approach to construct it. Phrase dependency parsing segments an input sentence into "phrases" and links segments with directed arcs. The parsing focuses on the "phrases" and the relations between them, rather than on the single words inside each phrase. Because phrase dependency parsing naturally divides the dependencies into local and global, a novel tree kernel method has also been proposed.

The remaining parts of this paper are organized as follows: In Section 2 we discuss our phrase dependency parsing and our approach. In Section 3, experiments are given to show the improvements. In Section 4, we present related work and Section 5 concludes the paper.

2 The Approach

Fig. 1 gives the architecture overview for our approach, which performs the opinion mining task in three main steps: (1) constructing phrase dependency tree from results of chunking and dependency parsing; (2) extracting candidate product features and candidate opinion expressions; (3) extracting relations between product features and opinion expressions.

2.1 Phrase Dependency Parsing

2.1.1 Overview of Dependency Grammar

Dependency grammar is a kind of syntactic theories presented by Lucien Tesnière(1959). In dependency grammar, structure is determined by the relation between a head and its dependents. In general, the dependent is a modifier or complement; the head plays a more important role in determining the behaviors of the pair. Therefore, criteria of how to establish dependency relations and how to distinguish the head and dependent in such relations is central problem for dependency grammar. Fig. 2(a) shows the dependency representation of an example sentence. The root of the sentence is "enjoyed". There are seven pairs of dependency relationships, depicted by seven arcs from heads to dependents.

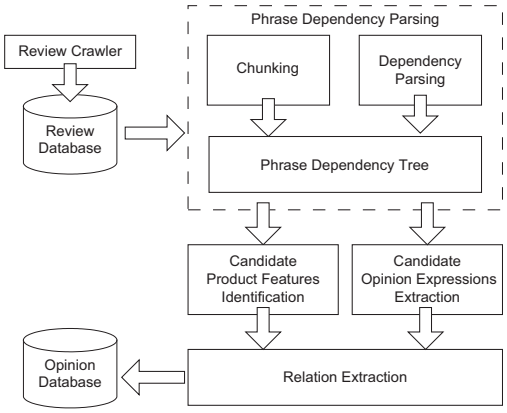

Figure 1: The architecture of our approach.

2.1.2 Phrase Dependency Parsing

Currently, the mainstream of dependency parsing is conducted on lexical elements: relations are built between single words. A major information loss of this word level dependency tree compared with constituent tree is that it doesn't explicitly provide local structures and syntactic categories (i.e. NP, VP labels) of phrases (Xia and Palmer, 2001). On the other hand, dependency tree provides connections between distant words, which are useful in extracting long distance relations. Therefore, compromising between the two, we extend the dependency tree node with phrases. That implies a noun phrase "Cannon SD500 PowerShot" can be a dependent that modifies a verb phrase head "really enjoy using" with relation type "dobj". The feasibility behind is that a phrase is a syntactic unit regardless of the length or syntactic category (Santorini and Kroch, 2007), and it is acceptable to substitute a single word by a phrase with same syntactic category in a sentence.

Formally, we define the dependency parsing with phrase nodes as *phrase dependency parsing*. A dependency relationship which is an asymmetric binary relationship holds between two phrases. One is called head, which is the central phrase in the relation. The other phrase is called dependent, which modifies the head. A label representing the

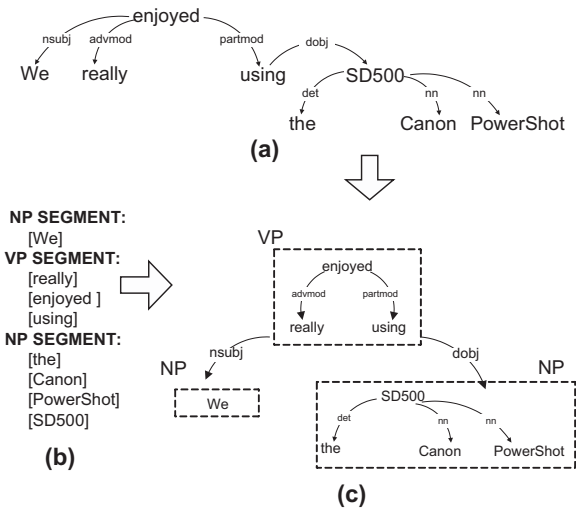

Figure 2: Example of Phrase Dependency Parsing.

relation type is assigned to each dependency relationship, such as subj (subject), obj (object), and so on. Fig.2(c) shows an example of phrase dependency parsing result.

By comparing the phrase dependency tree and the word level dependency tree in Fig.2, the former delivers a more succinct tree structure. Local words in same phrase are compacted into a single node. These words provide local syntactic and semantic effects which enrich the phrase they belong to. But they should have limited influences on the global tree topology, especially in applications which emphasis the whole tree structures, such as tree kernels. Pruning away local dependency relations by additional phrase structure information, phrase dependency parsing accelerates following processing of opinion relation extraction .

To construct phrase dependency tree, we propose a method which combines results from an existing shallow parser and a lexical dependency parser. A phrase dependency tree is defined as $\mathscr{T} = (\mathscr{V}, \mathscr{E})$, where $\mathscr{V}$ is the set of phrases, $\mathscr{E}$ is the dependency relations among the phrases in $\mathscr{V}$ representing by direct edges. To reserve the word level dependencies inside a phrase, we define a nested structure for a phrase T_i in $\mathscr{V}$: $T_i = (V_i, E_i)$. $V_i = \{v_1, v_2, \cdots, v_m\}$ is the internal words, E_i is the internal dependency relations.

We conduct the phrase dependency parsing in this way: traverses word level dependency tree in preorder (visits root node first, then traverses the children recursively). When visits a node R, searches in its children and finds the node set D which are in the same phrase with R according to the shallow parsing result. Compacts D and R into a single node. Then traverses all the remaining children in the same way. The algorithm is shown in Alg. 1.

Algorithm 1 Pseudo-Code for constructing the phrase dependency tree

INPUT:
$T' = (V', E')$ a word level dependency tree
P = phrases
OUTPUT:
phrase dependency tree $\mathscr{T} = (\mathscr{V}, \mathscr{E})$ where
$\mathscr{V} = \{T_1(V_1, E_1), T_2(V_2, E_2), \cdots, T_n(V_n, E_n)\}$
Initialize:
$\mathscr{V} \leftarrow \{(\{v'\}, \{\}) | v' \in V'\}$
$\mathscr{E} \leftarrow \{(T_i, T_j) | (v'_i, v'_j) \in E', v'_i \in V_i, v'_j \in V_j\}$
$R = (V_r, E_r)$ root of $\mathscr{T}$
PhraseDPTree(R, P)

```
Find p_i ∈ P where word[R] ∈ p_i
for each S = (V_s, E_s), (R, S) ∈ 𝓔 do
    if word[S] ∈ p_i then
        V_r ← V_r ∪ v_s; v_s ∈ V_s
        E_r ← E_r ∪ (v_r, root[S]); v_r ∈ V_r
        𝓥 ← 𝓥 − S
        𝓔 ← 𝓔 + (R, l); ∀(S, l) ∈ 𝓔
        𝓔 ← 𝓔 − (R, S)
    end if
end for
for each (R, S) ∈ 𝓔 do
    PhraseDPTree(S,P)
end for
return (𝓥, 𝓔)
```

The output of the algorithm is still a tree, for we only cut edges which are compacted into a phrase, the connectivity is keeped. Note that there will be inevitable disagrees between shallow parser and lexical dependency parser, the algorithm implies that we simply follow the result of the latter one: the phrases from shallow parser will not appear in the final result if they cannot be found in the procedure.

Consider the following example:

"*We really enjoyed using the Canon PowerShot SD500.*"

Fig.2 shows the procedure of phrase dependency parsing. Fig.2(a) is the result of the lexical dependency parser. Shallow parsers result is shown in Fig.2(b). Chunk phrases "NP(We)", "VP(really enjoyed using)" and "NP(the Canon PowerShot SD500)" are nodes in the output phrase dependency tree. When visiting node "enjoyed" in Fig.2(a), the shallow parser tells that "really" and "using" which are children of "enjoy" are in the same phrase with their parent, then the three nodes are packed. The final phrase dependency parsing tree is shown in the Fig. 2(c).

2.2 Candidate Product Features and Opinion Expressions Extraction

In this work, we define that *product features* are products, product parts, properties of products, properties of parts, company names and related objects. For example,in consumer electronic domain, "Canon PowerShot", "image quality","camera", "laptop" are all product features.

From analyzing the labeled corpus, we observe that more than 98% of product features are in a single phrase, which is either noun phrase (NP) or verb phrase (VP). Based on it, all NPs and VPs are selected as candidate product features. While prepositional phrases (PPs) and adjectival phrases (ADJPs) are excluded. Although it can cover nearly all the true product features, the precision is relatively low. The large amount of noise candidates may confuse the relation extraction classifier. To shrink the size of candidate set, we introduce language model by an intuition that the more likely a phrase to be a product feature, the more closely it related to the product review. In practice, for a certain domain of product reviews, a language model is build on easily acquired unlabeled data. Each candidate NP or VP chunk in the output of shallow parser is scored by the model, and cut off if its score is less than a threshold.

Opinion expressions are spans of text that express a comment or attitude of the opinion holder, which are usually evaluative or subjective phrases. We also analyze the labeled corpus for opinion expressions and observe that many opinion expressions are used in multiple domains, which is identical with the conclusion presented by Kobayashi et al. (2007). They collected 5,550 opinion expressions from various sources . The coverage of the dictionary is high in multiple domains. Motivated by those observations, we use a dictionary which contains 8221 opinion expressions to select candidates (Wilson et al., 2005b). An assumption we use to filter candidate opinion expressions is that opinion expressions tend to appear closely with product features, which is also used to extract product features by Hu and Liu (2004). In our experiments, the tree distance between product feature and opinion expression in a relation should be less than 5 in the phrase dependency parsing tree.

2.3 Relation Extraction

This section describes our method on extracting relations between opinion expressions and product features using phrase dependency tree. Manually built patterns were used in previous works which have an obvious drawback that those patterns can hardly cover all possible situations. By taking advantage of the kernel methods which can search a feature space much larger than that could be represented by a feature extraction-based approach, we define a new tree kernel over phrase dependency trees and incorporate this kernel within an SVM to extract relations between opinion expressions and product features.

The potential relation set consists of the all combinations between candidate product features and candidate opinion expressions in a sentence. Given a phrase dependency parsing tree, we choose the subtree rooted at the lowest common parent(LCP) of opinion expression and product feature to represent the relation.

Dependency tree kernels has been proposed by (Culotta and Sorensen, 2004). Their kernel is defined on lexical dependency tree by the convolution of similarities between all possible subtrees. However, if the convolution containing too many irrelevant subtrees, over-fitting may occur and decreases the performance of the classifier. In phrase dependency tree, local words in a same phrase are compacted, therefore it provides a way to treat "local dependencies" and "global dependencies" differently (Fig. 3). As a consequence, these two kinds of dependencies will not disturb each other in measuring similarity. Later experiments prove the validity of this statement.

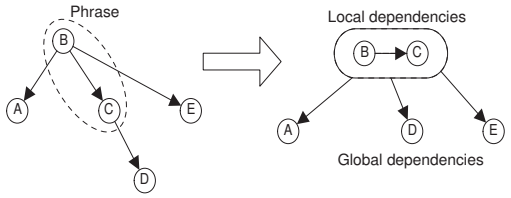

Figure 3: Example of "local dependencies" and "global dependencies".

We generalize the definition by (Culotta and Sorensen, 2004) to fit the phrase dependency tree. Use the symbols in Section 2.1.2, $\mathscr{T}^i$ and $\mathscr{T}^j$ are two trees with root R^i and R^j, $K(\mathscr{T}^i, \mathscr{T}^j)$ is the kernel function for them. Firstly, each tree node $T_k \in \mathscr{T}^i$ is augmented with a set of features F, and an instance of F for T_k is $F^k = \{f^k\}$. A match function $m(T_i, T_j)$ is defined on comparing a subset of nodes' features $M \subseteq F$. And in the same way, a similarity function $s(T_i, T_j)$ are de-

fined on $S \subseteq F$

$$m(T_i, T_j) = \begin{cases} 1 & if\ f_m^i = f_m^j \quad \forall f_m \in M \\ 0 & otherwise \end{cases} \quad (1)$$

and

$$s(T_i, T_j) = \sum_{f_s \in S} C(f_s^i, f_s^j) \quad (2)$$

where

$$C(f_s^i, f_s^j) = \begin{cases} 1 & if\ f_s^i = f_s^j \\ 0 & otherwise \end{cases} \quad (3)$$

For the given phrase dependency parsing trees, the kernel function $K(\mathscr{T}^i, \mathscr{T}^j)$ is defined as follow:

$$K(\mathscr{T}^i, \mathscr{T}^j) = \begin{cases} 0 & if\ m(R^i, R^j) = 0 \\ s(R^i, R^j) + K_{in}(R^i, R^j) & \\ + K_c(R^i.\mathbf{C}, R^j.\mathbf{C}) & otherwise \end{cases} \quad (4)$$

where $K_{in}(R^i, R^j)$ is a kernel function over $R^i = (V_r^i, E_r^i)$ and $R^j = (V_r^j, E_r^j)$'s internal phrase structures,

$$K_{in}(R^i, R^j) = K(R^i, R^j) \quad (5)$$

K_c is the kernel function over R^i and R^j's children. Denote **a** is a continuous subsequence of indices $a, a+1, \cdots a+l(\mathbf{a})$ for R^i's children where $l(\mathbf{a})$ is its length, $\mathbf{a}_s$ is the s-th element in **a**. And likewise **b** for R^j.

$$K_c(R^i.\mathbf{C}, R^j.\mathbf{C}) = \sum_{\mathbf{a},\mathbf{b},l(\mathbf{a})=l(\mathbf{b})} \lambda^{l(\mathbf{a})} K(R^i.[\mathbf{a}], R^j.[\mathbf{b}]) \times \prod_{s=1..l(\mathbf{a})} m(R^i.[\mathbf{a}_s], R^j.[\mathbf{b}_s]) \quad (6)$$

where the constant $0 < \lambda < 1$ normalizes the effects of children subsequences' length.

Compared with the definitions in (Culotta and Sorensen, 2004), we add term K_{in} to handle the internal nodes of a pharse, and make this extension still satisfy the kernel function requirements (composition of kernels is still a kernel (Joachims et al., 2001)). The consideration is that the local words should have limited effects on whole tree structures. So the kernel is defined on external children (K_c) and internal nodes (K_{in}) separately, as the result, the local words are not involved in subsequences of external children for K_c. After the kernel computing through training instances, support vector machine (SVM) is used for classification.

Table 1: Statistics for the annotated corpus

Category	# Products	# Sentences
Cell Phone	2	1100
Diaper	1	375
Digital Camera	4	1470
DVD Player	1	740
MP3 Player	3	3258

3 Experiments and Results

In this section, we describe the annotated corpus and experiment configurations including baseline methods and our results on in-domain and cross-domain.

3.1 Corpus

We conducted experiments with labeled corpus which are selected from Hu and Liu (2004), Jindal and Liu (2008) have built. Their documents are collected from Amazon.com and CNet.com, where products have a large number of reviews. They also manually labeled product features and polarity orientations. Our corpus is selected from them, which contains customer reviews of 11 products belong to 5 categories(Diaper, Cell Phone, Digital Camera, DVD Player, and MP3 Player). Table 1 gives the detail statistics.

Since we need to evaluate not only the product features but also the opinion expressions and relations between them, we asked two annotators to annotate them independently. The annotators started from identifying product features. Then for each product feature, they annotated the opinion expression which has relation with it. Finally, one annotator A_1 extracted 3595 relations, while the other annotator A_2 extracted 3745 relations, and 3217 cases of them matched. In order to measure the annotation quality, we use the following metric to measure the inter-annotator agreement, which is also used by Wiebe et al. (2005).

$$agr(a||b) = \frac{|A\ matches\ B|}{|A|}$$

Table 2: Results for extracting product features and opinion expressions

	P	R	F
Product Feature	42.8%	85.5%	57.0%
Opinion Expression	52.5%	75.2%	61.8%

Table 3: Features used in SVM-1: o denotes an opinion expression and t a product feature

1) Positions of o/t in sentence(start, end, other);
2) The distance between o and t (1, 2, 3, 4, other);
3) Whether o and t have direct dependency relation;
4) Whether o precedes t;
5) POS-Tags of o/t.

Table 4: Features used in SVM-PTree

Features for match function
1) The syntactic category of the tree node (e.g. NP, VP, PP, ADJP).
2) Whether it is an opinion expression node
3) Whether it is a product future node.
Features for similarity function
1) The syntactic category of the tree node (e.g. NP, VP, PP, ADJP).
2) POS-Tag of the head word of node's internal phrases.
3) The type of phrase dependency edge linking to node's parent.
4) Feature 2) for the node's parent
5) Feature 3) for the node's parent

where $agr(a||b)$ represents the inter-annotator agreement between annotator a and b, A and B are the sets of anchors annotated by annotators a and b. $agr(A_1||A_2)$ was 85.9% and $agr(A_2||A_1)$ was 89.5%. It indicates that the reliability of our annotated corpus is satisfactory.

3.2 Preprocessing Results

Results of extracting product features and opinion expressions are shown in Table 2. We use precision, recall and F-measure to evaluate performances. The candidate product features are extracted by the method described in Section 2.2, whose result is in the first row. 6760 of 24414 candidate product features remained after the filtering, which means we cut 72% of irrelevant candidates with a cost of 14.5%(1-85.5%) loss in true answers. Similar to the product feature extraction, the precision of extracting opinion expression is relatively low, while the recall is 75.2%. Since both product features and opinion expressions extractions are preprocessing steps, recall is more important.

3.3 Relation Extraction Experiments

3.3.1 Experiments Settings

In order to compare with state-of-the-art results, we also evaluated the following methods.

1. ***Adjacent*** method extracts relations between a product feature and its nearest opinion expression, which is also used in (Hu and Liu, 2004).

2. ***SVM-1***. To compare with tree kernel based approaches, we evaluated an SVM[1] result with a set of manually selected features(Table 3), which are also used in (Kobayashi et al., 2007).

3. ***SVM-2*** is designed to compare the effectiveness of cross-domain performances. The features used are simple bag of words and POS-Tags between opinion expressions and product features.

4. ***SVM-WTree*** uses head words of opinion expressions and product features in the word-level dependency tree, as the previous works in information extraction. Then conducts tree kernel proposed by Culotta and Sorensen (2004).

5. ***SVM-PTree*** denotes the results of our tree-kernel based SVM, which is described in the Section 2.3. Stanford parser (Klein and Manning, 2002) and Sundance (Riloff and Phillips, 2004) are used as lexical dependency parser and shallow parser. The features in match function and similarity function are shown in Table 4.

6. ***OERight*** is the result of SVM-PTree with correct opinion expressions.

7. ***PFRight*** is the result of SVM-PTree with correct product features.

Table 5 shows the performances of different relation extraction methods with in-domain data. For each domain, we conducted 5-fold cross validation. Table 6 shows the performances of the extraction methods on cross-domain data. We use the digital camera and cell phone domain as training set. The other domains are used as testing set.

[1]libsvm 2.88 is used in our experiments

Table 5: Results of different methods

	Cell Phone			MP3 Player			Digital Camera			DVD Player			Diaper		
Methods	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F
Adjacent	40.3%	60.5%	48.4%	26.5%	59.3%	36.7%	32.7%	59.1%	42.1%	31.8%	68.4%	**43.4%**	23.4%	78.8%	**36.1%**

3.3.2 Results Discussion

Table 5 presents different methods' results in five domains. We observe that the three learning based methods(SVM-1, SVM-WTree, SVM-PTree) perform better than the Adjacent baseline in the first three domains. However, in other domains, directly adjacent method is better than the learning based methods. The main difference between the first three domains and the last two domains is the size of data(Table 1). It implies that the simple Adjacent method is also competent when the training set is small.

A further inspection into the result of first 3 domains, we can also conclude that: 1) Tree kernels(SVM-WTree and SVM-PTree) are better than Adjacent, SVM-1 and SVM-2 in all domains. It proofs that the dependency tree is important in the opinion relation extraction. The reason for that is a connection between an opinion and its target can be discovered with various syntactic structures. 2) The kernel defined on phrase dependency tree (SVM-PTree) outperforms kernel defined on word level dependency tree(SVM-WTree) by 4.8% in average. We believe the main reason is that phrase dependency tree provides a more succinct tree structure, and the separative treatment of local dependencies and global dependencies in kernel computation can indeed improve the performance of relation extraction.

To analysis the results of preprocessing steps' influences on the following relation extraction, we provide 2 additional experiments which the product features and opinion expressions are all correctly extracted respectively: OERight and PFRight. These two results show that given an exactly extraction of opinion expression and product feature, the results of opinion relation extraction will be much better. Further, opinion expressions are more influential which naturally means the opinion expressions are crucial in opinion relation extraction.

For evaluations on cross domain, the Adjacent method doesn't need training data, its results are the same as the in-domain experiments. Note in Table 3 and Table 4, we don't use domain related features in SVM-1, SVM-WTree, SVM-PTree, but SVM-2's features are domain dependent. Since the cross-domain training set is larger than the original one in Diaper and DVD domain, the models are trained more sufficiently. The final results on cross-domain are even better than in-domain experiments on SVM-1, SVM-WTree, and SVM-PTree with percentage of 4.6%, 8.6%, 10.3% in average. And the cross-domain training set is smaller than in-domain in MP3, but it also achieve competitive performance with the

in-domain. On the other hand, SVM-2's result decreased compared with the in-domain experiments because the test domain changed. At the same time, SVM-PTree outperforms other methods which is similar in in-domain experiments.

4 Related Work

Opinion mining has recently received considerable attention. Amount of works have been done on sentimental classification in different levels (Zhang et al., 2009; Somasundaran et al., 2008; Pang et al., 2002; Dave et al., 2003; Kim and Hovy, 2004; Takamura et al., 2005). While we focus on extracting product features, opinion expressions and mining relations in this paper.

Kobayashi et al. (2007) presented their work on extracting opinion units including: opinion holder, subject, aspect and evaluation. Subject and aspect belong to product features, while evaluation is the opinion expression in our work. They converted the task to two kinds of relation extraction tasks and proposed a machine learning-based method which combines contextual clues and statistical clues. Their experimental results showed that the model using contextual clues improved the performance. However since the contextual information in a domain is specific, the model got by their approach can not easily converted to other domains.

Choi et al. (2006) used an integer linear programming approach to jointly extract entities and relations in the context of opinion oriented information extraction. They identified expressions of opinions, sources of opinions and the linking relation that exists between them. The sources of opinions denote to the person or entity that holds the opinion.

Another area related to our work is opinion expressions identification (Wilson et al., 2005a; Breck et al., 2007). They worked on identifying the words and phrases that express opinions in text. According to Wiebe et al. (2005), there are two types of opinion expressions, direct subjective expressions and expressive subjective elements.

5 Conclusions

In this paper, we described our work on mining opinions from unstructured documents. We focused on extracting relations between product features and opinion expressions. The novelties of our work included: 1) we defined the phrase dependency parsing and proposed an approach to construct the phrase dependency trees; 2) we proposed a new tree kernel function to model the phrase dependency trees. Experimental results show that our approach improved the performances of the mining task.

Abstract

This paper proposes a method that speeds up a classifier trained with many conjunctive features: combinations of (primitive) features. The key idea is to precompute as partial results the weights of primitive feature vectors that appear frequently in the target NLP task. A trie compactly stores the primitive feature vectors with their weights, and it enables the classifier to find for a given feature vector its longest prefix feature vector whose weight has already been computed. Experimental results for a Japanese dependency parsing task show that our method speeded up the SVM and LLM classifiers of the parsers, which achieved accuracy of 90.84/90.71%, by a factor of 10.7/11.6.

1 Introduction

Deep and accurate text analysis based on discriminative models is not yet efficient enough as a component of real-time applications, and it is inadequate to process Web-scale corpora for knowledge acquisition (Pantel, 2007; Saeger et al., 2009) or semi-supervised learning (McClosky et al., 2006; Spoustová et al., 2009). One of the main reasons for this inefficiency is attributed to the inefficiency of core classifiers trained with many feature combinations (*e.g.*, word n-grams). Hereafter, we refer to features that explicitly represent combinations of features as *conjunctive features* and the other atomic features as *primitive features*.

The feature combinations play an essential role in obtaining a classifier with state-of-the-art accuracy for several NLP tasks; recent examples include dependency parsing (Koo et al., 2008), parse re-ranking (McClosky et al., 2006), pronoun resolution (Nguyen and Kim, 2008), and semantic role labeling (Liu and Sarkar, 2007). However, 'explicit' feature combinations significantly increase the feature space, which slows down not only training but also testing of the classifier.

Kernel-based methods such as support vector machines (SVMs) consider feature combinations space-efficiently by using a polynomial kernel function (Cortes and Vapnik, 1995). The kernel-based classification is, however, known to be very slow in NLP tasks, so efficient classifiers should sum up the weights of the explicit conjunctive features (Isozaki and Kazawa, 2002; Kudo and Matsumoto, 2003; Goldberg and Elhadad, 2008).

ℓ_1-regularized log-linear models (ℓ_1-LLMs), on the other hand, provide sparse solutions, in which weights of irrelevant features are exactly zero, by assuming a Laplacian prior on the weights (Tibshirani, 1996; Kazama and Tsujii, 2003; Goodman, 2004; Gao et al., 2007). However, as Kazama and Tsujii (2005) have reported in a text categorization task and we later confirm in a dependency parsing task, when most features regarded as irrelevant during training ℓ_1-LLMs appear rarely in the task, we cannot greatly reduce the number of active features in each classification. In the end, when efficiency is a major concern, we must use exhaustive feature selection (Wu et al., 2007; Okanohara and Tsujii, 2009) or even restrict the order of conjunctive features at the expense of accuracy.

In this study, we provide a simple, but effective solution to the inefficiency of classifiers trained with higher-order conjunctive features (or polynomial kernel), by exploiting the Zipfian nature of language data. The key idea is to precompute the weights of primitive feature vectors and use them as partial results to compute the weight of a given feature vector. We use a trie called the *feature sequence trie* to efficiently find for a given feature vector its longest prefix feature vector whose weight has been computed. The trie is built from feature vectors generated by applying the classifier to actual data in the classification task. The time complexity of the classifier approaches time that

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1542–1551,
Singapore, 6-7 August 2009.

is linear with respect to the number of primitive features when the retrieved feature vector covers most of the features in the input feature vector.

We implemented our algorithm for SVM and LLM classifiers and evaluated the performance of the resulting classifiers in a Japanese dependency parsing task. Experimental results show that it successfully speeded up classifiers trained with higher-order conjunctive features by a factor of 10.

The rest of this paper is organized as follows. Section 2 introduces LLMs and SVMs. Section 3 proposes our classification algorithm. Section 4 presents experimental results. Section 5 concludes with a summary and addresses future directions.

2 Preliminaries

In this paper, we focus on linear classifiers that calculate the probability (or score) by summing up weights of individual features. Examples include not only log-linear models but also support vector machines with kernel expansion (Isozaki and Kazawa, 2002; Kudo and Matsumoto, 2003). Below, we introduce these two classifiers and their ways to consider feature combinations.

In classification-based NLP, the target task is modeled as one or more classification steps. For example in part-of-speech (POS) tagging, each classification decides whether to assign a particular *label* (POS tag) to a given *sample* (each word in a given sentence). Each sample is then represented by a *feature vector* $\boldsymbol{x}$, whose element x_i is a value of a feature function $f_i \in \mathcal{F}$.

Here, we assume a binary feature function $f_i(\boldsymbol{x}) \in \{0, 1\}$, in which a non-zero value means that particular context data appears in the sample. We say that a feature f_i is *active* in sample $\boldsymbol{x}$ when $x_i = f_i(\boldsymbol{x}) = 1$ and $|\boldsymbol{x}|$ represents the number of active features in $\boldsymbol{x}$ ($|\boldsymbol{x}| = |\{f_i | f_i(\boldsymbol{x}) = 1\}|$).

2.1 Log-Linear Models

The log-linear model (LLM), or also known as maximum-entropy model (Berger et al., 1996), is a linear classifier widely used in the NLP literature. Let the training data of LLMs be $\{\langle \boldsymbol{x}_i, y_i \rangle\}_{i=1}^{L}$, where $\boldsymbol{x}_i \in \{0, 1\}^n$ is a feature vector and y_i is a class label associated with $\boldsymbol{x}_i$. We assume a binary label $y_i \in \{\pm 1\}$ here to simplify the argument.

The classifier provides conditional probability $p(y|\boldsymbol{x})$ for a given feature vector $\boldsymbol{x}$ and a label y:

$$p(y|\boldsymbol{x}) = \frac{1}{Z(\boldsymbol{x})} \exp \sum_i w_{i,y} f_{i,y}(\boldsymbol{x}, y), \quad (1)$$

where $f_{i,y}(\boldsymbol{x}, y)$ is a feature function that returns a non-zero value when $f_i(\boldsymbol{x}) = 1$ and the label is y, $w_{i,y} \in \mathbb{R}$ is a weight associated with $f_{i,y}$, and $Z(\boldsymbol{x}) = \sum_y \exp \sum_i w_{i,y} f_{i,y}(\boldsymbol{x}, y)$ is the partition function. We can consider feature combinations in LLMs by explicitly introducing a new conjunctive feature $f_{\mathcal{F}',y}(\boldsymbol{x}, y)$ that is activated when a particular set of features $\mathcal{F}' \subseteq \mathcal{F}$ to be combined is activated (namely, $f_{\mathcal{F}',y}(\boldsymbol{x}, y) = \bigwedge_{f_{i,y} \in \mathcal{F}'} f_{i,y}(\boldsymbol{x}, y)$).

We then introduce an ℓ_1-regularized LLM (ℓ_1-LLM), in which the weight vector $\boldsymbol{w}$ is tuned so as to maximize the logarithm of the a posteriori probability of the training data:

$$\mathcal{L}(\boldsymbol{w}) = \sum_{i=1}^{L} \log p(y_i|\boldsymbol{x}_i) - C\|\boldsymbol{w}\|_1. \quad (2)$$

Hyper-parameter C thereby controls the degree of over-fitting (solution sparseness). Interested readers may refer to the cited literature (Andrew and Gao, 2007) for the optimization procedures.

2.2 Support Vector Machines

A support vector machine (SVM) is a binary classifier (Cortes and Vapnik, 1995). Training with samples $\{\langle \boldsymbol{x}_i, y_i \rangle\}_{i=1}^{L}$ where $\boldsymbol{x}_i \in \{0, 1\}^n$ and $y_i \in \{\pm 1\}$ yields the following decision function:

$$y(\boldsymbol{x}) = \mathrm{sgn}(g(\boldsymbol{x}) + b)$$
$$g(\boldsymbol{x}) = \sum_{\boldsymbol{x}_j \in \mathcal{SV}} y_j \alpha_j \phi(\boldsymbol{x}_j)^{\mathrm{T}} \phi(\boldsymbol{x}), \quad (3)$$

where $b \in \mathbb{R}$, $\phi : \mathbb{R}^n \mapsto \mathbb{R}^H$ and *support vectors* $\boldsymbol{x}_j \in \mathcal{SV}$ (subset of training samples), each of which is associated with weight $\alpha_j \in \mathbb{R}$. We hereafter call $g(\boldsymbol{x})$ the *weight function*. Nonlinear mapping function ϕ is chosen to make the training samples linearly separable in $\mathbb{R}^H$ space. Kernel function $k(\boldsymbol{x}_j, \boldsymbol{x}) = \phi(\boldsymbol{x}_j)^{\mathrm{T}} \phi(\boldsymbol{x})$ is then introduced to compute the dot product in $\mathbb{R}^H$ space without mapping $\boldsymbol{x}$ to $\phi(\boldsymbol{x})$.

To consider combinations of primitive features $f_j \in \mathcal{F}$, we use a *polynomial kernel* $k_d(\boldsymbol{x}_j, \boldsymbol{x}) = (\boldsymbol{x}_j^{\mathrm{T}} \boldsymbol{x} + 1)^d$. From Eq. 3, we obtain the weight function for the polynomial kernel as:

$$g(\boldsymbol{x}) = \sum_{\boldsymbol{x}_j \in \mathcal{SV}} y_j \alpha_j (\boldsymbol{x}_j^{\mathrm{T}} \boldsymbol{x} + 1)^d. \quad (4)$$

Since we assumed that x_i is a binary value representing whether a (primitive) feature f_i is active in the sample, the polynomial kernel of degree d implies a mapping ϕ_d from $\boldsymbol{x}$ to $\phi_d(\boldsymbol{x})$ that has

$H = \sum_{k=0}^{d} \binom{n}{k}$ dimensions. Each dimension represents a (weighted) conjunction of d features in the original sample $\boldsymbol{x}$.[1]

Kernel Expansion (SVM-KE) The time complexity of Eq. 4 is $O(|\boldsymbol{x}| \cdot |\mathcal{SV}|)$. This cost is usually high for classifiers used in NLP tasks because they often have many support vectors ($|\mathcal{SV}| > 10,000$). *Kernel expansion* (KE) was proposed by Isozaki and Kazawa (2002) to convert Eq. 4 into the linear sum of the weights in the mapped feature space as in LLM ($p(y|\boldsymbol{x})$ in Eq. 1):

$$g(\boldsymbol{x}) = \boldsymbol{w}^{\mathrm{T}} \boldsymbol{x}^d = \sum_i w_i x_i^d, \tag{5}$$

where $\boldsymbol{x}^d$ is a binary feature vector whose element x_i^d has a non-zero value when $(\phi_d(\boldsymbol{x}))_i > 0$, $\boldsymbol{w}$ is the weight vector for $\boldsymbol{x}^d$ in the expanded feature space $\mathcal{F}^d$ and is precalculated from the support vectors $\boldsymbol{x}_j$ and their weights α_j. Interested readers may refer to Kudo and Matsumoto (2003) for the detailed computation for obtaining $\boldsymbol{w}$.

The time complexity of Eq. 5 (and Eq. 1) is $O(|\boldsymbol{x}^d|)$, which is linear with respect to the number of active features in $\boldsymbol{x}^d$ within the expanded feature space $\mathcal{F}^d$.

Heuristic Kernel Expansion (SVM-HKE) To make the weight vector sparse, Kudo and Matsumoto (2003) proposed a heuristic method that filters out less useful features whose absolute weight values are less than a pre-defined threshold σ.[2] They reported that increased threshold value σ resulted in a dramatically sparse feature space $\mathcal{F}^d$, which had the side-effects of accuracy degradation and classifier speed-up.

3 Proposed Method

In this section, we propose a method that speeds up a classifier trained with many conjunctive features. Below, we focus on a kernel-based classifier trained with a polynomial kernel of degree d (here, SVMs), but an analogous argument is possible for linear classifiers (*e.g.*, LLMs).[3]

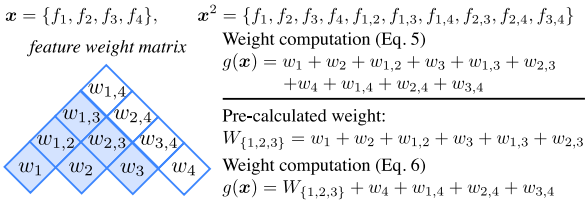

Figure 1: Efficient computation of $g(\boldsymbol{x})$.

We hereafter represent a binary feature vector $\boldsymbol{x}$ as a set of active features $\{f_i | f_i(\boldsymbol{x}) = 1\}$. $\boldsymbol{x}$ can thereby be represented as an element of the power set $2^{\mathcal{F}}$ of the set of features $\mathcal{F}$.

3.1 Idea

Let us remember that weight function $g(\boldsymbol{x})$ in Eq. 5 maps $\boldsymbol{x} \in 2^{\mathcal{F}}$ to $W \in \mathbb{R}$. If we could calculate $W_{\boldsymbol{x}} = g(\boldsymbol{x})$ for all possible $\boldsymbol{x}$ in advance, we could obtain $g(\boldsymbol{x})$ by simply checking $|\boldsymbol{x}|$ elements, namely, in $O(|\boldsymbol{x}|)$ time. However, because $|\{\boldsymbol{x} | \boldsymbol{x} \in 2^{\mathcal{F}}\}| = 2^{|\mathcal{F}|}$ and $|\mathcal{F}|$ is likely to be very large (often $|\mathcal{F}| > 10,000$ in NLP tasks), this calculation is impractical.

We then compute and store weight $W_{\boldsymbol{x}'} = g(\boldsymbol{x}')$ for $\boldsymbol{x}' \in \mathcal{V}_c (\subset 2^{\mathcal{F}})$, a certain subset of the possible value space, and compute $g(\boldsymbol{x})$ for $\boldsymbol{x} \notin \mathcal{V}_c$ by using precalculated weight $W_{\boldsymbol{x}_c}$ for $\boldsymbol{x}_c \subseteq$[4] $\boldsymbol{x}$ in the following way:

$$g(\boldsymbol{x}) = W_{\boldsymbol{x}_c} + \sum_{f_i \in \boldsymbol{x}^d - \boldsymbol{x}_c^d} w_i. \tag{6}$$

Intuitively speaking, starting from partial weight $W_{\boldsymbol{x}_c}$, we add up remaining weights of primitive features $f \in \mathcal{F}$ that are not active in $\boldsymbol{x}_c$ but active in $\boldsymbol{x}$ and conjunctive features that combine f and the other active features in $\boldsymbol{x}$.

An example of this computation ($d = 2$) is depicted in Figure 1. We can efficiently compute $g(\boldsymbol{x})$ for a vector $\boldsymbol{x}$ that has four active features f_1, f_2, f_3, and f_4 (and $\boldsymbol{x}^2$ has their six conjunctive features) using precalculated weight $W_{\{1,2,3\}}$; we should first check the three features f_1, f_2, and f_3 to retrieve $W_{\{1,2,3\}}$ and next check the remaining four features related to f_4, namely f_4, $f_{1,4}$, $f_{2,4}$, and $f_{3,4}$, in order to add up the remaining

[1] For example, given an input vector $\boldsymbol{x} = (x_1, x_2)^{\mathrm{T}}$ and a support vector $\boldsymbol{x}' = (x_1', x_2')^{\mathrm{T}}$, the 2nd-order polynomial kernel returns $k_2(\boldsymbol{x}', \boldsymbol{x}) = (x_1' x_1 + x_2' x_2 + 1)^2 = 3x_1' x_1 + 3x_2' x_2 + 2x_1' x_1 x_2' x_2 + 1$ ($\because x_i', x_i \in \{0, 1\}$). This function thus implies a mapping $\phi_2(\boldsymbol{x}) = (1, \sqrt{3}x_1, \sqrt{3}x_2, \sqrt{2}x_1 x_2)^{\mathrm{T}}$. In the following argument, we ignore the dimension of the constant in the mapped space and assume constant b is set to include it.

[2] Precisely speaking, they set different thresholds to positive ($\alpha_j > 0$) and negative ($\alpha_j < 0$) support vectors, considering the proportion of positive and negative support vectors.

[3] When a feature vector $\boldsymbol{x}$ includes (explicit) conjunctive features $f \in \mathcal{F}^d$, we assume weight function $g'(y|\boldsymbol{x}') = g(y|\boldsymbol{x})$, where $\boldsymbol{x}'$ is a projection of $\boldsymbol{x}$ (by $\phi_d^{-1} : \mathcal{F}^d \to \mathcal{F}$).

[4] This means that all active features in $\boldsymbol{x}_c$ are active in $\boldsymbol{x}$.

weights, while the normal computation in Eq. 5 should check the four primitive and six conjunctive features to get the individual weights.

Expected time complexity Counting the number of features to be checked in the computation, we obtain the time complexity $f(\boldsymbol{x}, d)$ of Eq. 6 as:

$$f(\boldsymbol{x}, d) = O(|\boldsymbol{x}_c| + |\boldsymbol{x}^d| - |\boldsymbol{x}_c^d|), \quad (7)$$

$$\textit{where} \quad |\boldsymbol{x}^d| = \sum_{k=1}^{d} \binom{|\boldsymbol{x}|}{k} \quad (8)$$

(*e.g.*, $|\boldsymbol{x}^2| = \frac{|\boldsymbol{x}|^2+|\boldsymbol{x}|}{2}$ and $|\boldsymbol{x}^3| = \frac{|\boldsymbol{x}|^3+5|\boldsymbol{x}|}{6}$).[5] Note that when $|\boldsymbol{x}_c|$ becomes close to $|\boldsymbol{x}|$, this time complexity actually approaches $O(|\boldsymbol{x}|)$.

Thus, to minimize this computational cost, $\boldsymbol{x}_c$ is to be chosen from $\mathcal{V}_c$ as follows:

$$\boldsymbol{x}_c = \underset{\boldsymbol{x}' \in \mathcal{V}_c, \boldsymbol{x}' \subseteq \boldsymbol{x}}{\operatorname{argmin}} (|\boldsymbol{x}'| + |\boldsymbol{x}^d| - |\boldsymbol{x}'^d|). \quad (9)$$

3.2 Construction of Feature Sequence Trie

There are two issues with speeding up the classifier by the computation shown in Eq. 6. First, since we can store weights for only a small fraction of possible feature vectors (namely, $|\mathcal{V}_c| \ll 2^{|\mathcal{F}|}$), we should choose $\mathcal{V}_c$ so as to maximize its impact on the speed-up. Second, we should quickly find an optimal $\boldsymbol{x}_c$ from $\mathcal{V}_c$ for a given feature vector $\boldsymbol{x}$.

The solution to the first problem is to enumerate partial feature vectors that frequently appear in the target task. Note that typical linguistic features used in NLP tasks usually consist of disjunctive sets of features (*e.g.*, word surface and POS), in which each set is likely to follow Zipf's law (Zipf, 1949) and correlate with each other. We can expect the distribution of feature vectors, the mixture of Zipf distributions, to be Zipfian. This has been confirmed for word n-grams (Egghe, 2000) and itemset support distribution (Chuang et al., 2008). We can thereby expect that a small set of partial feature vectors commonly appear in the task.

To solve the second problem, we introduce a *feature sequence trie* (*fstrie*), which represents a hierarchy of feature vectors, to enable the classifier to efficiently retrieve (sub-)optimal $\boldsymbol{x}_c$ (in Eq. 9) for a given feature vector $\boldsymbol{x}$. We build an fstrie in the following steps:

Step 1: Apply the target classifier to actual (raw) data in the task to enumerate possible feature vectors (hereafter, *source feature vectors*).

[5] This is the maximum number of conjunctive features.

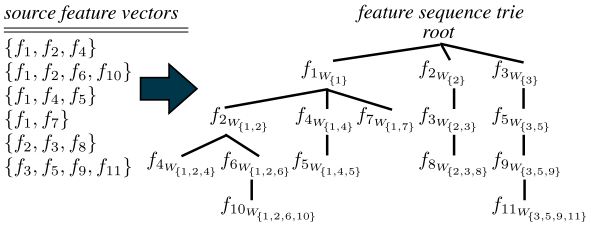

Figure 2: Feature sequence trie and completion of prefix feature vector weights.

Step 2: Sort the features in each source feature vector according to their frequency in the training data (in descending order).

Step 3: Build a trie from the source feature vectors by regarding feature indices as characters and store weights of all prefix feature vectors.

An fstrie built from six source feature vectors is shown in Figure 2. In fstries, a path from the root to another node represents a feature vector. An important point here is that the fstrie stores the weights of all prefix feature vectors of the source feature vectors, and the trie structure enables us to retrieve for a given feature vector $\boldsymbol{x}$ the weight of its longest prefix vector $\boldsymbol{x}_c \subseteq \boldsymbol{x}$ in $O(|\boldsymbol{x}_c|)$ time. To handle feature functions in LLMs (Eq. 1), we store partial weight $W_{\boldsymbol{x}_c,y} = \sum_i w_{i,y} f_{i,y}(\boldsymbol{x}_c, y)$ for each label y on the node that expresses $\boldsymbol{x}_c$.

Since we sort the features in the source feature vectors according to their frequency, the prefix feature vectors exclude less frequent features in the source feature vectors. Lexical features or finer-grained features (*e.g.*, POS-subcategory) are usually less frequent than coarse-grained features (*e.g.*, POS), so they lie in the latter part of the feature vectors. This sorting helps us to retrieve longer feature vector $\boldsymbol{x}_c$ for input feature vector $\boldsymbol{x}$ that will have diverse infrequent features. It also minimizes the size of fstrie by sharing the common frequent prefix (*e.g.*, $\{f_1, f_2\}$ in Figure 2).

Pruning nodes from fstrie We have so far described the way to construct an fstrie from the source feature vectors. However, a naive enumeration of source feature vectors will result in the explosion of the fstrie size, and we want to have a principled way to control the fstrie size rather than reducing the processed data size. Below, we present a method that prunes useless prefix feature vectors (nodes) from the constructed fstrie to maximize its impact on the classifier efficiency.

Algorithm 1 PRUNE NODES FROM FSTRIE

Input: fstrie T, node_limit $N \in \mathbb{N}$
Output: fstrie T

1: **while** # of nodes in $T > N$ **do**
2: $\quad \boldsymbol{x}_c \leftarrow \underset{\boldsymbol{x}' \in \mathit{leaf}(T)}{\operatorname{argmin}}\ u(\boldsymbol{x}')$
3: $\quad$ remove $\boldsymbol{x}_c$, T
4: **end while**
5: **return** T

We adopt a greedy strategy that iteratively prunes a leaf node (one prefix feature vector and its weight) from the fstrie built from all the source feature vectors, according to a certain utility score calculated for each node. In this study, we consider two metrics for each prefix feature vector $\boldsymbol{x}_c$ to calculate its utility score.

Probability $p(\boldsymbol{x}_c)$**,** which denotes how often the stored weight $W_{\boldsymbol{x}_c}$ will be used in the target task. The maximum-likelihood estimation provides probability:

$$p(\boldsymbol{x}_c) = \frac{\sum_{\boldsymbol{x}' \supseteq \boldsymbol{x}_c} n_{\boldsymbol{x}'}}{\sum_{\boldsymbol{x}} n_{\boldsymbol{x}}}, \qquad (10)$$

where $n_{\boldsymbol{x}} \in \mathbb{N}$ is the frequency count of a source feature vector $\boldsymbol{x}$ in the processed data.

Computation reduction $\Delta_d(\boldsymbol{x}_c)$**,** which denotes how much computation is reduced by $W_{\boldsymbol{x}_c}$ to calculate a weight of $\boldsymbol{x} \supseteq \boldsymbol{x}_c$. This can be estimated by counting the number of conjunctive features we additionally have to check when we remove $\boldsymbol{x}_c$. Since the fstrie stores the weight of a prefix feature vector $\boldsymbol{x}_{c\text{-}} \subset \boldsymbol{x}_c$ such that $|\boldsymbol{x}_{c\text{-}}| = |\boldsymbol{x}_c| - 1$ (*e.g.*, in Figure 2, $\boldsymbol{x}_{c\text{-}} = \{f_1, f_2\}$ for $\boldsymbol{x}_c = \{f_1, f_2, f_4\}$), we can define the computation reduction as:

$$\begin{aligned}\Delta_d(\boldsymbol{x}_c) &= (|\boldsymbol{x}_c^d| - |\boldsymbol{x}_{c\text{-}}^d|) - (|\boldsymbol{x}_c| - |\boldsymbol{x}_{c\text{-}}|) \\ &= \sum_{k=2}^{d} \binom{|\boldsymbol{x}_c|}{k} - \sum_{k=2}^{d} \binom{|\boldsymbol{x}_c| - 1}{k} \\ &\quad (\because \text{Eq. 8}).\end{aligned}$$

$$\Delta_2(\boldsymbol{x}_c) = |\boldsymbol{x}_c| - 1 \text{ and } \Delta_3(\boldsymbol{x}_c) = \tfrac{|\boldsymbol{x}_c|^2 - |\boldsymbol{x}_c|}{2}.$$

We calculate utility score of each node $\boldsymbol{x}_c$ in the fstrie as $u(\boldsymbol{x}_c) = p(\boldsymbol{x}_c) \cdot \Delta_d(\boldsymbol{x}_c)$, which means the expected computation reduction by $\boldsymbol{x}_c$ in the target task, and prune the lowest-utility-score leaf nodes from the fstrie one by one (Algorithm 1). If several prefix vectors have the same utility score, we eliminate them in numerical descending order.

Algorithm 2 COMPUTE WEIGHT WITH FSTRIE

Input: fstrie T, weight vector $\boldsymbol{w} \in \mathbb{R}^{|\mathcal{F}^d|}$
feature vector $\boldsymbol{x} \in 2^{\mathcal{F}}$
Output: weight $W = g(\boldsymbol{x}) \in \mathbb{R}$

1: $\boldsymbol{x} \leftarrow \text{sort}(\boldsymbol{x})$
2: $\langle \boldsymbol{x}_c, W_{\boldsymbol{x}_c} \rangle \leftarrow$ prefix_search(T, $\boldsymbol{x}$)
3: $W \leftarrow W_{\boldsymbol{x}_c}$
4: **for all** feature $f_j \in \boldsymbol{x}^d - \boldsymbol{x}_c^d$ **do**
5: $\quad W \leftarrow W + w_j$
6: **end for**
7: **return** W

3.3 Classification Algorithm

Our classification algorithm is shown in detail in Algorithm 2. The classifier first sorts the active features in input feature vector $\boldsymbol{x}$ according to their frequency in the training data. Then, for $\boldsymbol{x}$, it retrieves the longest common prefix vector $\boldsymbol{x}_c$ from the fstrie (line 2 in Algorithm 2). It then adds the weights of the remaining features to partial weight $W_{\boldsymbol{x}_c}$ (line 5 in Algorithm 2).

Note that the remaining features whose weights we sum up (line 4 in Algorithm 2) are primitive and conjunctive features that relate to $f \in \boldsymbol{x} - \boldsymbol{x}_c$, which appear less frequently than $f' \in \boldsymbol{x}_c$ in the training data. Thus, when we apply our algorithm to classifiers with the sparse solution (*e.g.*, SVM-HKEs or ℓ_1-LLMs), $|\boldsymbol{x}^d| - |\boldsymbol{x}_c^d|$ can be much smaller than the theoretical expectation (Eq. 8). We confirmed this in the following experiments.

4 Evaluation

We applied our algorithm to SVM-KE, SVM-HKE, and ℓ_1-LLM classifiers and evaluated the resulting classifiers in a Japanese dependency parsing task. To the best of our knowledge, there are no previous reports of an *exact* weight calculation faster than linear summation (Eqs. 1 and 5). We also compared our SVM classifier with a classifier called polynomial kernel inverted (PKI: Kudo and Matsumoto (2003)), which uses the polynomial kernel (Eq. 4) and inverted indexing to support vectors.

4.1 Experimental Settings

A Japanese dependency parser inputs *bunsetsu*-segmented sentences and outputs the correct head (bunsetsu) for each bunsetsu; here, a bunsetsu is a grammatical unit in Japanese consisting of one or more content words followed by zero or more function words. A parser generates a feature vec-

Modifier, modifiee bunsetsu	head word (surface-form, POS, POS-subcategory, inflection form), functional word (surface-form, POS, POS-subcategory, inflection form), brackets, quotation marks, punctuation marks, position in sentence (beginning, end)
Between bunsetsus	distance (1, 2–5, 6–), case-particles, brackets, quotation marks, punctuation marks

Table 1: Feature set used for experiments.

tor for a particular pair of bunsetsus (modifier and modifiee candidates) by exploiting the head-final and projective (Nivre, 2003) nature of dependency relations in Japanese. The classifier then outputs label y = '$+1$' (dependent) or '-1' (independent).

Since our classifier is independent of individual parsing algorithms, we targeted speeding up (a classifier in) the shift-reduce parser proposed by Sassano (2004), which has been reported to be the most efficient for this task, with almost state-of-the-art accuracy (Iwatate et al., 2008). This parser decreases the number of classification steps by using the fact that a bunsetsu is likely to modify a bunsetsu close to itself. Due to space limitations, we omit the details of the parsing algorithm.

We used the standard feature set tailored for this task (Kudo and Matsumoto, 2002; Sassano, 2004; Iwatate et al., 2008) (Table 1). Note that features listed in the 'Between bunsetsus' row represent contexts between the target pair of bunsetsus and appear independently from other features, which will become an obstacle to finding the longest prefix vector. This task is therefore a better measure of our method than simple sequential labeling such as POS tagging or named-entity recognition.

For evaluation, we used Kyoto Text Corpus Version 4.0 (Kurohashi and Nagao, 2003), Mainichi news articles in 1995 that have been manually annotated with dependency relations.[6] The training, development, and test sets included 24,283, 4833, and 9284 sentences, and 234,685, 47,571, and 89,874 bunsetsus, respectively. The training samples generated from the training set included 150,064 positive and 146,712 negative samples.

The following experiments were performed on a server with an Intel® Xeon™ 3.20-GHz CPU. We used TinySVM[7] and a simple C++ library for maximum entropy classification[8] to train SVMs and ℓ_1-LLMs, respectively. We used Darts-Clone,[9]

Table 2: Specifications of LLMs and SVMs. The accuracy marked with '$\gg$' or '$>$' was significantly better than the $d = 2$ counterpart ($p < 0.01$ or $0.01 \leq p < 0.05$ by McNemar's test).

a double-array trie (Aoe, 1989; Yata et al., 2008), as a compact trie implementation. All these libraries and algorithms are implemented in C++. The code for building fstries occupies 100 lines, while the code for the classifier occupies 20 lines (except those for kernel expansion).

4.2 Results

Specifications of SVMs and LLMs used here are shown in Table 2; $|\mathcal{F}^d|$ is the number of active features, while $|\boldsymbol{x}^d|$ is the average number of active features in each classification for the test corpus. Dependency accuracy is the ratio of dependency relations correctly identified by the parser, while sentence accuracy is the exact match accuracy of complete dependency relations in a sentence.

For LLM training, we designed explicit conjunctive features for all the d or lower-order feature combinations to make the results comparable to those of SVMs. We could not train $d = 4$ LLMs due to parameter explosion. We varied SVM soft margin parameter c from 0.1 to 0.000001 and LLM width factor parameter ω,[10] which controls the impact of the prior, from 1.0 to 5.0, and adjusted the values to maximize dependency accuracy for the development set: $(d, c) = (1, 0.1), (2, 0.005), (3, 0.0001), (4, 0.000005)$ for SVMs and $(d, \omega) = (1, 1.0), (2, 2.0), (3, 4.0)$ for ℓ_1-LLMs.

The accuracy of around 90.9% (SVM-KE, $d = 3, 4$) is close to the performance of state-of-the-

[10] The parameter C of ℓ_1-LLM in Eq. 2 was set to ω/L (referred to in Kazama and Tsujii (2003) as '*single width*').

Table 3: Parsing results for test corpus: SVM-KE classifiers with dense feature space.

art parsers (Iwatate et al., 2008), and the model statistics are considered to be complex (or realistic) enough to evaluate our classifier's utility. The number of support vectors of SVMs was $71,766 \pm 9.2\%$, which is twice as many as those used by Kudo and Matsumoto (2003) (34,996) in their experiments on the same task.

We could clearly observe that the number of active features $|\boldsymbol{x}^d|$ increased dramatically according to the order d of feature combinations. The density of $|\boldsymbol{x}^d|$ for SVMs was very high (*e.g.*, $|\boldsymbol{x}^3| = 3286.7$, close to the maximum shown in Eq. 8: $(27.3^3 + 5 \times 27.3)/6 \simeq 3414$.

For $d \geq 3$ models, we attempted to control the size of the feature space $|\mathcal{F}^d|$ by changing the model's hyper-parameters: threshold σ for the SVM-HKE and width factor ω for the ℓ_1-LLM. Although we successfully reduced the size of the feature space $|\mathcal{F}^d|$, we could not dramatically reduce the average number of active features $|\boldsymbol{x}^d|$ in each classification while keeping the accuracy advantage. This confirms that the solution sparseness does not suffice to obtain an efficient classifier.

We obtained source feature vectors to build fstries by applying parsers with the target classifiers to a raw corpus in the target domain, 3,258,313 sentences of 1991–94 Mainichi news articles that were morphologically analyzed by JUMAN[6] and segmented into bunsetsus by KNP.[6] We first built fstrie$_L$ using all the source feature vectors. We then attempted to reduce the number of prefix feature vectors in fstrie$_L$ to $1/2^n$ the size by Algorithm 1. We refer to fstries built from 1/32 and 1/1024 of the prefix feature vectors in fstrie$_L$ as fstrie$_M$ and fstrie$_S$ in the following experiments.

Because we exploited Algorithm 2 to calculate the weights of the prefix feature vectors, it took less than one hour (59 min. 29 sec.) on the 3.20-GHz server to build fstrie$_L$ (and calculate the utility score for all the nodes in it) for the slowest SVM-KE ($d = 4$) from the 40,409,190 source feature vectors (62,654,549 prefix feature vectors) generated by parsing the 3,258,313 sentences.

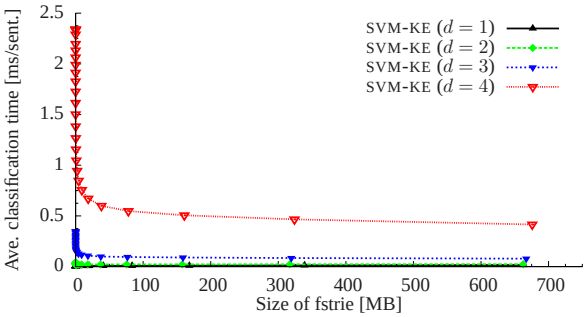

Figure 3: Average classification time per sentence plotted against size of fstrie: SVM-KE.

Results for SVM-KE with dense feature space The performances of parsers having SVM-KE classifiers with and without the fstrie are given in Table 3. The 'speed-up' column shows the speed-up factor of the most efficient classifier (bold) versus the baseline classifier without fstries. Since each classifier solved a slightly different number of classification steps ($112,853 \pm 0.15\%$), we show the (average) cumulative classification time for a sentence. The Mem. columns show the size of weight vectors for SVM-KE classifiers and the size of fstries$_S$, fstries$_M$, and fstries$_L$, respectively.

The fstries successfully speeded up SVM-KE classifiers with the dense feature space.[11] The SVM-KE classifiers without fstries were still faster than PKI, but as expected from a large $|\boldsymbol{x}^d|$ value, the classifiers with higher conjunctive features were much slower than the classifier with only primitive features by factors of 13 ($d = 2$), 109 ($d = 3$) and 738 ($d = 4$) and the classification time accounted for most of the parsing time.

The average classification time of our classifiers plotted against fstrie size is shown in Figure 3. Surprisingly, we obtained a significant speed-up even with tiny fstrie sizes of < 1 MB. Furthermore, we naively controlled the fstrie size by sim-

[11] The inefficiency of the classifier ($d = 1$) results from the cost of the additional sort function (line 1 in Algorithm 2) and CPU cache failure due to random accesses to the huge fstries.

ply reducing the number of sentences processed to $1/2^n$. The impact on the speed-up of the resulting fstries (*naive*) and the fstries constructed by our utility score (*utility-score*) on SVM-KE ($d = 4$) is shown in Figure 4. The Zipfian nature of language data let us obtain a substantial speed-up even when we naively reduced the fstrie size, and the utility score further decreased the fstrie size required to obtain the same speed-up. We needed less than 1/3 size fstries to achieve the same speed-up: 0.671 ms./sent. (18.6 MB) (*utility-score*) vs. 0.680 ms./sent. (67.1 MB) (*naive*).

Results for SVM-HKE and ℓ_1-LLM classifiers with sparse feature space The performances of parsers having SVM-HKE and ℓ_1-LLM classifiers with and without the fstrie are given in Table 4. The fstries successfully speeded up the SVM-HKE and ℓ_1-LLM classifiers by factors of 10.7 (SVM-HKE, $d = 4$, $\sigma = 0.0006$) and 11.6 (ℓ_1-LLM, $d = 3$, $\omega = 3.0$). We obtained more speed-up when we used fstries for classifiers with more sparse feature space $\mathcal{F}^d$ (Figures 5 and 6). The parsing speed with $d = 3$ models are now comparable to the parsing speed with $d = 2$ models.

Without fstries, little speed-up of SVM-HKE classifiers versus the SVM-KE classifiers (in Table 3) was obtained due to the mild reduction in the average number of active features $|\boldsymbol{x}^d|$ in the classification. This result conforms to the results reported in (Kudo and Matsumoto, 2003).

The parsing speed reached 14,937 sentences per second with accuracy of 90.91% (SVM-HKE, $d = 3$, $\sigma = 0.002$). We used this parser to process 1,005,918 sentences (5,934,184 bunsetsus) randomly extracted from Japanese weblog feeds

updated in November 2008, to see how much the impact of fstries lessens when the test data and the data processed to build fstries mismatch. The parsing time was 156.4 sec. without fstrie$_{\mathrm{L}}$, while it was just 35.9 sec. with fstrie$_{\mathrm{L}}$. The speed-up factor of 4.4 on weblog feeds was slightly worse than that on news articles ($0.346/0.067 = 5.2$) but still evident. This implies that sorting features in building fstries yielded prefix features vectors that commonly appear in this task, by excluding domain-specific features such as lexical features.

In summary, our algorithm successfully minimized the efficiency gap among classifiers with different degrees of feature combinations and made accurate classifiers trained with higher-order feature combinations practical.

5 Conclusion and Future Work

Our simple method speeds up a classifier trained with many conjunctive features by using precalculated weights of (partial) feature vectors stored in a feature sequence trie (fstrie). We experimentally demonstrated that it speeded up SVM and LLM classifiers for a Japanese dependency parsing task by a factor of 10. We also confirmed that the sparse feature space provided by ℓ_1-LLMs and SVM-HKEs contributed much to size reduction of the fstrie required to achieve the same speed-up. The implementations of the proposed algorithm for LLMs and SVMs (with a polynomial kernel) and the Japanese dependency parser will be available at http://www.tkl.iis.u-tokyo.ac.jp/~ynaga/.

We plan to apply our method to wider range of classifiers used in various NLP tasks. To speed up classifiers used in a real-time application, we can build fstries incrementally by using feature vectors generated from user inputs. When we run our classifiers on resource-tight environments such as cell-phones, we can use a random feature mixing technique (Ganchev and Dredze, 2008) or a memory-efficient trie implementation based on a succinct data structure (Jacobson, 1989; Delpratt et al., 2006) to reduce required memory usage.

We will combine our method with other techniques that provide sparse solutions, for example, kernel methods on a budget (Dekel and Singer, 2007; Dekel et al., 2008; Orabona et al., 2008) or kernel approximation (surveyed in Kashima et al. (2009)). It is also easy to combine our method with SVMs with partial kernel expansion (Goldberg and Elhadad, 2008), which will yield slower but more space-efficient classifiers. We will in the future consider an issue of speeding up decoding with structured models (Lafferty et al., 2001; Miyao and Tsujii, 2002; Sutton et al., 2004).

Abstract

In this paper, we propose a linear model-based general framework to combine k-best parse outputs from multiple parsers. The proposed framework leverages on the strengths of previous system combination and re-ranking techniques in parsing by integrating them into a linear model. As a result, it is able to fully utilize both the logarithm of the probability of each k-best parse tree from each individual parser and any additional useful features. For feature weight tuning, we compare the simulated-annealing algorithm and the perceptron algorithm. Our experiments are carried out on both the Chinese and English Penn Treebank syntactic parsing task by combining two state-of-the-art parsing models, a head-driven lexicalized model and a latent-annotation-based un-lexicalized model. Experimental results show that our F-Scores of 85.45 on Chinese and 92.62 on English outperform the previously best-reported systems by 1.21 and 0.52, respectively.

1 Introduction

Statistical models have achieved great success in language parsing and obtained the state-of-the-art results in a variety of languages. In general, they can be divided into two major categories, namely lexicalized models (Collins 1997, 1999; Charniak 1997, 2000) and un-lexicalized models (Klein and Manning 2003; Matsuzaki et al. 2005; Petrov et al. 2006; Petrov and Klein 2007). In lexicalized models, word information play a key role in modeling grammar rule generation, while un-lexicalized models usually utilize latent information derived from the parse structure diversity. Although the two models are different from each other in essence, both have achieved state-of-the-art results in a variety of languages and are complementary to each other (this will be empirically verified later in this paper). Therefore, it is natural to combine the two models for better parsing performance.

Besides individual parsing models, many system combination methods for parsing have been proposed (Henderson and Brill 1999; Zeman and Žabokrtský 2005; Sagae and Lavie 2006) and promising performance improvements have been reported. In addition, parsing re-ranking (Collins 2000; Riezler et al. 2002; Charniak and Johnson 2005; Huang 2008) has also been shown to be another effective technique to improve parsing performance. This technique utilizes a bunch of linguistic features to re-rank the k-best (Huang and Chiang 2005) output on the forest level or tree level. In prior work, system combination was applied on multiple parsers while re-ranking was applied on the k-best outputs of individual parsers.

In this paper, we propose a linear model-based general framework for multiple parsers combination. The proposed framework leverages on the strengths of previous system combination and re-ranking methods and is open to any type of features. In particular, it is capable of utilizing the logarithm of the parse tree probability from each individual parser while previous combination methods are unable to use this feature since the probabilities from different parsers are not comparable. In addition, we experiment on k-best combination while previous methods are only verified on 1-best combination. Finally, we apply our method in combining outputs from both the lexicalized and un-lexicalized parsers while previous methods only carry out experiments on multiple lexicalized parsers. We also compare two learning algorithms in tuning the feature weights for the linear model.

We perform extensive experiments on the Chinese and English Penn Treebank corpus. Experimental results show that our final results, an F-Score of 92.62 on English and 85.45 on Chinese, outperform the previously best-reported systems by 0.52 point and 1.21 point, respectively. This convincingly demonstrates the effectiveness of our proposed framework. Our study also shows that the simulated-annealing algorithm (Kirkpatrick et al. 1983) is more effective

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1552–1560,
Singapore, 6-7 August 2009.

than the perceptron algorithm (Collins 2002) for feature weight tuning.

The rest of this paper is organized as follows. Section 2 briefly reviews related work. Section 3 discusses our method while section 4 presents the feature weight tuning algorithm. In Section 5, we report our experimental results and then conclude in Section 6.

2 Related Work

As discussed in the previous section, system combination and re-ranking are two techniques to improve parsing performance by post-processing parsers' k-best outputs.

Regarding the system combination study, Henderson and Brill (1999) propose two parser combination schemes, one that selects an entire tree from one of the parsers, and one that builds a new tree by selecting constituents suggested by the initial trees. According to the second scheme, it breaks each parse tree into constituents, calculates the count of each constituent, then applies the majority voting to decide which constituent would appear in the final tree. Sagae and Lavie (2006) improve this second scheme by introducing a threshold for the constituent count, and search for the tree with the largest number of count from all the possible constituent combination. Zeman and Žabokrtský (2005) study four combination techniques, including voting, stacking, unbalanced combining and switching, for constituent selection on Czech dependency parsing. Promising results have been reported in all the above three prior work. Henderson and Brill (1999) combine three parsers and obtained an F1 score of 90.6, which is better than the score of 88.6 obtained by the best individual parser as reported in their paper. Sagae and Lavie (2006) combine 5 parsers to obtain a score of 92.1, while they report a score of 91.0 for the best single parser in their paper. Finally, Zeman and Žabokrtský (2005) reports great improvements over each individual parsers and show that a parser with very low accuracy can also help to improve the performance of a highly accurate parser. However, there are two major limitations in these prior works. First, only one-best output from each individual parsers are utilized. Second, none of these works uses the parse probability of each parse tree output from the individual parser.

Regarding the parser re-ranking, Collins (2000) proposes a dozen of feature types to re-rank k-best outputs of a single head-driven parser. He uses these feature types to extract around half a million different features on the training set, and then examine two loss functions, MRF and Boosting, to do feature selection. Charniak and Johnson (2005) generate a more accurate k-best output and adopt MaxEnt method to estimate the feature weights for more than one million features extracted from the training set. Huang (2008) further improves the re-ranking work of Charniak and Johnson (2005) by re-ranking on packed forest, which could potentially incorporate exponential number of k-best list. The re-ranking techniques also achieve great improvement over the original individual parser. Collins (2002) improves the F1 score from 88.2% to 89.7%, while Charniak and Johnson (2005) improve from 90.3% to 91.4%. This latter work was then further improved by Huang (2008) to 91.7%, by utilizing the benefit of forest structure. However, one of the limitations of these techniques is the huge number of features which makes the training very expensive and inefficient in space and memory usage.

3 K-best Combination of Lexicalized and Un-Lexicalized Parsers with Model Probabilities

In this section, we first introduce our proposed k-best combination framework. Then we apply this framework to the combination of two state-of-the-art lexicalized and un-lexicalized parsers with an additional feature inspired by traditional combination techniques.

3.1 K-best Combination Framework

Our proposed framework consists of the following steps:

1) Given an input sentence and N different parsers, each parser generates K-best parse trees.
2) We combine the N*K output trees and remove any duplicates to obtain M unique tress.
3) For each of the M unique trees, we re-evaluate it with all the N models which are used by the N parsers. It is worth noting that this is the key point (i.e. one of the major advantages) of our method since some parse trees are only generated from one or I (I<N) parsers. For example, if a tree is only generated from head-driven lexicalized model, then it only has the head-driven model score. Now we re-evaluate it with the latent-annotation un-lexicalized model to reflect the latent-

annotation model's confidence for this tree. This enables our method to effectively utilize the confidence measure of all the individual models without any bias. Without this re-evaluation step, the previous combination methods are unable to utilize the various model scores.

4) Besides model scores, we also compute some additional feature scores for each tree, such as the widely-used "constituent count" feature.
5) Then we adopt the linear model to balance and combine these feature scores and generate an overall score for each parse tree.
6) Finally we re-rank the M best trees and output the one with the highest score.

$$f(t) = \lambda_1 f_1(t) + \cdots + \lambda_N f_N(t) + \lambda'_1 f'_1(t) + \cdots + \lambda'_L f'_L(t)$$

The above is the linear function used in our method, where t is the tree to be evaluated, f_1 to f_N are the model confidence scores (in this paper, we use logarithm of the parse tree probability) from the N models, λ_1 to λ_N are their weights, f'_1 to f'_L are the L additional features, λ'_1 to λ'_L are their weights.

In this paper, we employ two individual parsing model scores and only one additional feature. Let f_1 be the head-driven model score, f_2 be the latent-annotation model score, f'_1 be the constituent count feature and λ'_1 is the weight of feature f'_1.

3.2 Confidences of Lexicalized and Unlexicalized Model

The term "confidence" was used in prior parser combination studies to refer to the accuracy of each individual parser. This reflects how much we can trust the parse output of each parser. In this paper, we use the term "confidence" to refer to the logarithm of the tree probability computed by each model, which is a direct measurement of the model's confidence on the target tree being the best or correct parse output. In fact, the feature weight λ_i in our linear model functions similarly as the traditional "confidence". However, we do not directly use parser's accuracy as its value. Instead we tune it automatically on development set to optimize it against the parsing performance directly. In the following, we introduce the state-of-the-art head-driven lexicalized and latent-annotation un-lexicalized models (which are used as two individual models in this paper), and describe how they compute the tree probability briefly.

Head-driven model is one of the most representative lexicalized models. It attaches the head word to each non-terminal and views the generation of each rule as a Markov process first from father to head child, and then to the head child's left and right siblings.

Take following rule r as example,

$$F \rightarrow L_n \ldots L_2 L_1 M R_1 R_2 \ldots R_m$$

F is the rule's left hand side (i.e. father label), M is the head child, L_i is M's left sibling and R_i is M's right sibling. Let h be M's head word, the probability of this rule is

$$P(r) = P(M|h,F) \cdot \prod_{i=1}^{n} P(L_i|L_{i-1},M,h,F) \cdot \prod_{j=1}^{m} P(R_j|R_{j-1},M,h,F)$$

The probability of a tree is just the product of the probabilities of all the rules in it. The above is the general framework of head-driven model. For a specific model, there may be some additional features and modification. For example, the model2 in Collins (1999) introduces subcategorization and model3 introduces gap as additional features. Charniak (2000)'s model introduces pre-terminal as additional features.

The latent-annotation model (Matsuzaki et al. 2005; Petrov et al. 2006) is one of the most effective un-lexicalized models. Briefly speaking, latent-annotation model views each non-terminal in the Treebank as a non-terminal followed by a set of latent variables, and uses EM algorithms to automatically learn the latent variables' probability functions to maximize the probability of the given training data. Take the following binarized rule as example,

$$A \rightarrow B\ C$$

could be viewed as the set of rules

$$\{A_i \rightarrow B_j\ C_k | i,j,k\ are\ latent\ variables\}$$

The process of computing the probability of a normal tree is to first binarized all the rules in it, and then replace each rule to the corresponding set of rules with latent variables. Now the previous tree becomes a packed forest (Klein and Manning 2001; Petrov et al. 2007) in the latent-annotation model, and its probability is the inside probability of the root node. This model is quite different from the head-driven model in which

the probability of a tree is just the product all the rules' probability.

3.3 Constituent Counts

Besides the two model scores, we also adopt constituent count as an additional feature inspired by (Henderson and Brill 1999) and (Sagae and Lavie 2006). A constituent is a non-terminal node covering a special span. For example, "NP[2,4]" means a constituent labelled as "NP" which covers the span from the second word to the fourth word. If we have 100 trees and NP[2,4] appears in 60 of them, then its constituent count is 60. For each tree, its constituent count is the sum of all the counts of its constituent. However, as suggested in (Sagae and Lavie 2006), this feature favours precision over recall. To solve this issue, Sagae and Lavie (2006) use a threshold to balance them. For any constituent, we calculate its count if and only if it appears more than X times in the k-best trees; otherwise we set it as 0. In this paper, we normalize this feature by dividing the constituent count by the number of k-best. Note that the threshold value and the additional feature value are not independent. Once the threshold changes, the feature value has to be recalculated.

In conclusion, we have four parameters to estimate: two model score weights, one additional feature weight and a threshold for the additional feature.

4 Parameter Estimation

We adopt the minimum error rate principle to tune the feature weights by minimizing the error rate (i.e. maximizing the F1 score) on the development set. In our study, we implement and compare two algorithms, the simulated-annealing style algorithm and the average perceptron algorithm.

4.1 Simulated Annealing

Simulated-annealing algorithm has been proved to be a powerful and efficient algorithm in solving NP problem (Černý 1985). Fig 1 is the pseudo code of the simulated-annealing algorithm that we apply.

In a single iteration (line 4-11), the simulated algorithm selects some random points (the Markov link) for hill climbing. However, it accepts some bad points with a threshold probability controlled by the annealing temperature (line 7-10). The hill climbing nature gives this algorithm the ability of converging at local maximal point and the random nature offers it the chance to jump from some local maximal points to global maximal point. We do a slight modification to save the best parameter so far across all the finished iterations and let it be the initial point for upcoming iterations (line 12-17).

RandomNeighbour(p) is the function to generate a random neighbor for the p (the four-tuple parameter to be estimated). F1(p) is the function to calculate the F1 score over the entire test set. Given a fixed parameter p, it selects the candidate tree with best score for each sentence and computes the F1 score with the PARSEVAL metrics.

Pseudo code 1. *Simulated-annealing algorithm*
Input: *k-best trees combined from two model output*
Notation:
p: the current parameter value
F1(p): the F1 score with the parameter value p
TMF: the max F1 score of each iteration
TMp: the optimal parameter value during iteration
MaxF1: the max F1 score on dev set
Rp: the parameter value which maximizes the F1 score of the dev set
T: annealing temperature
L: length of Markov link
Output: Rp

```
1.  MaxF1:= 0, Rp:= (0,0,0,0), T:=1, L=100 // initialize
2.  Repeat                                  // iteration
3.      TMp :=Rp
4.      for  i := 1 to L  do
5.          p := RandomNeighbour(TMp)
6.          d= F1(p)- TMF
7.          if d>0 or exp(d/T) > random[0,1) then
8.              TMF:=F1(p)
9.              TMp:=p
10.         end if
11.     end for
12.     if TMF > MaxF1 then
13.         MaxF:=TMF
14.         Rp:=TMp
15.     else
16.         TMp:=Rp
17.     end if
18.     T=T*0.9
19. Until convergence
```

Fig 1. Simulated Annealing Algorithm

4.2 Averaged Perceptron

Another algorithm we apply is the averaged perceptron algorithm. Fig 2 is the pseudo code of this algorithm. Averaged perceptron is an online algorithm. It iterates through each instance. In each instance, it selects the candidate answer with the maximum function score. Then it updates the weight by the margin of feature value between the select answer and the oracle answer (line 5-9). After each iteration, it does average to generate a new weight (line 10). The averaged

perceptron has a solid theoretical fundamental and was proved to be effective across a variety of NLP tasks (Collins 2002).

However, it needs a slightly modification to adapt to our problem. Since the threshold and the constituent count are not independent, they are not linear separable. In this case, the perceptron algorithm cannot be guaranteed to converge. To solve this issue, we introduce an outer loop (line 2) to iterate through the value range of threshold with a fixed step length and in the inner loop we use perceptron to estimate the other three parameters. Finally we select the final parameter which has maximum F1 score across all the iteration (line 14-17).

Pseudo code 2. *Averaged perceptron algorithm*
Input: *k-best trees combined from two model output*
Notation:

MaxF1, Rp: already defined in pseudo code 1
T: the max number of iterations
I: the number of instances
Threshold: the threshold for constituent count
w: the three feature weights other than threshold
y': the candidate tree with max function score given a fixed weight w
y^+: the candidate tree with the max F1 score (since the oracle tree may not appeared in our candidate set, we choose this one as the pseudo orcale tree)
cand(i): the set of candidate tree for ith sentence

Output: Rp

1. MaxF1:=0, T=30
2. **for** Threshold :=0 to 1 with step 0.01 **do**
3. Initialize w
4. **for** iter : 1 to T **do**
5. **for** i := 1 to I **do**
6. $y' := \text{argmax}_{y \in \text{cand(i)}} w \cdot f(y)$
7. $w := w + f(y^+) - f(y')$
8. $w_i := w$
9. **end for**
10. $w := \frac{\sum_{i=1}^{I} w_i}{I}$
11. **if** converged **then break**
12. **end for**
13. p := (Threshold, w)
14. **if** F1(p) > MaxF1 **then**
15. MaxF1 := F1(p)
16. Rp:=p
17. **end if**
18. **end for**

5 Experiments

We evaluate our method on both Chinese and English syntactic parsing task with the standard division on Chinese Penn Treebank Version 5.0 and WSJ English Treebank 3.0 (Marcus et al. 1993) as shown in Table 1.

We use Satoshi Sekine and Michael Collins' EVALB script modified by David Ellis for accuracy evaluation. We use Charniak's parser (Charniak 2000) and Berkeley's parser (Petrov and Klein 2007) as the two individual parsers, where Charniak's parser represents the best performance of the lexicalized model and the Berkeley's parser represents the best performance of the un-lexicalized model. We retrain both of them according to the division in Table. 1. The number of EM iteration process for Berkeley's parser is set to 5 on English and 6 on Chinese. Both the Charniak's parser and Berkeley's parser provide function to evaluate an input parse tree's probability and output the logarithm of the probability.

Lang. \ Div.	Train	Dev	Test
English	Sec.02-21	Sec. 22	Sec. 23
Chinese	Art. 001-270, 400-1151	Art. 301-325	Art. 271-300

Table 1. Data division

5.1 Effectiveness of our Combination Method

This sub-section examines the effectiveness of our proposed methods. The experiment is set up as follows: 1) for each sentence in the dev and test sets, we generate 50-best from Charniak's parser (Charniak 2000) and Berkeley's parser (Petrov and Klein 2007), respectively; 2) the two 50-best trees are merged together and duplication was removed; 3) we tune the parameters on the dev set and test on the test set. (Without specific statement, we use simulated-annealing as default weight tuning algorithm.)

The results are shown in Table 2 and Table 3. "P" means precision, "R" means recall and "F" is the F1-measure (all is in % percentage metrics); "Charniak" represents the parser of (Charniak 2000), "Berkeley" represents the parser of (Petrov and Klein 2007), "Comb." represents the combination of the two parsers.

accuracy \ parser		Charniak	Berkeley	Comb.
<=40 words	P	85.20	86.65	**90.44**
	R	83.70	84.18	**85.96**
	F	84.44	85.40	**88.15**
All	P	82.07	84.63	**87.76**
	R	79.66	81.69	**83.27**
	F	80.85	83.13	**85.45**

Table 2. Results on Chinese

parser / accuracy		Charniak	Berkeley	Comb.
<=40 words	P	90.45	90.27	**92.36**
	R	90.14	89.76	**91.42**
	F	90.30	90.02	**91.89**
All	P	89.86	89.77	**91.89**
	R	89.53	89.26	**90.97**
	F	89.70	89.51	**91.43**

Table 3. Results on English

From Table 2 and Table 3, we can see our method outperforms the single systems in all test cases with all the three evaluation metrics. Using the entire Chinese test set, our method improves the performance by 2.3 (85.45-83.13) point in F1-Score, representing 13.8% error rate reduction. Using the entire English test set, our method improves the performance by 1.7 (91.43-89.70) point in F1-Score, representing 16.5% error rate reduction. These improvements convincingly demonstrate the effectiveness of our method.

5.2 Effectiveness of K

Fig 3 and Fig. 4 show the relationship between F1 score and the number of K-best used when doing combination on Chinese and English respectively.

From Fig 3 and Fig. 4, we could see that the F1 score first increases with the increasing of K (there are some vibration points, this may due to statistical noise) and reach the peak when K is around 30-50, then it starts to drop. It shows that k-best list did provide more information than one-best and thus can help improve the accuracy; however more k-best list may also contain more noises and these noises may hurt the final combination quality.

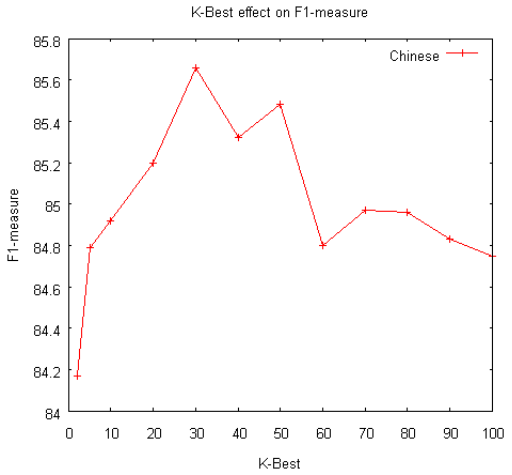

Fig 3. F1-measure vs. K on Chinese

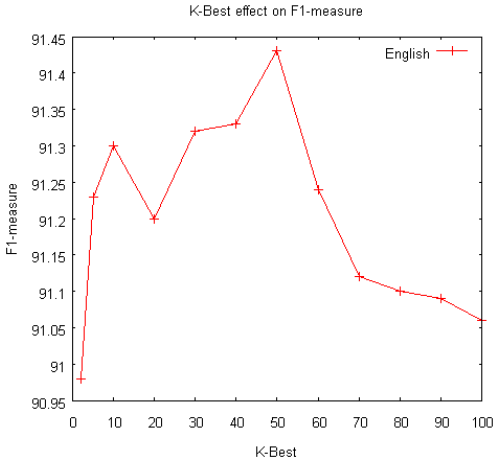

Fig 4. F1-measure vs. K on English

5.3 Diversity on the K-best Output of the Head-driven and Latent-annotation-driven Model

In this subsection, we examine how different of the 50-best trees generated from Charnriak's parser (head-driven model) (Charnriak, 2000) and Berkeley's parser (latent-annotation model) (Petrov and Klein, 2007).

Table 4 reports the statistics on the 50-best output for Chinese and English test set. Since for some short sentences the parser cannot generate up to 50 best trees, the average number of trees is less than 50 for each sentence. Each cell reports the total number of trees generated over the entire test set followed by the average count for each sentence in bracket. "Total" means simply combine the number of trees from the two parsers while "Unique" means the number after removing the duplicated trees for each sentence. In the last row, we report the averaged redundant rate for each sentence, which is derived by dividing the figures in the row "Duplicated" by those in the row "Total".

	Chinese	English
Charniak	14577 (41.9)	120438 (49.9)
Berkeley	14524 (41.7)	114299 (47.3)
Total	29101 (83.6)	234737 (97.2)
Unique	27747 (79.7)	221633 (91.7)
Duplicated	1354 (3.9)	13104 (5.4)
Redundant rate	4.65%	5.58%

Table 4. The statistics on the 50-best output for Chinese and English test set.

The small redundant rate clearly suggests that the two parsing models are quite different and are complementary to each other.

Oracle \ parser		Charniak	Berkeley	Comb.
Chinese	P	88.95	90.07	**92.45**
	R	86.51	87.12	**89.67**
	F	87.71	88.57	**91.03**
English	P	97.06	95.86	**98.10**
	R	96.57	95.53	**97.68**
	F	96.82	95.70	**97.89**

Table 5. The oracle over 50-best output for individual parser and our method

The k-best oracle score is the upper bound of the quality of the k-best trees. Table 5 reports the oracle score for the 50-best of the two individual parsers and our method. Similar to Table 4, Table 5 shows again that the two models are complementary to each other and our method is able to take the strength of the two models.

5.4 Effectiveness of Model Confidence

One of the advantages of our method that we claim is that we can utilize the feature of the model confidence score (logarithm of the parse tree probability).

Table 6 shows that all the three features contribute to the final accuracy improvement. Even if we only use the "B+C" confidence scores, it also outperforms the baseline individual parser (as reported in Table 2 and Table 3) greatly. All these together clearly verify the effective of the model confidence feature and our method can effectively utilize this feature.

Lang \ Feat.	I	B+C	B+C+I
Chinese	82.34	84.67	**85.45**
English	90.20	91.02	**91.43**

Table 6. F1 score on 50-best combination with different feature configuration. "I" means the constituent count, "B" means Berkeley parser confidence score and "C" means Charniak parser confidence score.

5.5 Comparison of the Weight Tuning Algorithms

In this sub-section, we compare the two weight tuning algorithms on 50-best combination tasks on both Chinese and English. Dan Bikel's randomized parsing evaluation comparator (Bikel 2004) was used to do significant test on precision and recall metrics. The results are shown in Table 7.

We can see, simulated annealing outperforms the averaged perceptron significantly in both precision ($p<0.005$) and recall ($p<0.05$) metrics of Chinese task and precision ($p<0.005$) metric of English task. Though averaged perceptron got slightly better recall score on English task, it is not significant according to the p-value ($p>0.2$).

From table 8, we could see the simulated annealing algorithm is around 2-4 times slower than averaged perceptron algorithm.

Lang \ Algo.		SA.	AP.	P-value
Chinese	P	**87.76**	86.85	0.003
	R	**83.27**	82.90	0.030
English	P	**91.89**	91.72	0.004
	R	90.97	**91.02**	0.205

Table 7. Precision and Recall score on 50-best combination by the two parameter estimation algorithms with significant test; "SA." is simulated annealing, "AP." is averaged perceptron, "P-value" is the significant test p-value.

Lang \ Algo.	Simulated Annealing	Averaged Perceptron
Chinese	2.3	0.6
English	12	6

Table 8. Time taken (in minutes) on 50-best combination of the two parameter estimation algorithms

5.6 Performance-Enhanced Individual Parsers on English

For Charniak's lexicalized parser, there are two techniques to improve its performance. One is reranking as explained in section 2. The other is the self-training (McClosky et al. 2006) which first parses and reranks the NANC corpus, and then use them as additional training data to retrain the model. In this sub-section, we apply our method to combine the Berkeley parser and the enhanced Charniak parser by using the new model confidence score output from the enhanced Charniak parser.

Table 9 and Table 10 show that the Charniak parser enhanced by re-ranking and self-training is able to help to further improve the performance of our method. This is because that the enhanced Charniak parser provides more accurate model confidence score.

parser / accuracy		reranking	Comb.	baseline
<=40 words	P	92.34	**93.41**	92.36
	R	91.61	**92.15**	91.42
	F	91.97	**92.77**	91.89
All	P	91.78	**92.92**	91.89
	R	91.03	**91.70**	90.97
	F	91.40	**92.30**	91.43

Table 9. Performance with Charniak parser enhanced by re-ranking; "baseline" is the performance of the combination of Table 3.

parser / accuracy		self-train+ reranking	Comb.	baseline
<=40 words	P	92.87	**93.69**	92.36
	R	92.12	**92.44**	91.42
	F	92.49	**93.06**	91.89
All	P	92.41	**93.25**	91.89
	R	91.64	**92.00**	90.97
	F	92.02	**92.62**	91.43

Table 10. Performance with Charniak parser enhanced by re-ranking plus self-training

5.7 Comparison with Other State-of-the-art Results

Table 11 and table 12 compare our method with the other state-of-the-art methods; we use I, B, R, S and C to denote individual model (Charniak 2000; Collins 2000; Bod 2003; Petrov and Klein 2007), bilingual-constrained model (Burkett and Klein 2008)[1], re-ranking model (Charniak and Johnson 2005, Huang 2008), self-training model (David McClosky 2006) and combination model (Sagae and Lavie 2006) respectively. The two tables clearly show that our method advance the state-of-the-art results on both Chinese and English syntax parsing.

System		F1-Measure
I	Charniak (2000)	80.85
	Petrov and Klein (2007)	83.13
B	Burkett and Klein (2008)[1]	84.24
C	**Our method**	**85.45**

Table 11. Accuracy comparison on Chinese

System		F1-Measure
I	Petrov and Klein (2007)	89.5
	Charniak (2000)	89.7
	Bod (2003)	90.7
R	Collins (2000)	89.7
	Charniak and Johnson (2005)	91.4
	Huang (2008)	91.7
S	David McClosky (2006)	92.1
C	Sagae and Lavie (2006)	92.1
	Our method	**92.6**

Table 12. Accuracy comparison on English.

6 Conclusions

In this paper, we propose a linear model-based general framework for multiple parser combination. Compared with previous methods, our method is able to use diverse features, including logarithm of the parse tree probability calculated by the individual systems. We verify our method by combining the two representative parsing models, lexicalized model and un-lexicalized model, on both Chinese and English. Experimental results show our method is very effective and advance the state-of-the-art results on both Chinese and English syntax parsing. In the future, we will explore more features and study the forest-based combination methods for syntactic parsing.

Acknowledgement

We would like to thank Prof. Hwee Tou Ng for his help and support; Prof. Charniak for his suggestion on doing the experiments with the self-trained parser and David McCloksy for his help on the self-trained model; Yee Seng Chan and the anonymous reviewers for their valuable comments.

Abstract

Automated mining of novel documents or sentences from chronologically ordered documents or sentences is an open challenge in text mining. In this paper, we describe the preprocessing techniques for detecting novel Chinese text and discuss the influence of different Part of Speech (POS) filtering rules on the detection performance. Experimental results on AP-WSJ and TREC 2004 Novelty Track data show that the Chinese novelty mining performance is quite different when choosing two dissimilar POS filtering rules. Thus, the selection of words to represent Chinese text is of vital importance to the success of the Chinese novelty mining. Moreover, we compare the Chinese novelty mining performance with that of English and investigate the impact of preprocessing steps on detecting novel Chinese text, which will be very helpful for developing a Chinese novelty mining system.

1 Introduction

The bloom of information nowadays brings us rich useful information as well as tons of redundant information in news articles, social networks (Tsai et al., 2009), and blogs (Chen et al., 2008). Novelty mining (NM), or novelty detection, aims at mining novel information from a chronologically ordered list of relevant documents/sentences. It can facilitate users to quickly get useful information without going through a lot of redundant information, which is usually a tedious and time-consuming task.

The process of detecting novel text contains three main steps, (i) preprocessing, (ii) categorization, and (iii) novelty mining. The first step preprocesses the text documents/sentences by removing stop words, performing word stemming, implementing POS tagging etc. Categorization classifies each incoming document/sentence into its relevant topic bin. Then, within each topic bin containing a group of relevant documents/sentences, novelty mining searches through the time sequence of documents/sentences and retrieves only those with "novel" information. This paper focuses on applying document/sentence-level novelty mining on Chinese. In this task, we need to identify all novel Chinese text given groups of relevant documents/sentences.

Novelty mining has been performed at three different levels: event level, sentence level and document level (Li and Croft, 2005). Works on novelty mining at the event level originated from research on Topic Detection and Tracking (TDT), which is concerned with online new event detection/first story detection (Allan et al., 1998; Yang et al., 2002; Stokes and Carthy, 2001; Franz et al., 2001; Brants et al., 2003). Research on document and sentence-level novelty mining aims to find relevant and novel documents/sentences given a stream of documents/sentences. Previous studies on document and sentence-level novelty mining tend to apply some promising content-oriented techniques (Li and Croft, 2005; Allan et al., 1998; Yang et al., 1998; Zhang and Tsai, 2009). Similarity metrics that can be used for detecting novel text are word overlap, cosine similarity (Yang et al., 1998), new word count (Brants et al., 2003), etc. Other works utilize ontological knowledge, especially taxonomy, such as WordNet (Zhang et al., 2002; Allan et al., 2003), synonym dictionary (Franz et al., 2001), HowNet (Eichmann and Srinivasan, 2002), etc.

Previous studies for novelty mining have been conducted on the English and Malay languages (Kwee et al., 2009; Tang et al., 2009; Tang and Tsai, 2009). Novelty mining studies on the Chinese language have been performed on topic de-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1561–1570,
Singapore, 6-7 August 2009.

tection and tracking, which identifies and collects relevant stories on certain topics from information stream (Zheng et al., 2008; Hong et al., 2008). Also many works have discussed the issues, such as word segmentation, POS tagging etc, between English and Chinese (Wang et al., 2006; Wu et al., 2003). However, to the best of our knowledge, no studies have been reported on discussing preprocessing techniques on Chinese document and sentence-level novelty mining, which is the focus of our paper.

The rest of this paper is organized as follows. Section 2 gives a brief overview of related work on detecting novel documents and sentences on English and Chinese. Section 3 introduces the details of preprocessing steps for English and Chinese. A general novelty mining algorithm is described in Section 4. Section 5 reports experimental results. Section 6 summarizes the research findings and discusses issues for further research.

2 Related Work

In the pioneering work for detecting novel documents (Zhang et al., 2002), document novelty was predicted based on the distance between the new document and the previously delivered documents in history. The detected document which is very similar to any of its history documents is regarded as a redundant document. To serve users better, it could be more helpful to further highlight novel information at the sentence level. Therefore, later studies focused on detecting novel sentences, such as those reported in TREC 2002-2004 Novelty Tracks (Harman, 2002; Soboroff and Harman, 2003; Soboroff, 2004), which compared various novelty metrics (Allan et al., 2003), and integrated different natural language techniques (Ng et al., 2007; Li and Croft, 2008).

Although novelty mining studies have mainly been conducted on the English language, studies on the Chinese language have been performed on topic detection and tracking. A prior study (Zheng et al., 2008) proposed an improved relevance model to detect the novelty information in topic tracking feedback and modified the topic model based on this information. Experimental results on Chinese datasets TDT4 and TDT2003 proved the effectiveness in topic tracking. Another study proposed a method of applying semantic domain language model to link detection, based on the structure relation among contents and the semantic distribution in a story (Hong et al., 2008).

3 Preprocessing for English and Chinese

3.1 English

Since the focus of this paper is on novelty mining, we begin from a list of relevant documents or sentences that have already undergone the categorization process.

The first step for English preprocessing is to remove all stop words from documents or sentences, such as conjunctions, prepositions, and articles. Stop words are words that are too common to be informative. These words should be removed, otherwise it will influence the novelty prediction of documents or sentences. After stop words removal, the remaining words are then stemmed. The inflected (or sometimes derived) words are reduced to their root forms. This paper used Porter stemming algorithm (Porter, 1997) for English word stemming. This algorithm removes the commoner morphological and inflexional endings from the words in English. The entire preprocessing steps in English novelty mining can be seen in Figure 1.

3.2 Chinese

In Chinese, the word is the smallest independent meaningful element. There is no obvious boundary between words so that Chinese lexical analysis, such as Chinese word segmentation, is the prerequisite for novelty mining.

Unlike English, Chinese word segmentation is a very challenging problem because of the difficulties in defining what constitutes a word (Gao et al., 2005). While each criteria provides valuable insights into "word-hood" in Chinese, they do not consistently lead us to the same conclusions. Moreover, there is no white space between Chinese words or expressions and there are many ambiguities in the Chinese language, such as: '主板和服务器' (means 'mainboard and server' in English) might be '主板/和/服务器' (means 'mainboard/and/server' in English) or '主板/和服/务/器' (means 'mainboard/kimono/task/utensil' in English). This ambiguity is a great challenge for Chinese word segmentation. In addition, there is no obvious inflected or derived words in Chinese so that word stemming is not applicable.

Therefore, in order to reduce the noise brought by Chinese word segmentation and get a better

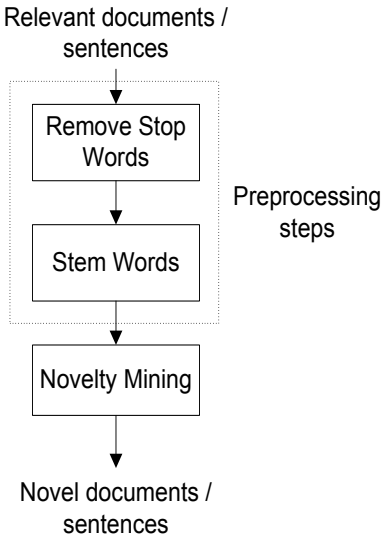

Figure 1: Preprocessing steps on English.

word list for one document or sentence, we firstly apply word segmentation on the Chinese text and then utilize Part-of-Speech (POS) tagging to select the meaningful candidate words. Figure 2 shows the preprocessing steps on the Chinese text for novelty mining. POS tagging is a process of marking up the word in a text as corresponding to a particular part of speech. It is learnt that the idea of a text mainly relies on some meaningful words, such as nouns and verbs, so that we can get the main content by extracting these meaningful words. Moreover, it will decrease the impact of the errors in Chinese word segmentation on novelty mining because only meaningful words are considered and other words (including stop words) such as '虽然' (means 'although' in English) will not appear in the word list for the following similarity computation in novelty mining. Losee also mentioned that POS tagging shows a great potential to avoid lexical ambiguity and it can help to improve the performance of information retrieval (Losee, 2001).

ICTCLAS is used when performing word segmentation and POS tagging in our experiments (ICTCLAS, 2008). It is an open source project and achieves a better precision in Chinese word segmentation and POS tagging than other Chinese POS tagging softwares (ICTCLAS, 2008). First, we apply word segmentation on the relevant Chinese documents/sentences. Chinese word segmentation includes atom segmentation, N-shortest path based rough segmentation and unknown words recognition (see Figure 3). Atom segmentation is an initial step of the Chinese language segmentation process, where atom is defined to be the minimal unit that cannot be split further. The atom can be a Chinese character, punctuation, symbol string, etc. Then, rough segmentation tries to discover the correct segmentation with as few candidates as possible. The N-Shortest Path (NSP) method (Zhang and Liu, 2002) is applied for rough segmentation. Next, we detect some unknown words such as person name, location name so as to optimize the segmentation result. Finally, we POS tag the words and keep some kinds of words in the word list according to the selective rule, which are used in novelty mining.

4 Novelty Mining

From the output of preprocessing, we can obtain a bag of words. The corresponding term-document matrix (TDM)/term-sentence matrix (TSM) can be constructed by counting the term frequency (TF) of each word. The novelty mining system predicts any incoming document/sentence by comparing it with its history documents/sentences in this vector space. Therefore, given a Chinese TDM/TSM, the novelty mining system designed for English can also be applied to Chinese.

In novelty mining, the novelty of a document/sentence can be quantitatively measured by a novelty metric and represented by a novelty score. The most popular novelty metric, i.e. cosine similarity (see (Allan et al., 2003)), is adopted. This metric first calculates the similarities between the current document/sentence d_t and each of its his-

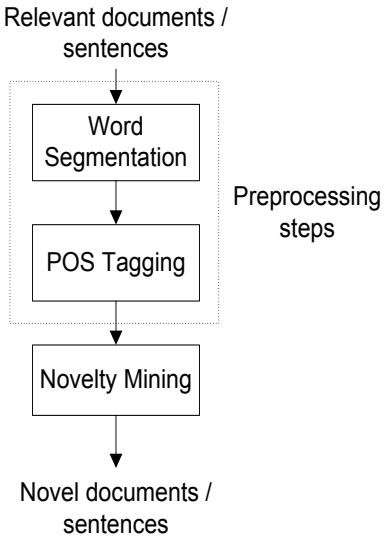

Figure 2: Preprocessing steps on Chinese.

tory documents/sentences d_i ($1 \leq i \leq t-1$). Then, the novelty score is simply one minus the maximum of these cosine similarities, as shown in Eq.(1).

$$Novelty\ Score(d_t) = 1 - \max_{1 \leq i \leq t-1} cos(d_t, d_i) \quad (1)$$

$$cos(d_t, d_i) = \frac{\sum_{k=1}^{n} w_k(d_t) \cdot w_k(d_i)}{\|d_t\| \cdot \|d_i\|}$$

where $N_{cos}(d)$ denotes the cosine similarity score of the document/sentence d and $w_k(d)$ is the weight of k^{th} element in the document/sentence weighted vector d. The term weighting function used in our work is TF(term frequency).

The final decision on whether a document/sentence is novel or not depends on whether the novelty score falls above or below a threshold. The document/sentence predicted as "novel" will be placed into the list of history documents/sentences.

5 Experiments and Results

5.1 Datasets

Two public datasets APWSJ (Zhang et al., 2002) and TREC Novelty Track 2004 (Soboroff, 2004) are selected as our experimental datasets for the document-level and the sentence-level novelty mining respectively. APWSJ data consists of news articles from Associated Press (AP) and Wall Street Journal (WSJ). There are 50 topics from Q101 to Q150 in APWSJ and 5 topics (Q131, Q142, Q145, Q147, Q150) are excluded from the experiments because they lack non-novel documents (Zhao et al., 2006). The assessors provide two degrees of judgements on non-novel documents, *absolute redundant* and *somewhat redundant*. In our experiments, we adopt the strict definition used in (Zhang et al., 2002) where only *absolute redundant* documents are regarded as non-novel. TREC 2004 Novelty Track data is developed from AQUAINT collection. Both relevant and novel sentences are selected by TREC's assessors. The statistics of these two datasets are summarized in Table 1.

Table 1: Statistics of experimental data

Dataset	Novel	Non-novel
APWSJ	10839(91.10%)	1057(8.90%)
TREC2004	3454(41.40%)	4889(58.60%)

5.2 Evaluation Measures

From many previous works, redundancy precision (RP), redundancy recall (RR) and redundancy F Score (RF) are used to evaluate the performance of document-level novelty mining (Zhang et al., 2002). Precision (P), recall (R) and F Score (F) are mainly used in evaluating the performance for sentence-level novelty mining (Allan et al., 2003). Therefore, we use RP, RR, RF and redundancy precision-recall (R-PR) curve to evaluate our experimental results on the document level. P, R, F and precision-recall (PR) curve are used to evaluate the performance on the sentence-level novelty mining. The larger the area under the R-PR

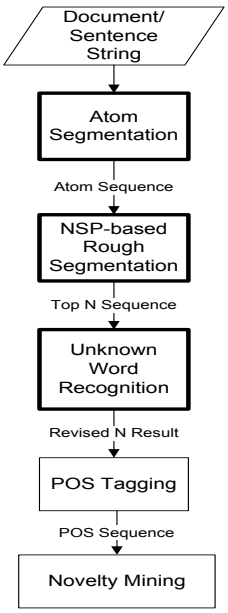

Figure 3: Word segmentation on Chinese.

curve/PR curve, the better the algorithm. Also we drew the standard redundancy F Score/F Score contours (Soboroff, 2004), which indicate the F Score values when setting precision and recall from 0 to 1 with a step of 0.1. These contours can facilitate us to compare redundancy F Scores/F Scores in R-PR curves/PR curves. Redundancy precision, redundancy recall, precision and recall on a certain topic are defined as:

$$Redundancy\ Precision = \frac{R^-}{R^- + N^-} \quad (2)$$

$$Redundancy\ Recall = \frac{R^-}{R^- + R^+} \quad (3)$$

$$Precision = \frac{N^+}{N^+ + R^+} \quad (4)$$

$$Recall = \frac{N^+}{N^+ + N^-} \quad (5)$$

where R^+,R^-,N^+,N^- correspond to the number of documents/sentences that fall into each category (see Table 2).

Based on all the topics' RP/P and RR/R, we could get the average RP/P and average RR/R by calculating the arithmetic mean of these scores on all topics. Then, the average redundancy F Score (RF)/F Score (F) is obtained by the harmonic average of the average RP/P and average RR/R.

Table 2: Categories for evaluation

	Non-novel	Novel
Delivered	R^+	N^+
Not Delivered	R^-	N^-

5.3 Experimental Results

In this experimental study, the focus was novelty mining rather than relevant documents/sentences categorization. Therefore, our experiments started with all given relevant Chinese text, from which the novel text should be identified.

Since the datasets that we used for document-level novelty mining and sentence-level novelty mining both were written in English, we first translated them into Chinese. During this process, we investigated issues on machine translation vs. manually corrected translation.

We compared the novelty mining performance on 107 text in TREC 2004 Novelty Track between automatically translated using Google Translate API[1] and the manually corrected translation. For example, here is an English sentence in Topic 51:

According to a Chilean government report, a total of 4,299 political opponents died or disappeared during Pinochet's term.

After machine translation using Google Translator, the above sentence is translated as:

根据智利政府的报告，共有4299政敌的死亡或失踪期间，皮诺切特的任期。

[1]http://code.google.com/p/google-api-translate-java

Then we manually corrected the machine translation and obtained the corrected translation:

根据智利政府的报告，在皮诺切特的任期期间，共有4299政敌死亡或失踪。

After novelty mining on the machine translation sentences and the humanly corrected translation sentences individually, we found that there is a slight difference (<2%) in precision and F Score. Thus, we used machine translation to translate the remaining documents/sentences to Chinese. This indicates that the noise in machine translation for Chinese had little impact on our actual results.

Then on English text, we applied the preprocessing steps discussed in Section 3.1, including stop word removing and word stemming. For Chinese datasets, we segmented the documents/sentences into words and then performed POS filtering to acquire the candidate words for the space vector.

Based on the vectors of Chinese text, we calculated the similarities between documents/sentences and predicted the novelty for each document/sentence in the Chinese and English datasets. An incoming Chinese/English document will be compared with all the system delivered 10 novel documents. If the novelty score is above the novelty score threshold, the document is considered to be novel. Thresholds used were between 0.05 and 0.65. We also performed Chinese/English sentence-level novelty mining. Whether an incoming Chinese/English sentence is novel is predicted by comparing with the most recent system-delivered 1000 novel sentences. Thresholds adopted were between 0.05 and 0.95 with an equal step of 0.10. Then, we evaluated the Chinese/English novel text detection performance by setting a series of novelty score thresholds.

5.3.1 POS Filtering Rule

We adopted two different rules to select the candidate words to represent one document/sentence and investigated the POS filtering influence on detecting the novel Chinese text.

- Rule1: only some non-meaningful words, including pronouns ('r' in Peking University/Chinese Academy of Sciences Chinese POS tagging criterions (PKU and CAS, 1999)), auxiliary words ('u'), tone words ('y'), conjunctions ('c'), prepositions ('p') and punctuation words ('w') are removed.
- Rule2: fewer kinds of words are selected to represent a document/sentence. Only nouns (including 'n' short for common nouns, 'nr' short for person name, 'ns' short for location name, 'nt' short for organization name, 'nz' short for other proper nouns), verbs ('v'), adjectives ('a') and adverbs ('d') are kept.

For example, here is a simple Chinese sentence: "墙上挂着一幅画。" (There is a picture on the wall). After POS filtering using Rule1, the words we keep are: "墙('n'), 上('v'), 挂('v'), 一('m'), 幅('q'), 画('n')". After POS filtering using Rule2, the remaining words are: "墙('n'), 上('v'), 挂('v'), 画('n')". It is noticed that by using Rule2, we can remove more non-important words.

Figure 4 and Figure 5 show the performances on the document and sentence-level novelty mining when choosing the stricter rule (Rule2) and the less strict rule (Rule1) in POS filtering. The grey dashed lines show contours at intervals of 0.1 points of F Score.

From Figure 4 and Figure 5, we learn that the Chinese novelty mining performance varies when choosing the stricter rule (Rule2) and the less strict rule (Rule1) in POS filtering. We can obtain a better performance when choosing a stricter rule (Rule2). Therefore, it is necessary to perform POS filtering in the preprocessing steps on Chinese and just removing some non-meaningful words (like stop words) may not be enough. POS filtering can help to remove the less meaningful words so that each vector is represented better. Compared to choosing more kinds of words (Rule1), only keeping nouns, verbs, adjectives and adverbs (Rule2) will be a better choice for novelty mining. We also noticed that the selection of words to represent Chinese text is of vital importance to the success of Chinese novelty mining.

5.3.2 Comparison with English

We compared the novelty mining performance on the English and Chinese documents/sentences datasets. For Chinese, we chose Rule2 to select the candidate words. Figure 6 and Figure 7 show the R-PR and PR curves of document/sentence-level novelty mining in English and Chinese when given a series of novelty score thresholds.

From Figure 6 and Figure 7, we observe that the performance on detecting novel Chinese documents is slightly lower than that on English. This may be due to the different linguistical characteris-

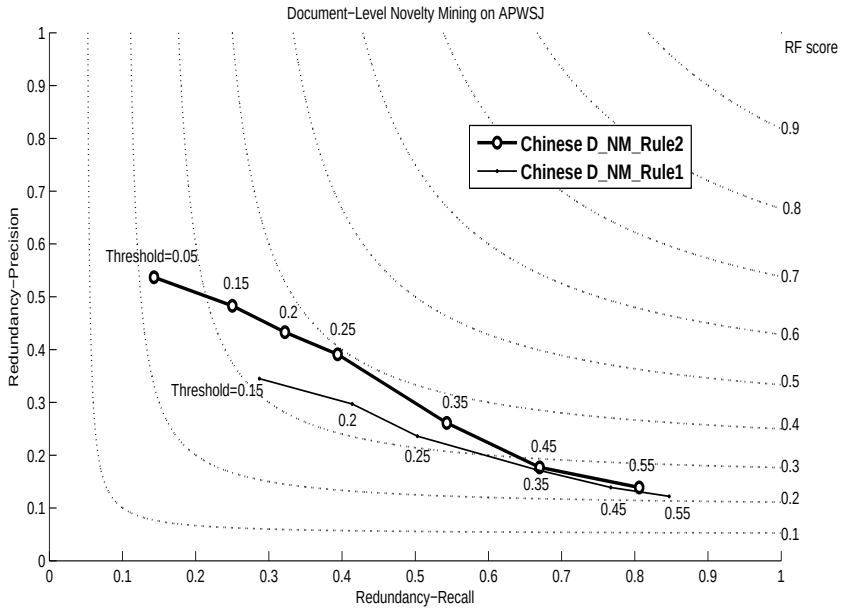

Figure 4: R-PR curves for document-level novelty mining on Chinese when choosing different rules on APWSJ. The grey dashed lines show contours at intervals of 0.1 points of RF.

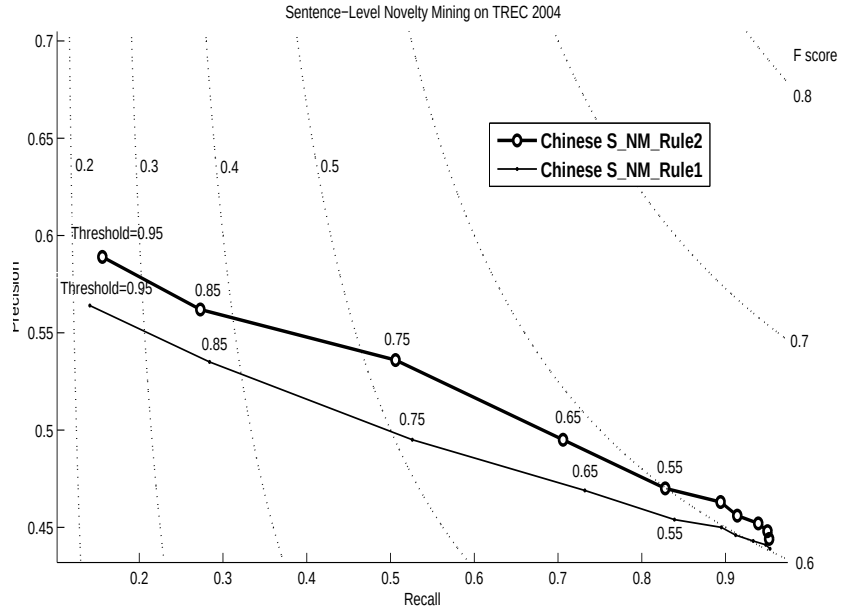

Figure 5: PR curves for sentence-level novelty mining on Chinese when choosing different rules on TREC 2004. The grey dashed lines show contours at intervals of 0.1 points of F.

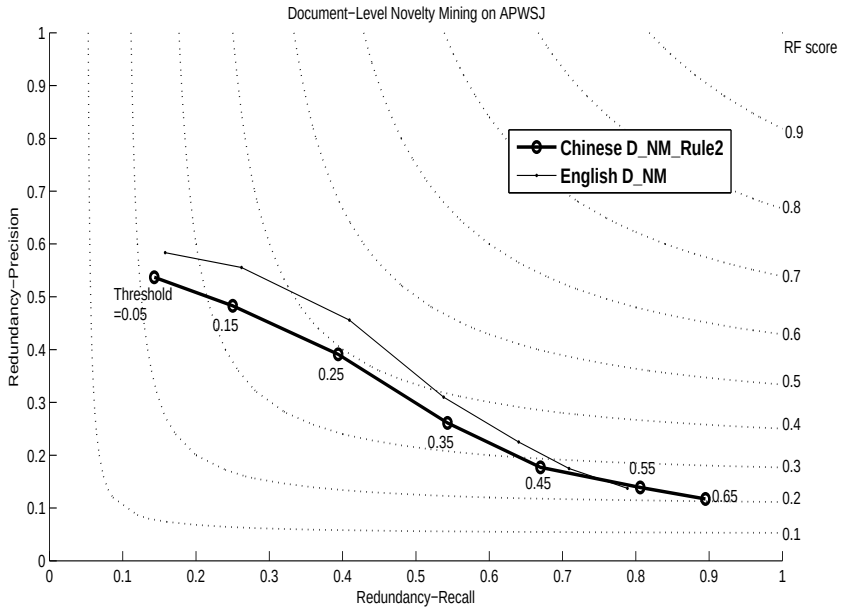

Figure 6: R-PR curves for document-level novelty mining on Chinese and English on APWSJ. The grey dashed lines show contours at intervals of 0.1 points of RF.

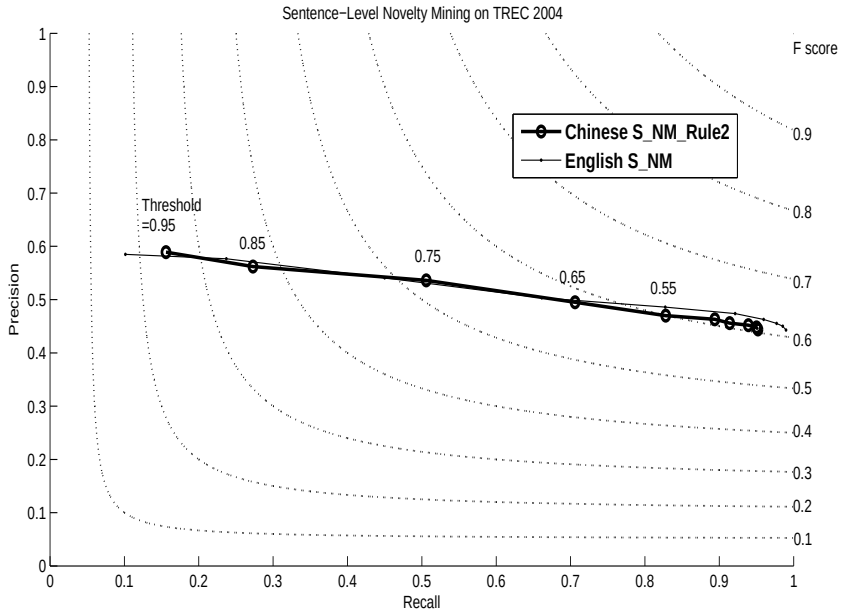

Figure 7: PR curves for sentence-level novelty mining on Chinese and English on TREC 2004. The grey dashed lines show contours at intervals of 0.1 points of F.

tics of each language so that the preprocessing influence on each language's novelty mining is dissimilar. Furthermore, the Chinese preprocessing quality is not as good as that on English so that it is difficult to obtain a good "bag of words" from a document. Moreover, the errors in word segmentation will influence the result of POS tagging. These issues make tokenizing and POS tagging extremely difficult for the Chinese text.

However, the performance of Chinese sentence-level novelty mining is almost the same as that on English. The reason is that the novelty mining performance at the sentence level is not so sensitive to the preprocessing steps as that at the document level. If the similarity computation is based on the sentence level, the word segmentation and POS tagging errors actually will not have a big influence on the result as that on documents.

6 Conclusion

This paper studied the preprocessing issues on mining novel Chinese text, which, to the best of our knowledge, have not been sufficiently addressed in previous studies. We described the Chinese preprocessing steps and discussed the influence when choosing different Part-of-Speech (POS) filtering rules. Then we applied novelty mining on Chinese and English documents/sentences and compared their performance.

The experimental results on APWSJ and TREC 2004 Novelty Track showed that after adopting a stricter POS filtering rule, the Chinese novelty mining performed better on both documents and sentences. This is because non-meaningful words have a negative influence on detecting novel text. However, compared to English, Chinese performed worse on the document level and similarly on the sentence level. The reason may be due to the lower sensitivity of preprocessing at the sentence level. The main contributions of this work are as follows:

1) We investigated the preprocessing techniques for detecting novel Chinese text on both document and sentence level.

2) The POS filtering rule, telling how to select words to represent one document/sentence, was discussed.

3) Several experiments were conducted to compare the novelty mining performance between Chinese and English. The novelty mining performance on Chinese can be improved as good as that on English if we can increase the preprocessing precision on Chinese text.

Our findings will be very helpful for developing a real-time Chinese novelty mining system at both the document and sentence level. In future work, we will try other word combinations and investigate better ways to represent the Chinese text. In addition, we will explore how to utilize the better Chinese sentence-level novelty mining result to improve the detection performance on documents.

Abstract

The problem of re-ranking initial retrieval results exploring the intrinsic structure of documents is widely researched in information retrieval (IR) and has attracted a considerable amount of time and study. However, one of the drawbacks is that those algorithms treat queries and documents separately. Furthermore, most of the approaches are predominantly built upon graph-based methods, which may ignore some hidden information among the retrieval set.

This paper proposes a novel document re-ranking method based on Latent Dirichlet Allocation (LDA) which exploits the implicit structure of the documents with respect to original queries. Rather than relying on graph-based techniques to identify the internal structure, the approach tries to find the latent structure of "topics" or "concepts" in the initial retrieval set. Then we compute the distance between queries and initial retrieval results based on latent semantic information deduced. Empirical results demonstrate that the method can comfortably achieve significant improvement over various baseline systems.

1 Introduction

Consider a traditional IR problem, where there exists a set of documents $\mathbb{D}$ in the collection. In response to an information need (as expressed in a query q), the system determines a best fit between the query and the documents and returns a list of retrieval results, sorted in a decreasing order of their relevancy. In practice, high precision at the top rankings of the returned results is of particular interest. Generally, there are two ways to automatically assist in achieving this ultimate goal after an initial retrieval process (Baeza-Yates and Ribeiro-Neto, 1999): document re-ranking and query expansion/re-weighting. Since the latter normally need a second round of retrieval process, our method focuses on the document re-ranking approach. We will focus on adjusting the ranking positions directly over initial retrieval results set $\mathbb{D}_{init}$.

Recently, there is a trend of exploring the hidden structure of documents to re-rank results. Some of the approaches represent the document entities as a connected graph G. It is usually constructed by links inferred from the content information as a nearest-neighbor graph. For example, Zhang et al. (2005) proposed an affinity ranking graph to re-rank search results by optimizing diversity and information richness. Kurland and Lee (2005) introduced a structural re-ranking approach by exploiting asymmetric relationships between documents induced by language models. Diaz (2005); Deng et al. (2009) use a family of semi-supervised machine learning methods among documents graph constructed by incorporating different evidences. However in this work we are more interested in adopting an automatic approach.

There are two important factors that should be taken into account when designing any re-ranking algorithms: the original queries and initial retrieval scores. One of issues is that previous structural re-ranking algorithms treat the query and the content individually when computing re-ranking scores. Each document is assigned a score independent of other documents without considering of queries. The problem we want to address in this paper is how we can leverage the interconnections between query and documents for the re-ranking purpose.

Another problem with such approaches concerns the fundamental re-ranking strategy they adopted. HITS (Kleinberg, 1999) and PageRank

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1571–1580, Singapore, 6-7 August 2009.

(Brin and Page, 1998) style algorithms were widely used in the past. However, approaches depend only on the structure of the global graph or sub-graph may ignore important information content of a document entity. As pointed out by Deng et al. (2009), re-ranking algorithms that rely only on the structure of the global graph are likely lead to the problem of topic drift.

Instead, we introduce a new document re-ranking method based on Latent Dirichlet Allocation (LDA) (Blei et al., 2003) which exploits implicit structure of the documents with respect to original queries. Rather than relying on graph-based techniques to identify the internal structure, the approach tries to directly model the latent structure of "topics" or "concepts" in the initial retrieval set. Then we can compute the distance between queries and initial retrieval results based on latent semantic information inferred. To prevent the problem of topic drift, the generative probability of a document is summed over all topics induced. By combining the initial retrieval scores calculated by language models, we are able to gather important information for re-ranking purposes. The intuition behind this method is the hidden structural information among the documents: *similar documents are likely to have the same hidden information with respect to a query*. In other words, if a group of documents are talking about the same topic which shares a strong similarity with a query, in our method they will get allocated similar ranking as they are more likely to be relevant to the query. In addition, the refined ranking scores should be relevant to the initial ranking scores, which, in our method, are combined together with the re-ranking score either using a linear fashion or multiplication process.

To illustrate the effectiveness of the proposed methodology, we apply the framework to ad-hoc document retrieval and compare it with the initial language model-based method and other three PageRank style re-ranking methods. Experimental results show that the improvement brought by our method is consistent and promising.

The rest of the paper is organized as follows. Related work on re-ranking algorithms and LDA based methods is briefly summarized in Section 2. Section 3 describes the re-ranking framework based on latent information induced together with details of how to build generative model. In Section 4 we report on a series of experiments performed over three different test collections in English and French as well as results obtained. Finally, Section 5 concludes the paper and speculates on future work.

2 Related Work

There exist several groups of related work in the areas of document retrieval and re-ranking.

The first category performs re-ranking by using inter-document relationship (Lee et al., 2001), evidences obtained from external resources (Kamps, 2004), or through local context analysis (Xu and Croft, 2000). In the past, document distances (Balinski and Daniowicz, 2005), manually built external thesaurus (Qu et al., 2001), and structural information (such as document title) (Luk and Wong, 2004), etc have been used extensively for this very purpose.

A second category of work is related to recent advances in structural re-ranking paradigm over graphs. Kurland and Lee performed re-ranking based on measures of centrality in the graph formed by generation links induced by language model scores, through a weighted version of PageRank algorithm (Kurland and Lee, 2005) and HITS-style cluster-based approach (Kurland and Lee, 2006). Zhang et al. (2005) proposed a similar method to improve web search based on a linear combination of results from text search and authority ranking. The graph, which they named affinity graph, shares strong similarities with Kurland and Lee's work with the links induced by a modified version of cosine similarity using the vector space model. Diaz (2005) used score regularization to adjust document retrieval rankings from an initial retrieval by a semi-supervised learning method. Deng et al. (2009) further developed this method. They built a latent space graph based on content and explicit links information. Unlike their approach we are trying to model the latent information directly.

This work is also related to a family of methods so called latent semantic analysis (LSA) (Landauer et al., 1998), especially topic models used for document representation. Latent Dirichlet Allocation (LDA), after it was first introduced by Blei et al. (2003), has quickly become one of the most popular probabilistic text modeling techniques and has inspired research ranging from text classification and clustering (Phan et al., 2008), information discovery (Mei et al., 2007; Titov and McDonald, 2008) to information retrieval (Wei and Croft, 2006). In this model, each topic is represented by a set of words and each word corresponds with a weight to measure its contribution to the topic. Wei and Croft

(2006) described large-scale information retrieval experiments by using LDA. In their work, LDA-based document model and language model-based document model were linearly combined to rank the entire corpus. However, unlike this approach we only apply LDA to a small set of documents. There are two reasons by doing so. One is the concern of computational cost. LDA is a very complex model and the complexity will grow linearly with the number of topics and the number of documents. Only running it through a document set significantly smaller than the whole corpus has obvious advantages. Secondly, it is well known that LSA-based method suffers from an incremental build problem. Normally adding new documents to the corpus needs to "be folded in" to the latent representation. Such incremental addition fails to capture the co-occurrences of the newly added documents (and even ignores all new terms they contain). As such, the quality of the LSA representation will degrade as more documents are added and will eventually require a re-computation of the LSA representation. Because our method only requires running LDA once for a small number of documents, this problems could be easily avoided. In addition, we also introduce two new measures to calculate the distance between a query and a document.

3 Latent Re-Ranking Framework

In this section, we describe a novel document re-ranking method based on extracting the latent structure among the initial retrieval set and measuring the distance between queries and documents.

3.1 Problem Definition

Let $\mathbb{D} = \{d_1, d_2, \dots, d_n\}$ denote the set of documents to be retrieved. Given a query q, a set of initial results $\mathbb{D}_{init} \in \mathbb{D}$ of top documents are returned by a standard information retrieval model (initial ranker). However, the initial ranker tends to be imperfect. The purpose of our re-ranking method is to re-order a set of documents $\mathbb{D}'_{init}$ so as to improve retrieval accuracy at the very top ranks of the final results.

3.2 Latent Dirichlet Allocation

We will first introduce Latent Dirichlet Allocation model which forms the basis of the re-ranking framework that will be detailed in the next subsection. It was previously shown that co-occurrence structure of terms in text documents can be used to recover some latent topic structures without any usage of background information (Landauer et al., 1998). This means that latent-topic representations of text allow modeling of linguistic phenomena such as synonymy and polysemy. By doing so, information retrieval systems can match the information needs with content items on a meaning level rather than by just lexical congruence.

The basic generative process of LDA closely resembles PLSA (Hofmann, 1999). LDA extends PLSA method by defining a complete generative model of text. The topic mixture is drawn from a conjugate Dirichlet prior that remains the same for all documents. The process of generating a document corpus is as follows:

1) Pick a multinomial distribution $\vec{\varphi}_z$ for each topic k from a Dirichlet distribution with hyperparameter $\vec{\beta}$.
2) For each document d, pick a multinomial distribution $\vec{\theta}_d$, from a Dirichlet distribution with hyperparameter $\vec{\alpha}$.
3) For each word token w in document d, pick a topic $z \in \{1 \dots k\}$ from the multinomial distribution $\vec{\theta}_d$.
4) Pick word w from the multinomial distribution $\vec{\varphi}_z$.

Thus, the likelihood of generating a corpus is:

$$p(d_1, \dots, d_n | \vec{\alpha}, \vec{\beta}) = \iint \prod_{d=1}^{n} p(\vec{\theta}_d | \vec{\alpha}) \cdot \prod_{z=1}^{k} p(\vec{\varphi}_z | \vec{\beta}) \cdot \prod_{i=1}^{N_d} \sum_{z_i=1}^{k} p(z_i | \vec{\theta}_d) p(w_i | z, \vec{\varphi}_z) \, d\vec{\theta}_d \, d\vec{\varphi}_z$$

Unlike PLSA model, LDA possesses fully consistent generative semantics by treating the topic mixture distribution as a k-parameter hidden random variable. LDA offers a new and interesting framework to model a set of documents. The documents and new text sequences (for example, queries) could be easily connected by "mapping" them to the topics in the corpus. In the next subsection we will introduce how to achieve this goal and apply it to document re-ranking.

LDA is a complex model and cannot be solved by exact inference. There are a few approximate inference techniques available in the literature: variational methods (Blei et al., 2003), expectation propagation (Griffiths and Steyvers, 2004)

and Gibbs sampling (Griffiths and Steyvers, 2004). Gibbs sampling is a special case of Markov-Chain Monte Carlo (MCMC) simulation and often yields relatively simple algorithms. For this reason, we choose to use Gibbs sampling to estimate LDA.

According to Gibbs sampling, we need to compute the conditional probability $p(z_i|\vec{z}_{\neg i}, \vec{w})$, where $\vec{w}$ denotes the vector of all words and $\vec{z}_{\neg i}$ denotes the vector of topic assignment except the considered word at position i. This probability distribution can be derived as:

$$p(z_i|\vec{z}_{\neg i}, \vec{w}) = \frac{n^{w_i}_{z,\neg i} + \beta_{w_i}}{(\sum_{v=1}^{V} n^{v}_{z} + \beta_v) - 1} \cdot \frac{n^{z}_{d_i,\neg i} + \alpha_k}{(\sum_{z=1}^{k} n^{z}_{d_i} + \alpha_z) - 1}$$

where $n^{t}_{z,\neg i}$ indicates the number of instances of word w_i assigned to topic $z = k$, not including the current token and $n^{z}_{d_i,\neg i}$ denotes the number of words in document d_i assigned to topic $z = k$, not including the current token.

Then we can obtain the multinomial parameter sets:

$$\theta_{d_i,k} = \frac{n^{k}_{d_i} + \alpha_k}{\sum_{z=1}^{k} n^{z}_{d_i} + \alpha_z}$$

$$\varphi_{k,w_i} = \frac{n^{w_i}_{k} + \beta_{w_i}}{\sum_{v=1}^{V} n^{v}_{z} + \beta_v}$$

The Gibbs sampling algorithm runs over three periods: initialization, burn-in and sampling. We do not tune to optimize these parameters because in our experiments the markov chain turns out to converge very quickly.

3.3 LDA-based Re-Ranking

Armed with this LDA methodology, we now describe the main idea of our re-ranking method. Given a set of initial results $\mathbb{D}_{init}$, we are trying to re-measure the distance between the query and a document. In the vector space model, this distance is normally the cosine or inner product measure between two vectors. Under the probabilistic model framework, this distance can be obtained from a non-commutative measure of the difference between two probability distributions. The distance used in our approach is the Kullback-Leibler (KL) divergence (Kullback and Leibler, 1951). Given two probability mass function $p(x)$ and $q(x)$, the KL divergence (or relative entropy) between p and q is defined as:

$$D(p||q) = \sum_{x} p(x) log \frac{p(x)}{q(x)}$$

In terms of text sequences (either queries or documents), the probability distribution can be regarded as a probabilistic language model M_d or M_q from each document d or each query q. In other words, it assumes that there is an underlying language model which "generates" a term (sequence) (Ponte and Croft, 1998). The unigram language model is utilized here. There are several ways to estimate the probabilities. Let $g(w \in d)$ denotes the number of times the term w occurs in a document d (same idea can be used on a query). The Maximum-likelihood estimation (MLE) of w with respect to d is defined as:

$$MLE_d w \stackrel{\text{def}}{=} \frac{g(w \in d)}{\sum_{w'} g(w' \in d)}$$

Previous work in language-model-based information retrieval (Zhai and Lafferty, 2004) advocates the use of a Dirichlet-smoothed estimation:

$$DIR_d w \stackrel{\text{def}}{=} \frac{g(w \in d) + \mu \cdot MLE_w \mathbb{D}}{\sum_{w'} g(w' \in d) + \mu}$$

where smoothing parameter μ controls the degree of reliance on relative frequencies in the document corpus rather than on the counts in d. The initial ranker that we choose to use later in the experiment computes the KL divergence between the $MLE_q w$ and a modified version of $DIR_d w$ (Zhai and Lafferty, 2001).

Both estimations can be easily extended to distributions over text sequences by assuming that the terms are independent:

$$MLE_d(w_1 w_2 \ldots w_n) \stackrel{\text{def}}{=} \prod_{j=1}^{n} MLE_d(w_j)$$

$$DIR_d(w_1 w_2 \ldots w_n) \stackrel{\text{def}}{=} \prod_{j=1}^{n} DIR_d(w_j)$$

In the re-ranking setting, we estimate that the probability of a document d generates w, using a mixture model LDA. It uses a convex combination of a set of component distributions to model observations. In this model, a word w is generated from a convex combination of some hidden topics z:

$$LDA_d(w) = \sum_{z=1}^{k} p(w|z) p(z|d)$$

where each mixture model $p(w|z)$ is a multinomial distribution over terms that correspond to one of the latent topics z. Similar to MLE and DIR estimations, this could be generated to give a distribution on a sequence of text:

Collection	Contents	Language	Num of docs	Size	Queries
BL (CLEF2008)	British Library Data	English (Main)	1,000,100	1.2 GB	50
BNF (CLEF2008)	Bibliothèque Nationale de France	French (Main)	1,000,100	1.3 GB	50
LAT (CLEF2007)	Los Angeles Times 2002	English	135,153	434 MB	50

Table 1. Statistics of test collections

$$LDA_d(w_1 w_2 \dots w_n) \stackrel{\text{def}}{=} \prod_{j=1}^{n} LDA_d(w_j)$$

Then the distance between a query and a document based on this model can be obtained. The first method we propose here adopts the KL divergence between the query terms and document terms to compute a Re-Rank score RS_{LDA}^{KL1}:

$$RS_{LDA}^{KL1} = -D(MLE_q(\cdot)||LDA_d(\cdot))$$

This method also has the property of length-normalization to ameliorate long document bias problems (Kurland and Lee, 2005).

The second method also measures a KL divergence between a query and a document, however, in a different way. As in the original LDA model, the multinomial parameter $\vec{\theta}_d$ indicates the topic distribution of a document d. Query q can be considered as topic estimation of a unknown document $\tilde{\vec{w}}$. Thus by first randomly assigning topics to words and then performing a number of loops through the Gibbs sampling update, we have:

$$p(z_i|\tilde{\vec{z}}_{\neg i}, \tilde{\vec{w}}; \vec{z}_{\neg i}, \vec{w}) = \frac{n_{z,\neg i}^{w_i} + \tilde{n}_{z,\neg i}^{w_i} + \beta_{w_i}}{(\sum_{v=1}^{V} n_z^v + \tilde{n}_z^v + \beta_v) - 1} \cdot \frac{n_{\tilde{d}_i,\neg i}^{z} + \alpha_k}{(\sum_{z=1}^{k} n_{\tilde{d}_i}^z + \alpha_z) - 1}$$

where $\tilde{n}_{z,\neg i}^{w_i}$ counts the observations of word w_i and topic k in unseen document. Then the topic distribution for the query (just the unseen document $\tilde{d}_i$) is:

$$\tilde{\theta}_{\tilde{d}_i,k} = \frac{n_{\tilde{d}_i}^k + \alpha_k}{\sum_{z=1}^{k} n_{\tilde{d}_i}^z + \alpha_z}$$

so that the distance between a query q and a document d is defined as the KL divergence between the topic distributions of q and d. Then the re-ranking score is calculated as:

$$RS_{LDA}^{KL2} = -D(\vec{\theta}_q||\vec{\theta}_d)$$

Thus we can re-rank the initial retrieved documents according to the scores acquired. However, as in other topic models, a topic in the LDA model represents a combination of words, and it may not be as precise a representation as words in language model. Hence we need to further consider how to combine initial retrieval scores with the re-ranking scores calculated. Two combination methods will be presented in the next subsection.

3.4 Combining Initial Retrieval Scores

Motivated by the significant improvement obtained by (Wei and Croft, 2006) and (Zhang et al., 2005), we formulate our method through a linear combination of the re-ranking scores based on initial ranker and the latent document re-ranker, shown as follow:

$$RS1 = (1-\lambda) \cdot OS + \lambda \cdot RS_{LDA}^{KL};$$

where OS denotes original scores returned by the initial ranker and λ is a parameter that can be tuned with $\lambda = 0$ meaning no re-ranking is performed.

Another scheme considers a multiplication combination to incorporate the original score. It does not need to tune any parameters:

$$RS2 = OS \cdot RS_{LDA}^{KL};$$

This concludes our overview of the proposed latent re-ranking method.

4 Evaluation

In this section, we will empirically study the effectiveness of the latent document re-ranking method over three different data collections.

4.1 Experimental Setup

Data The text corpus used in our experiment was made up from elements of the CLEF-2007 and CLEF-2008 the European Library (TEL) collections[1] written in English and French. These collections are described in greater detail in Table 1. All of the documents in the experiment were indexed using the Lemur toolkit[2]. Prior to

[1] http://www.clef-campaign.org
[2] http://www.lemurproject.org

indexing, Porter's stemmer and a stopword list[3] were used for the English documents. We use a French analyzer[4] to analyze French documents.

It is worth noting that the CLEF-2008 TEL data is actually multilingual: all collections to a greater or lesser extent contain records pointing to documents in other languages. However this is not a major problem because the majority of documents in the test collection are written in main languages of those test collections (BL-English, BNF-French). Furthermore, documents written in different languages tend not to match the queries in main languages. Also the data is very different from the newspaper articles and news agency dispatches previously used in the CLEF as well as TREC[5]. The data tends to be very sparse. Many records contain only title, author and subject heading information; other records provide more detail. The average document lengths are 14.66 for BL and 24.19 for BNF collections after pre-processing, respectively. Please refer to (Agirre et al., 2008) for a more detailed discussion about this data. The reason we choose these data collections is that we wanted to test the scalability of the proposed method in different settings and over different guages. In addition we also select a more tional collection (LAT from CLEF2007) as a test base.

We also used the CLEF-2007 and CLEF-2008 query sets. The query sets consist of 50 topics in English for LAT, BL and in French for BNF, all of which were used in the experiment. Each topic is composed of several parts such as: *Title*, *Description*, *Narrative*. We chose to conduct *Title+Description* runs as queries. The queries are processed similarly to the treatment in the test collections. The relevance judgments are taken from the judged pool of top retrieved documents by various participating retrieval systems from previous CLEF workshops.

We compare the proposed latent re-ranking method with four other approaches: the initial ranker, mentioned above, is a KL-divergence retrieval function using the language models. Three other baseline systems are: Kurland and Lee's structural re-ranking approach (Recursive Weighted Influx + Language Model), chosen as it demonstrates the best performance in their paper (Kurland and Lee, 2005), Zhang et al.'s affinity graph-based approach (Zhang et al., 2005) and a variant of Kurland and Lee's work with links in the graph calculated by the vector-space model (cosine similarity as mentioned in (Kurland and Lee, 2005)). We denote these four systems as InR, RWILM, AFF, and VEC respectively. Furthermore, we denote the permutations of our methods as follows: LDA1: $RS2\ with\ RS_{LDA}^{KL1}$, LDA2: $RS1\ with\ RS_{LDA}^{KL1}$, LDA3: $RS2\ with\ RS_{LDA}^{KL2}$, LDA4: $RS1\ with\ RS_{LDA}^{KL2}$.

Because the inconsistency of the evaluation metrics employed in the past work, we choose to employ all of them to measure the effectiveness of various approaches. These include: mean average precision (MAP), the precision of the top 5 documents (Prec@5), the precision of the top 10 documents (Prec@10), normalized discounted cumulative gain (NDCG) (Jarvelin and Kekalainen, 2002) and Bpref (Buckley and Voorhees, 2004). Statistical-significant differences in performance were determined using a paired t-test at a confidence level of 95%.

It is worth pointing out that the above measurements are not directly comparable with those of the CLEF participants because we restricted our initial pool to a smaller number of documents and the main purpose in the paper is to compare the proposed method with different baseline systems.

Parameter Two primary parameters need to be determined in our experiments. For the re-ranking experiments, the combination parameter λ must be defined. For the LDA estimation, the number of topics k must be specified. We optimized settings for these parameters with respect to MAP, not with all other metrics over the BL collection and apply them to all three collections directly.

The search ranges for these two parameters were:

λ : 0.1, 0.2, …, 0.9
k : 5, 10, 15, …, 45

As it turned out, for many instances, the optimal value of λ with respect to MAP was either 0.1 or 0.2, suggesting the initial retrieval scores have valuable information inside them. In contrast, the optimal value of k was between 20 and 40. Although this demonstrates a relatively large variance, the differences in terms of MAP have remained small and statistically insignificant. We set $\mathbb{D}_{init}$ to 50 in all results reported, as in Kurland and Lee's paper (Kurland and Lee, 2005) and we later show that the performance turns out to be very stable when this set enlarged.

Table 2. Experimental Results. For each evaluation setting, improvements over the RWILM baseline are given in italics (because it has highest performance); statistically significant differences between our methods and InR, RWILM, AFF, VEC are indicated by o, l, a, v, respectively. Bold highlights the best results over all algorithms.

Lastly, the parameters in the baseline systems are set according to the tuning procedures in their original papers[6].

[6] More specifically, the combination parameter was set to 0.5 for AFF, the number of links was set to 4 for RWILM.

4.2 Results

Primary Evaluation The main experimental results are presented in Table 2. The first four rows in each collection specify reference-comparison data. The first question we are interested in is how our latent re-ranking methods

perform (taken as a whole). It is shown that our methods bring improvements upon the various baselines in 75% of the 48 relevant comparisons (4 latent re-ranking methods × 4 corpora × 4 baselines). Only the algorithm permutation LDA3 performs less well. Furthermore, our methods are able to achieve the highest performance across all the evaluation metrics over three test collections except in one case (MAP in BL collection). An even more exciting observation is that in many cases, our methods, even though tuned for MAP, can outperform various baselines for all the evaluation metrics, with statistically significant improvements in many runs.

A closer examination of the results in Table 2 reveals some interesting properties. As expected, the RWILM method bought improvements in many cases in CLEF-2008 test collections. However, the performance over CLEF-2007 collection was somewhat disappointing. This seems to indicate that the language model induced graph method tends to perform better in sparse data rather than longer documents. Also Language Modeling requires large set training data to be effective, while the complexity of our method is only linear with number of topics and the number of documents for each iteration. The affinity and vector graph based methods demonstrated poor performance across all the collections. This may be due to the fact that the approach Zhang et al. (Zhang et al., 2005) developed focuses more on diversity and information richness and cares less about the precision of the retrieval results while asymmetric graph as constructed by the vector space model fails in capturing important relationship between the documents.

Another observation we can draw from Table 2 is that the relative performance tends to be stable during test collections written in different languages. This shows a promising future for studying structure of the documents with respect to queries for re-ranking purpose. At the same time, efficiency is always an issue in all re-ranking methods. Although this is not a primary concern in the current work, it would definitely worth thinking in the future.

We also conducted some experiments over queries constructed by using *Title* field only. This forms some more realistic short queries. The experiments showed very similar results compared to longer queries. This demonstrates that the query length is a trivial issue in our methods (as in other graph-based structural re-ranking). We examined the best and worse performed queries, their performance are generally consistent across all the methods. This phenomenon should be investigated further in the follow up evaluation.

Comparison of Different Methods In comparison of performance between four permutations of our methods, LDA2 is the clear winner over CLEF-2008 test collections. The results obtained by LDA2 and LDA4 over CLEF-2007 test collection were mixed. LDA2 performed better in precision at top n documents while LDA4 showed promising results in terms of more general evaluation metrics. On the other hand, the linear combination approach performed much better than multiplication based combination. The situation is even worse when we adopted the RS_{LDA}^{KL2} method, which was inferior in several cases. Thus the linear combination should be highly recommended.

Scalability We have shown that our latent document re-ranking method is successful at accomplishing the goal of improving the results returned by an initial retrieval engine. But one may raise a question of whether it is necessary to restrict our attention to an initial pool $\mathbb{D}_{init}$ at such a small size. As it happens, preliminary experiments with LDA2 on larger size of the initial pool are presented in Figure 1. As we can see, our method can bring consistently stable improvements.

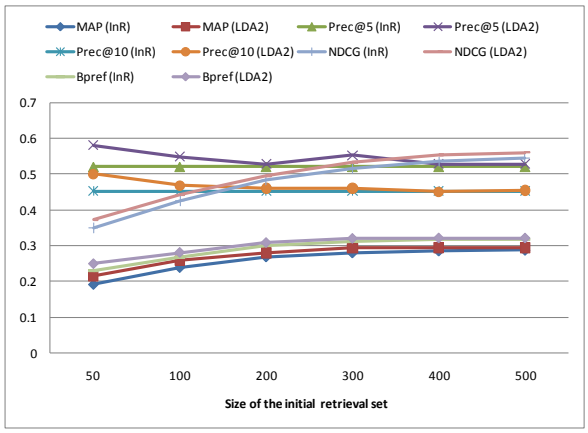

Figure 1. Experiments with larger initial pools

5 Conclusion and Future Work

In this paper we proposed and evaluated a latent document re-ranking method for re-ordering the initial retrieval results. The key to refine the results is finding the latent structure of "topics" or "concepts" in the document set, which leve-

rages the latent Dirichlet allocation technique for the query-dependent ranking problem and results in state-of-art performance.

There are many research directions we are planning to investigate. It has been shown that LDA-based retrieval is a promising method for ranking the whole corpus. There is a desire to call for a direct comparison between ranking and re-ranking using the proposed algorithmic variations. Future work will also include the comparison between our methods with other related approaches, such as Kurland and Lee's cluster-based approach (Kurland and Lee, 2006).

There exist a sufficient number of latent semantic techniques such as singular vector decomposition, non-negative matrix factorization, PLSA, etc. We are planning to explore these methods to compare their performance. Also direct re-ranking can be used to improve automatic query expansion since better ranking in top retrieved documents can be expected to improve the quality of the augmented query. We believe this is another fruitful line for future research.
