ACL 2007

Proceedings of the 45th Annual Meeting of the Association for Computational Linguistics

June 23–30, 2007
Prague, Czech Republic

The Association for Computational Linguistics

It is with great sadness that we record the death on 4 April 2007 of Karen Spärck Jones, who among many other honors and awards, was the President of ACL in 1994 and recipient of the ACL Lifetime Achievement Award in 2004.

These proceedings are dedicated to her memory.

Table of Contents

Preface: General Chair

On behalf of the organizing committee I am delighted to welcome you to the 45th Annual Meeting of the Association for Computational Linguistics, in Prague.

Setting up and running the ACL conference involves a lot of work by many people. Some of them are officially identified as being responsible for various aspects of the conference, while the contributions of others are less visible. I would like to say a warm thank you to the people named below, with apologies to anyone I have overlooked.

The Program Chairs, **Antal van den Bosch** and **Annie Zaenen** have done a great job in managing the almost 600 submissions for the main conference and putting together a high quality program. Through this process Antal has become a 'grandmaster' of the START paper management system and has given a lot of help to other chairs who have had to deal with their own sets of submissions. Many thanks also to their Area Chairs and the program committee of reviewers, and to **Florence Reeder** for coordinating the pre-submission mentoring service. (Antal and Annie reflect on their PC experience overleaf).

Sophia Ananiadou is Chair of the Demo/Poster part of the conference, and has overseen a separate review process to select a high quality set of presentations.

The Student Research Workshop Chairs, **Chris Biemann**, **Violeta Seretan** and **Ellen Riloff** have assembled an excellent program of papers and posters. I encourage everyone to attend the student workshop to hear about the exciting work being carried out by researchers just starting out on their careers in computational linguistics.

Workshops Chair **Simone Teufel** is overseeing 15 workshops – the most ever at an ACL conference – chosen (with the help of **Beth Ann Hockey**, **Katja Markert** and **Dekai Wu**) from a total of 27 proposals. The scale of the workshop program can be gauged by the fact that they received an aggregate total of 470 submissions (without even counting IWPT and EMNLP-CoNLL). **Joakim Nivre**, as Tutorials Chair, has assembled a program of 5 attractive and complementary tutorials, selected from 20 proposals with advice from **Walter Daelemans**, **Robert Dale**, **Nancy Ide**, **Diane Litman** and **Chris Manning**.

One of the most demanding yet least noticed organizational roles is that of Publications Chair. **Su Jian** has done a fantastic job in producing the hardcopy and electronic record of the conference, supported by his team—with notable contributions from **Upali Kohomban** who has cheerfully helped at all stages and whenever needed, day and night, weekdays and weekends.

Sponsorship is another success story, thanks to the Sponsorship Chairs **Martha Palmer**, **Gabor Proszeky**, **Jan Hajic** and **Jun'ichi Tsujii**, who have recruited 12 corporate sponsors. We are very grateful for their financial support.

Eva Hajicova, the Local Arrangements Chair, assisted by **Jan Hajic** and **Anna Kotesovcova**, have put in an enormous amount of detailed work to make this conference a success, ably supported by the local team of **Milan Fucik**, **Jaroslava Hlavacova**, **Marketa Lopatkova**, **Jiri Mirovsky**, **Pavel Pecina**,

Pavel Schlesinger, **Juraj Simlovic**, **Miroslav Spousta**, **Pavel Stranak**, **Zlatka Subrova**, **Jan Votrubec**, **Zdenek Zabokrtsky** and **Daniel Zeman**. From the ACL itself, **Kathy McCoy**, **Dragomir Radev**, **Priscilla Rasmussen**, **Mark Steedman** and **Jun'ichi Tsujii** have played strong roles in making decisions and giving advice, and kept everything on track while I was out of action due to ill health last year.

And finally, many thanks to the authors and presenters in the main conference, workshops and co-located events... and to all the participants. I hope you enjoy the formally organized aspects of the conference, take advantage of the opportunity to network with colleagues old and new, and that you also have a chance to appreciate the history and sights of Prague while you are here.

John Carroll
ACL 2007 General Chair

Preface: Program Chairs

The number of submissions for this ACL broke a new record: the program committee's selection of 131 papers was based on 588 submissions (after withdrawals). An updated program design with four parallel sessions and 25-minute papers allowed an acceptance rate of 22.3%, and an acceptance of all submissions that were recommended with priority by the area chairs.

First and foremost, we thank all the authors for submitting papers describing their recent work; the sheer amount of submissions reflects how active our field is. We thank **Florence Reeder** for provided mentoring to 17 author teams who felt they needed some writing support. For the selection, we are indebted to the 332 program committee members, who produced one to eleven reviews per reviewer, for a total of close to 1,800 reviews, and to the ten area chairs on whose shoulders rested most of the work of organizing the review process. We decided to work without an area chairs meeting: the two program co-chairs met for two days at Tilburg University, and interacted during that time vigorously with the area chairs by email and sometimes by phone.

As usual the main program will run for three days: there will be four parallel sessions of main session presentations, a demo/poster session organized by **Sophia Ananiadou**, nameMiroslav Spousta and **Zdenek Zabokrtsky**, and a Student Research Workshop – thanks to **Ellen Riloff**, **Violeta Seretan** and **Chris Biemann** for organizing it. Also as usual the conference is flanked by tutorial sessions and workshops; our thanks go to **Joakim Nivre** and **Simone Teufel** for organizing and compiling an excellent package.

The announcements of the ACL Lifetime Award and of the Best Paper Award will provide the customary suspense. They will take place in plenary sessions. Other plenary sessions will be devoted to the business meeting and the two invited talks, which this year will be delivered by **Tom Mitchell** and **Barney Pell**. We are grateful for their kind acceptation of our invitation.

We thank **John Carroll**, General Conference Chair, the Local Arrangements Committee headed by **Eva Hajicova**, and the ACL executive, especially **Dragomir Radev**, for their help and advice, and last year's co-chairs, **Claire Cardie** and **Pierre Isabelle**, for sharing their experience. Our sincere thanks go to **Su Jian** for putting together the proceedings.

Enjoy the conference,

Antal van den Bosch and Annie Zaenen
ACL-2007 Program Chairs

Organizers

General Chair:

John Carroll, University of Sussex, UK

Local Arrangements Chair:

Eva Hajicova, Charles University, Czech Republic

Program Chairs:

Antal van den Bosch, Tilburg University, The Netherlands
Annie Zaenen, Palo Alto Research Center (PARC), USA

Student Research Workshop:

Violeta Seretan, University of Geneva, Switzerland
Chris Biemann, University of Leipzig, Germany
Ellen Riloff (Faculty Advisor), University of Utah, USA

Workshop Chair:

Simone Teufel, University of Cambridge, UK

Tutorial Chair:

Joakim Nivre, Växjö University, Sweden

Demo/Poster Chair:

Sophia Ananiadou, The University of Manchester, UK

Exhibits Chairs:

Jaroslava Hlavacova, Charles University, Czech Republic
Pavel Pecina, Charles University, Czech Republic

Sponsorship Chairs:

Martha Palmer, University of Colorado, USA
Gabor Proszeky, Morphologic, Hungary
Jan Hajic, Charles University, Czech Republic
Jun'ichi Tsujii, University of Tokyo, Japan

Publicity Chairs:

Pavel Stranak, Charles University, Czech Republic
Jiri Mirovsky, Charles University, Czech Republic

Publication Chair:

Su Jian, Institute for Infocomm Research (I2R), Singapore

Mentoring Service:

Florence Reeder, The MITRE Corporation, USA

Student Volunteers:

Marketa Lopatkova, Charles University, Czech Republic

Webmasters:

Zlatka Subrova, Czech Republic
Juraj Simlovic, Czech Republic

Secretariat:

Anna Kotesovcova, Charles University, Czech Republic

Registration:

Priscilla Rasmussen, Association for Computational Linguistics (ACL)

ACL Executive Committee:

Mark Steedman, University of Edinburgh, UK
Bonnie Dorr, University of Maryland, USA
Steven Bird, University of Melbourne, Australia
Jun'ichi Tsujii, The University of Tokyo, Japan
Kathleen F. McCoy, University of Delaware, USA
Dragomir R. Radev, University of Michigan, USA
Owen Rambow, Columbia University, USA
Alex Lascarides, University of Edinburgh, UK
Keh-Yih Su, Behavior Design Corporation, Taiwan
Claire Cardie, Cornell University, USA
Nicoletta Calzolari, Istituto di Linguistica Computazionale del CNR, Italy

Program Committee

Program Chairs:

Antal van den Bosch, Tilburg University, The Netherlands
Annie Zaenen, Palo Alto Research Center, USA

Area Chairs:

Tim Baldwin, University of Melbourne, Australia
Kees van Deemter, University of Aberdeen, UK
Barbara Di Eugenio, University of Illinois at Chicago, USA
Josef van Genabith, Dublin City University, Ireland
Claire Grover, University of Edinburgh, UK
Diana McCarthy, University of Sussex, UK
Dan Roth, University of Illinois at Urbana-Champaign, USA
Richard Sproat, University of Illinois at Urbana-Champaign, USA
Marc Swerts, Tilburg University, The Netherlands
Andy Way, Dublin City University, Ireland

Program Committee Members:

Takeshi Abekawa, Eneko Agirre, Gregory Aist, Cyril Allauzen, Elisabeth André, Shlomo Argamon, Ron Artstein,

Collin Baker, Srinivas Bangalore, Colin Bannard, Regina Barzilay, Roberto Basili, John Bateman, Kenneth Beesley, Anja Belz, Slaven Bilac, Steven Bird, Guido Boella, Francis Bond, Kalina Bontcheva, Johan Bos, Gosse Bouma, Susan Brennan, Chris Brew, Ted Briscoe, Ralf Brown, Paul Buitelaar, Razvan Bunescu, Harry Bunt,

Aoife Cahill, Janet Cahn, Mary Elaine Califf, Charles Callaway, Chris Callison-Burch, Nicoletta Calzolari, Giuseppe Carenini, Michael Carl, Jean Carletta, Xavier Carreras, Justine Cassell, Joyce Chai, Jing-Shin Chang, Ming-Wei Chang, Jinying Chen, Keh-Jiann Chen, Colin Cherry, David Chiang, Grzegorz Chrupala, Jennifer Chu-Carroll, Ilyas Cicekli, Philipp Cimiano, Stephen Clark, Michael Collins, Michael Connor, Mark Core, Mathias Creutz, James Curran,

Walter Daelemans, Ido Dagan, Hercules Dalianis, Hal Daume, Eric de la Clergerie, Maarten de Rijke, Barbara Di Eugenio, Mona Diab, Gael Diaz, Bonnie Dorr, Laila Dybkjær,

Jason Eisner, Noemie Elhadad, Katrin Erk, Dominique Estival, Stefan Evert,

David Farwell, Afsaneh Fazly, Marcello Federico, Katja Filippova, Kate Forbes Riley, Mikel Forcada, George Foster, Mary Ellen Foster, Anette Frank, Reva Freedman, Guohong Fu, Pascale Fung,

Rob Gaizauskas, Jianfeng Gao, Kallirroi Georgila, Daniel Gildea, Roxana Girju, Alfio Gliozzo, Sharon Goldwater, Fernando Gomez, Nancy Green, Mark Greenwood, Ralph Grishman, Declan Groves,

Nizar Habash, Keith Hall, Susan Haller, Sanda Harabagiu, Henk Harkema, Tony Hartley, Sven Hartrumpf, Mary Hearne, Marti Hearst, Peter Heeman, James Henderson, Mark Hepple, Ryuichiro Higashinaka, Julia Hirschberg, Graeme Hirst, Barbora Hladka, Julia Hockenmaier, Deirdre Hogan, Baden Hughes,

Diana Inkpen, Kentaro Inui,

Martin Jansche, Valentin Jijkoun, Mark Johnson, Kristiina Jokinen, Pamela Jordan,

Laura Kallmeyer, Stephan Kanthak, Vangelis Karkaletsis, Daisuke Kawahara, John Kelleher, Frank Keller, Andre Kempe, Rodger Kibble, Adam Kilgarriff, Tracy King, Ewan Klein, Alexandre Klementiev, Kevin Knight, Alistair Knott, Philipp Koehn, Rob Koeling, Alexander Koller, Grzegorz Kondrak, Moshe Koppel, Valia Kordoni, Anna Korhonen, Emiel Krahmer, Sandra Kuebler, Jonas Kuhn, Sadao Kurohashi,

Philippe Langlais, Guy Lapalme, Mirella Lapata, Staffan Larsson, Alberto Lavelli, Alon Lavie, Lillian Lee, Jochen Leidner, Oliver Lemon, Yves Lepage, Leonardo Lesmo, Gina Levow, Ian Lewin, William Lewis, Mu Li, Dekang Lin, Jimmy Lin, Diane Litman, Ting Liu, Saturnino Luz,

Bernardo Magnini, Gideon Mann, Chris Manning, Daniel Marcu, Katja Markert, Lluis Marquez, Erwin Marsi, David Martinez, Carlos Martin-Vide, Evgeny Matusov, John Maxwell, Mike Maxwell, Diana Maynard, Andrew McCallum, Ryan McDonald, Kathy McKeown, Susan McRoy, Mike McTear, Dan Melamed, Chris Mellish, Arul Menezes, Helen Meng, Paola Merlo, Detmar Meurers, Rada Mihalcea, Maria Milosavljevic, Eleni Miltsakaki, David Milward, Yusuke Miyao, Dan Moldovan, Diego Molla, Raymond Mooney, Roger Moore, Alessandro Moschitti, Karin Mueller, Reinhard Muskens,

Conference Program

Monday, June 25, 2007

8:45–9:00 Opening Session

9:00–10:00 Invited Talk by Tom Mitchell

10:00–10:30 Break

Session 1A: Machine Translation 1

10:30–10:55 *Guiding Statistical Word Alignment Models With Prior Knowledge*
Yonggang Deng and Yuqing Gao

10:55–11:20 *A Discriminative Syntactic Word Order Model for Machine Translation*
Pi-Chuan Chang and Kristina Toutanova

11:20–11:45 *Tailoring Word Alignments to Syntactic Machine Translation*
John DeNero and Dan Klein

11:45–12:10 *Transductive Learning for Statistical Machine Translation*
Nicola Ueffing, Gholamreza Haffari and Anoop Sarkar

Session 1B: Word Sense Disambiguation

10:30–10:55 *Word Sense Disambiguation Improves Statistical Machine Translation*
Yee Seng Chan, Hwee Tou Ng and David Chiang

10:55–11:20 *Learning Expressive Models for Word Sense Disambiguation*
Lucia Specia, Mark Stevenson and Maria das Graças Volpe Nunes

11:20–11:45 *Domain Adaptation with Active Learning for Word Sense Disambiguation*
Yee Seng Chan and Hwee Tou Ng

11:45–12:10 *Making Lexical Ontologies Functional and Context-Sensitive*
Tony Veale and Yanfen Hao

Monday, June 25, 2007 (continued)

Session 1C: Language Modeling 1

10:30–10:55 *A Bayesian Model for Discovering Typological Implications*
Hal Daumé III and Lyle Campbell

10:55–11:20 *A Discriminative Language Model with Pseudo-negative Samples*
Daisuke Okanohara and Jun'ichi Tsujii

11:20–11:45 *Detecting Erroneous Sentences using Automatically Mined Sequential Patterns*
Guihua Sun, Xiaohua Liu, Gao Cong, Ming Zhou, Zhongyang Xiong, John Lee and Chin-Yew Lin

11:45–12:10 *Vocabulary Decomposition for Estonian Open Vocabulary Speech Recognition*
Antti Puurula and Mikko Kurimo

Session 1D: Phonology and Morphology 1

10:30–10:55 *Phonological Constraints and Morphological Preprocessing for Grapheme-to-Phoneme Conversion*
Vera Demberg, Helmut Schmid and Gregor Möhler

10:55–11:20 *Redundancy Ratio: An Invariant Property of the Consonant Inventories of the World's Languages*
Animesh Mukherjee, Monojit Choudhury, Anupam Basu and Niloy Ganguly

11:20–11:45 *Multilingual Transliteration Using Feature based Phonetic Method*
Su-Youn Yoon, Kyoung-Young Kim and Richard Sproat

11:45–12:10 *Semantic Transliteration of Personal Names*
Haizhou Li, Khe Chai Sim, Jin-Shea Kuo and Minghui Dong

12:10–13:30 Lunch

Session 2A: Machine Translation 2

13:30–13:55 *Generating Complex Morphology for Machine Translation*
Einat Minkov, Kristina Toutanova and Hisami Suzuki

13:55–14:20 *Assisting Translators in Indirect Lexical Transfer*
Bogdan Babych, Anthony Hartley, Serge Sharoff and Olga Mudraya

Monday, June 25, 2007 (continued)

14:20–14:45 *Forest Rescoring: Faster Decoding with Integrated Language Models*
Liang Huang and David Chiang

14:45–15:10 *Statistical Machine Translation through Global Lexical Selection and Sentence Reconstruction*
Srinivas Bangalore, Patrick Haffner and Stephan Kanthak

Session 2B: Grammars

13:30–13:55 *Mildly Context-Sensitive Dependency Languages*
Marco Kuhlmann and Mathias Möhl

13:55–14:20 *Transforming Projective Bilexical Dependency Grammars into Efficiently-parsable CFGs with Unfold-Fold*
Mark Johnson

14:20–14:45 *Parsing and Generation as Datalog Queries*
Makoto Kanazawa

14:45–15:10 *Optimizing Grammars for Minimum Dependency Length*
Daniel Gildea and David Temperley

Session 2C: Semantic Role Labeling

13:30–13:55 *Generalizing Semantic Role Annotations Across Syntactically Similar Verbs*
Andrew Gordon and Reid Swanson

13:55–14:20 *A Grammar-driven Convolution Tree Kernel for Semantic Role Classification*
Min Zhang, Wanxiang Che, Aiti Aw, Chew Lim Tan, Guodong Zhou, Ting Liu and Sheng Li

14:20–14:45 *Learning Predictive Structures for Semantic Role Labeling of NomBank*
Chang Liu and Hwee Tou Ng

14:45–15:10 *A Simple, Similarity-based Model for Selectional Preferences*
Katrin Erk

Monday, June 25, 2007 (continued)

Session 2D: Language Resources

13:30–13:55 *SVM Model Tampering and Anchored Learning: A Case Study in Hebrew NP Chunking*
Yoav Goldberg and Michael Elhadad

13:55–14:20 *Fully Unsupervised Discovery of Concept-Specific Relationships by Web Mining*
Dmitry Davidov, Ari Rappoport and Moshe Koppel

14:20–14:45 *Adding Noun Phrase Structure to the Penn Treebank*
David Vadas and James Curran

14:45–15:10 *Formalism-Independent Parser Evaluation with CCG and DepBank*
Stephen Clark and James Curran

15:10–15:45 Break

Session 3A, Machine Learning Methods 1

15:45–16:10 *Frustratingly Easy Domain Adaptation*
Hal Daumé III

16:10–16:35 *Instance Weighting for Domain Adaptation in NLP*
Jing Jiang and ChengXiang Zhai

16:35–17:00 *The Infinite Tree*
Jenny Rose Finkel, Trond Grenager and Christopher D. Manning

17:00–17:25 *Guiding Semi-Supervision with Constraint-Driven Learning*
Ming-Wei Chang, Lev Ratinov and Dan Roth

Session 3B: Machine Translation 3

15:45–16:10 *Supertagged Phrase-Based Statistical Machine Translation*
Hany Hassan, Khalil Sima'an and Andy Way

16:10–16:35 *Regression for Sentence-Level MT Evaluation with Pseudo References*
Joshua S. Albrecht and Rebecca Hwa

16:35–17:00 *Bootstrapping Word Alignment via Word Packing*
Yanjun Ma, Nicolas Stroppa and Andy Way

17:00–17:25 *Improved Word-Level System Combination for Machine Translation*
Antti-Veikko Rosti, Spyros Matsoukas and Richard Schwartz

Monday, June 25, 2007 (continued)

Session 3C: Generation

15:45–16:10 *Generating Constituent Order in German Clauses*
Katja Filippova and Michael Strube

16:10–16:35 *A Symbolic Approach to Near-Deterministic Surface Realisation using Tree Adjoining Grammar*
Claire Gardent and Eric Kow

16:35–17:00 *Sentence Generation as a Planning Problem*
Alexander Koller and Matthew Stone

17:00–17:25 *GLEU: Automatic Evaluation of Sentence-Level Fluency*
Andrew Mutton, Mark Dras, Stephen Wan and Robert Dale

Session 3D: Multimodality 1

15:45–16:10 *Conditional Modality Fusion for Coreference Resolution*
Jacob Eisenstein and Randall Davis

16:10–16:35 *The Utility of a Graphical Representation of Discourse Structure in Spoken Dialogue Systems*
Mihai Rotaru and Diane Litman

16:35–17:00 *Automated Vocabulary Acquisition and Interpretation in Multimodal Conversational Systems*
Yi Liu, Joyce Chai and Rong Jin

17:00–17:25 *A Multimodal Interface for Access to Content in the Home*
Michael Johnston, Luis Fernando D'Haro, Michelle Levine and Bernard Renger

Tuesday, June 26, 2007

Session 4A, Parsing 1

09:00–09:25 *Fast Unsupervised Incremental Parsing*
Yoav Seginer

09:25–09:50 *K-best Spanning Tree Parsing*
Keith Hall

09:50–10:15 *Is the End of Supervised Parsing in Sight?*
Rens Bod

10:15–10:40 *An Ensemble Method for Selection of High Quality Parses*
Roi Reichart and Ari Rappoport

Session 4B: Sentiment 1

09:00–09:25 *Opinion Mining using Econometrics: A Case Study on Reputation Systems*
Anindya Ghose, Panagiotis Ipeirotis and Arun Sundararajan

09:25–09:50 *PageRanking WordNet Synsets: An Application to Opinion Mining*
Andrea Esuli and Fabrizio Sebastiani

09:50–10:15 *Structured Models for Fine-to-Coarse Sentiment Analysis*
Ryan McDonald, Kerry Hannan, Tyler Neylon, Mike Wells and Jeff Reynar

10:15–10:40 *Biographies, Bollywood, Boom-boxes and Blenders: Domain Adaptation for Sentiment Classification*
John Blitzer, Mark Dredze and Fernando Pereira

Session 4C: Paraphrasing, Textual Entailment

09:00–09:25 *Clustering Clauses for High-Level Relation Detection: An Information-theoretic Approach*
Samuel Brody

09:25–09:50 *Instance-based Evaluation of Entailment Rule Acquisition*
Idan Szpektor, Eyal Shnarch and Ido Dagan

09:50–10:15 *Statistical Machine Translation for Query Expansion in Answer Retrieval*
Stefan Riezler, Alexander Vasserman, Ioannis Tsochantaridis, Vibhu Mittal and Yi Liu

10:15–10:40 *A Computational Model of Text Reuse in Ancient Literary Texts*
John Lee

Tuesday, June 26, 2007 (continued)

Session 4D: Discourse and Dialog 1

09:00–09:25 *Finding Document Topics for Improving Topic Segmentation*
Olivier Ferret

09:25–09:50 *The Utility of Parse-derived Features for Automatic Discourse Segmentation*
Seeger Fisher and Brian Roark

09:50–10:15 *PERSONAGE: Personality Generation for Dialogue*
François Mairesse and Marilyn Walker

10:15–10:40 *Making Sense of Sound: Unsupervised Topic Segmentation over Acoustic Input*
Igor Malioutov, Alex Park, Regina Barzilay and James Glass

10:40–11:10 Break

11:10-12:10 LifeTime Achievement Award

12:10–13:30 Lunch

13:00-14:30 ACL Business Meeting

Session 5A: Language Modeling 2

14:30–14:55 *Randomised Language Modelling for Statistical Machine Translation*
David Talbot and Miles Osborne

14:55–15:20 *Bilingual-LSA Based LM Adaptation for Spoken Language Translation*
Yik-Cheung Tam, Ian Lane and Tanja Schultz

Session 5B: Coreference

14:30–14:55 *Coreference Resolution Using Semantic Relatedness Information from Automatically Discovered Patterns*
Xiaofeng Yang and Jian Su

14:55–15:20 *Semantic Class Induction and Coreference Resolution*
Vincent Ng

Tuesday, June 26, 2007 (continued)

Session 5C: Summarization

14:30–14:55 *Generating a Table-of-Contents*
S. R. K. Branavan, Pawan Deshpande and Regina Barzilay

14:55–15:20 *Towards an Iterative Reinforcement Approach for Simultaneous Document Summarization and Keyword Extraction*
Xiaojun Wan, Jianwu Yang and Jianguo Xiao

Session 5D: Semantic Relations

14:30–14:55 *Fast Semantic Extraction Using a Novel Neural Network Architecture*
Ronan Collobert and Jason Weston

14:55–15:20 *Improving the Interpretation of Noun Phrases with Cross-linguistic Information*
Roxana Girju

15:20–15:45 Break

Session 6A: Information Extraction

15:45–16:10 *Learning to Extract Relations from the Web using Minimal Supervision*
Razvan Bunescu and Raymond Mooney

16:10–16:35 *A Seed-driven Bottom-up Machine Learning Framework for Extracting Relations of Various Complexity*
Feiyu Xu, Hans Uszkoreit and Hong Li

16:35–17:00 *A Multi-resolution Framework for Information Extraction from Free Text*
Mstislav Maslennikov and Tat-Seng Chua

17:00–17:25 *Using Corpus Statistics on Entities to Improve Semi-supervised Relation Extraction from the Web*
Benjamin Rosenfeld and Ronen Feldman

Tuesday, June 26, 2007 (continued)

Session 6B: Parsing 2

15:45–16:10 *Beyond Projectivity: Multilingual Evaluation of Constraints and Measures on Non-Projective Structures*
Jiří Havelka

16:10–16:35 *Self-Training for Enhancement and Domain Adaptation of Statistical Parsers Trained on Small Datasets*
Roi Reichart and Ari Rappoport

16:35–17:00 *HPSG Parsing with Shallow Dependency Constraints*
Kenji Sagae, Yusuke Miyao and Jun'ichi Tsujii

17:00–17:25 *Constituent Parsing with Incremental Sigmoid Belief Networks*
Ivan Titov and James Henderson

Session 6C: Multilinguality 1

15:45–16:10 *Corpus Effects on the Evaluation of Automated Transliteration Systems*
Sarvnaz Karimi, Andrew Turpin and Falk Scholer

16:10–16:35 *Collapsed Consonant and Vowel Models: New Approaches for English-Persian Transliteration and Back-Transliteration*
Sarvnaz Karimi, Falk Scholer and Andrew Turpin

16:35–17:00 *Alignment-Based Discriminative String Similarity*
Shane Bergsma and Grzegorz Kondrak

17:00–17:25 *Bilingual Terminology Mining - Using Brain, not brawn comparable corpora*
Emmanuel Morin, Béatrice Daille, Koichi Takeuchi and Kyo Kageura

Session 6D: Language Modeling 3

15:45–16:10 *Unsupervised Language Model Adaptation Incorporating Named Entity Information*
Feifan Liu and Yang Liu

16:10–16:35 *Coordinate Noun Phrase Disambiguation in a Generative Parsing Model*
Deirdre Hogan

16:35–17:00 *A Unified Tagging Approach to Text Normalization*
Conghui Zhu, Jie Tang, Hang Li, Hwee Tou Ng and Tiejun Zhao

17:00–17:25 *Sparse Information Extraction: Unsupervised Language Models to the Rescue*
Doug Downey, Stefan Schoenmackers and Oren Etzioni

Wednesday, June 27, 2007

Session 7A: Machine Translation 4

09:00–09:25 *Forest-to-String Statistical Translation Rules*
Yang Liu, Yun Huang, Qun Liu and Shouxun Lin

09:25–09:50 *Ordering Phrases with Function Words*
Hendra Setiawan, Min-Yen Kan and Haizhou Li

09:50–10:15 *A Probabilistic Approach to Syntax-based Reordering for Statistical Machine Translation*
Chi-Ho Li, Minghui Li, Dongdong Zhang, Mu Li, Ming Zhou and Yi Guan

10:15–10:40 *Machine Translation by Triangulation: Making Effective Use of Multi-Parallel Corpora*
Trevor Cohn and Mirella Lapata

Session 7B: Sequence Processing

09:00–09:25 *A Maximum Expected Utility Framework for Binary Sequence Labeling*
Martin Jansche

09:25–09:50 *A Fully Bayesian Approach to Unsupervised Part-of-speech Tagging*
Sharon Goldwater and Tom Griffiths

09:50–10:15 *Computationally Efficient M-Estimation of Log-Linear Structure Models*
Noah A. Smith, Douglas L. Vail and John D. Lafferty

10:15–10:40 *Guided Learning for Bidirectional Sequence Classification*
Libin Shen, Giorgio Satta and Aravind Joshi

Session 7C: Question Answering

09:00–09:25 *Different Structures for Evaluating Answers to Complex Questions: Pyramids Won't Topple, and Neither Will Human Assessors*
Hoa Trang Dang and Jimmy Lin

09:25–09:50 *Exploiting Syntactic and Shallow Semantic Kernels for Question Answer Classification*
Alessandro Moschitti, Silvia Quarteroni, Roberto Basili and Suresh Manandhar

09:50–10:15 *Language-independent Probabilistic Answer Ranking for Question Answering*
Jeongwoo Ko, Teruko Mitamura and Eric Nyberg

Wednesday, June 27, 2007 (continued)

Session 7D: Discourse and Dialog 2

09:00–09:25 *Learning to Compose Effective Strategies from a Library of Dialogue Components*
Martijn Spitters, Marco De Boni, Jakub Zavrel and Remko Bonnema

09:25–09:50 *On the Role of Context and Prosody in the Interpretation of 'okay'*
Agustín Gravano, Stefan Benus, Héctor Chávez, Julia Hirschberg and Lauren Wilcox

09:50–10:15 *Predicting Success in Dialogue*
David Reitter and Johanna D. Moore

10:15–10:40 *Resolving It, This, and That in Unrestricted Multi-Party Dialog*
Christoph Müller

10:40–11:10 Break

11:10–12:10 Invited Talk by Barney Pell

12:10–13:30 Lunch

Session 8A: Machine Learning Methods 2

13:30–13:55 *A Comparative Study of Parameter Estimation Methods for Statistical Natural Language Processing*
Jianfeng Gao, Galen Andrew, Mark Johnson and Kristina Toutanova

Guiding Statistical Word Alignment Models With Prior Knowledge

Yonggang Deng and **Yuqing Gao**

Abstract

We present a general framework to incorporate prior knowledge such as heuristics or linguistic features in statistical generative word alignment models. Prior knowledge plays a role of probabilistic soft constraints between bilingual word pairs that shall be used to guide word alignment model training. We investigate knowledge that can be derived automatically from entropy principle and bilingual latent semantic analysis and show how they can be applied to improve translation performance.

1 Introduction

Statistical word alignment models learn word associations between parallel sentences from statistics. Most models are trained from corpora in an unsupervised manner whose success is heavily dependent on the quality and quantity of the training data. It has been shown that human knowledge, in the form of a small amount of manually annotated parallel data to be used to seed or guide model training, can significantly improve word alignment F-measure and translation performance (Ittycheriah and Roukos, 2005; Fraser and Marcu, 2006).

As formulated in the competitive linking algorithm (Melamed, 2000), the problem of word alignment can be regarded as a process of word linkage disambiguation, that is, choosing correct associations among all competing hypothesis. The more reasonable constraints are imposed on this process, the easier the task would become. For instance, the most relaxed IBM Model-1, which assumes that any source word can be generated by any target word equally regardless of distance, can be improved by demanding a Markov process of alignments as in HMM-based models (Vogel et al., 1996), or implementing a distribution of number of target words linked to a source word as in IBM fertility-based models (Brown et al., 1993).

Following the path, we shall put more constraints on word alignment models and investigate ways of implementing them in a statistical framework. We have seen examples showing that names tend to align to names and function words are likely to be linked to function words. These observations are independent of language and can be understood by common sense. Moreover, there are other linguistically motivated constraints. For instance, words aligned to each other presumably are semantically consistent; and likely to be, they are syntactically agreeable. In these paper, we shall exploit some of these constraints in building better word alignments in the application of statistical machine translation.

We propose a simple framework that can integrate prior knowledge into statistical word alignment model training. In the framework, prior knowledge serves as probabilistic soft constraints that will guide word alignment model training. We present two types of constraints that are derived in an unsupervised way: one is based on the entropy principle, the other comes from bilingual latent semantic analysis. We investigate their impact on word alignments and show their effectiveness in improving translation performance.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 1–8,
Prague, Czech Republic, June 2007.

2 Constrained Word Alignment Models

The framework that we propose to incorporate statistical constraints into word alignment models is generic. It can be applied to complicated models such IBM Model-4 (Brown et al., 1993). We shall take HMM-based word alignment model (Vogel et al., 1996) as an example and follow the notation of (Brown et al., 1993). Let $\mathbf{e} = e_1^l$ represent a source string and $\mathbf{f} = f_1^m$ a target string. The random variable $\mathbf{a} = a_1^m$ specifies the indices of source words that target words are aligned to.

In an HMM-based word alignment model, source words are treated as Markov states while target words are observations that are generated when jumping to states:

$$P(\mathbf{a}, \mathbf{f}|\mathbf{e}) = \prod_{j=1}^{m} P(a_j|a_{j-1}, \mathbf{e}) t(f_j|e_{a_j})$$

Notice that a target word f is generated from a source state e by a simple lookup of the translation table, a.k.a., t-table $t(f|e)$, as depicted in (A) of Figure 1. To incorporate prior knowledge or impose constraints, we introduce two nodes E and F representing the hidden tags of the source word e and the target word f respectively, and organize the dependency structure as in (B) of Figure 1. Given this generative procedure, f will also depend on its tag F, which is determined probabilistically by the source tag E. The dependency from E to F functions as a soft constraint showing how the two hidden tags are agreeable to each other. Mathematically, the conditional distribution follows:

$$\begin{aligned} P(f|e) &= \sum_{E,F} P(f, E, F|e) \\ &= \sum_{E,F} P(E|e) P(F|E) P(f|e, F) \\ &= t(f|e) \cdot Con(f, e), \end{aligned} \quad (1)$$

where

$$Con(f, e) = \sum_{E,F} P(E|e) P(F|E) P(F|f) / P(F) \quad (2)$$

is the soft weight attached to the t-table entry. It considers all possible hidden tags of e and f and serves as constraint between the link.

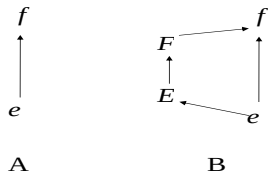

Figure 1: A simple table lookup (A) vs. a constrained procedure (B) of generating a target word f from a source word e.

We do not change the value of $Con(f, e)$ during iterative model training but rather keep it constant as an indicator of how strong the word pair should be considered as a candidate. This information is derived before word alignment model training and will act as soft constraints that need to be respected during training and alignments. For a given word pair, the soft constraint can have different assignment in different sentence pairs since the word tags can be context dependent.

To understand why we take the "detour" of generating a target word rather than directly from a t-table, consider the hidden tag as binary value indicating being a name or not. Without these constraints, t-table entries for names with low frequency tend to be flat and word alignments can be chosen randomly without sufficient statistics or strong lexical preference under maximum likelihood criterion. If we assume that a name is produced by a name with a high probability but by a non-name with a low probability, i.e. $P(F = E) >> P(F \neq E)$, proper names with low counts then are encouraged to link to proper names during training; and consequently, conditional probability mass would be more focused on correct name translations. On the other hand, names are discouraged to produce non-names. This will potentially avoid incorrect word associations. We are able to apply this type of constraint since usually there are many monolingual resources available to build a high performance probabilistic name tagger. The example suggests that putting reasonable constraints learned from monolingual analysis can alleviate data spareness problem in bilingual applications.

The weights $Con(f, e)$ are the prior knowledge that shall be assigned with care but respected during training. The baseline is to set all these weights

to 1, which is equivalent to placing no prior knowledge on model training. The introduction of these weights does not complicate parameter estimation procedure. Whenever a source word e is hypothesized to generate a target word f, the translation probability $t(f|e)$ should be weighted by $Con(f, e)$.

We point out that the constraints between f and e through their hidden tags are in probabilities. There are no hard decisions made before training. A strong preference between two words can be expressed by assigning corresponding weights close to 1. This will affect the final alignment model.

Depending on the hidden tags, there are many realizations of reasonable constraints that can be put beforehand. They can be semantic classes, syntactic annotations, or as simple as whether being a function word or content word. Moreover, the source side and the target side do not have to share the same set of tags. The framework is also flexible to support multiple types of constraints that can be implemented in parallel or cascaded sequence. Moreover, the constraints between words can be dependent on context within parallel sentences. Next, we will describe two types of constraints that we proposed. Both of them are derived from data in an unsupervised way.

2.1 Entropy Principle

It is assumed that generally speaking, a source function word generates a target function word with a higher probability than generating a target content word; similar assumption applies to a source content word as well. We capture this type of constraint by defining the hidden tag E and F as binary labels indicating being a content word or not. Based on the assumption, we design probabilistic relationship between the two hidden tags as:

$$P(E = F) = 1 - P(E \neq F) = \alpha,$$

where α is a scalar whose value is close to 1, say 0.9. The bigger α is, the tighter constraint we put on word pairs to be connected requiring the same type of label.

To determine the probability of a word being a function word, we apply the entropy principle. A function word, say "of","in" or "have", appears more frequently than a content word, say "journal" or "chemistry", in a document or sentence. We will approximate the probability of a word as a function word with the relative uncertainty of its being observed in a sentence.

More specifically, suppose we have N parallel sentences in the training corpus. For each word w_i[1], let c_{ij} be the number of word w_i observed in the j-th sentence pair, and let c_i be the total number of occurrences of w_i in the corpus. We define the relative entropy of word w_i as

$$\epsilon_{w_i} = -\frac{1}{\log N} \sum_{j=1}^{N} \frac{c_{ij}}{c_i} \log \frac{c_{ij}}{c_i}.$$

With the entropy of a word, the likelihood of word w being tagged as a function word is approximated with $w^{(1)} = \epsilon_w$ and being tagged as a content word with $w^{(0)} = 1 - \epsilon_w$.

We ignore the denominator in Equ. (2) and find the constraint under the entropy principle:

$$\begin{aligned} Con(f, e) &= \alpha(e^{(0)} f^{(0)} + e^{(1)} f^{(1)}) + \\ &\quad (1 - \alpha)(e^{(1)} f^{(0)} + e^{(0)} f^{(1)}). \end{aligned}$$

As can be seen, the connection between two words is simulated with a binary symmetric channel. An example distribution of the constraint function is illustrated in Figure 2. A high value of α encourages connecting word pairs with comparable entropy; When $\alpha = 0.5$, $Con(f, e)$ is constant which corresponds to applying no prior constraint; When α is close to 0, the function plays opposite role on word alignment training where a high frequency word is pushed to associate with a low frequency word.

2.2 Bilingual Latent Semantic Analysis

Latent Semantic Analysis (LSA) is a theory and method for extracting and representing the meaning of words by statistically analyzing word contextual usages in a collection of text. It provides a method by which to calculate the similarity of meaning of given words and documents. LSA has been successfully applied to information retrieval (Deerwester et al., 1990), statistical langauge modeling (Bellegarda, 2000) and etc.

[1]We prefix 'E_' to source words and 'F_' to target words to distinguish words that have the same spelling but are from different languages.

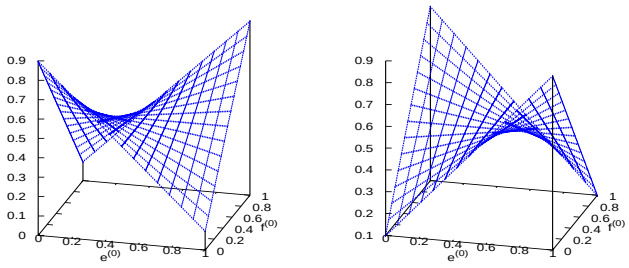

Figure 2: Distribution of the constraint function based on entropy principle when $\alpha = 0.9$ on the left and $\alpha = 0.1$ on the right.

We explore LSA techniques in bilingual environment to derive semantic constraints as prior knowledge for guiding a word alignment model training. The idea is to find semantic representation of source words and target words in the so-called low-dimensional LSA-space, and then to use their similarities to quantitatively establish semantic consistencies. We propose two different approaches.

2.2.1 A Simple Bag-of-word Model

One method we investigate is a simple bag-of-word model as in monolingual LSA. We treat each sentence pair as a document and do not distinguish source words and target words as if they are terms generated from the same vocabulary. A sparse matrix W characterizing word-document co-occurrence is constructed. Following the notation in section 2.1, the ij-th entry of the matrix W is defined as in (Bellegarda, 2000)

$$W_{ij} = (1 - \epsilon_{w_i}) \frac{c_{ij}}{c_j},$$

where c_j is the total number of words in the j-th sentence pair. This construction considers the importance of words globally (corpus wide) and locally (within sentence pairs). Alternative constructions of the matrix are possible using raw counts or TF-IDF (Deerwester et al., 1990).

W is a $M \times N$ sparse matrix, where M is the size of vocabulary including both source and target words. To obtain a compact representation, singular value decomposition (SVD) is employed (cf. Berry et al (1993)) to yield $W \approx \hat{W} = U \times S \times V^T$ as Figure 3 shows, where, for some order $R \ll \min(M, N)$ of the decomposition, U is a $M \times R$ left singular matrix with rows u_i, $i = 1, \cdots, M$, S is a $R \times R$ diagonal matrix of singular values $s_1 \geq s_2 \geq \ldots \geq s_R \gg 0$, and V is $N \times R$ a right singular matrix with rows v_j, $j = 1, \cdots, N$. For each i, the scaled R-vector $u_i S$ may be viewed as representing w_i, the i-th word in the vocabulary, and similarly the scaled R-vector $v_j S$ as representing d_j, j-th document in the corpus. Note that the $u_i S$'s and $v_j S$'s both belong to $\mathbb{R}^R$, the so-called LSA-space. All target and source words are projected into the same LSA-space too.

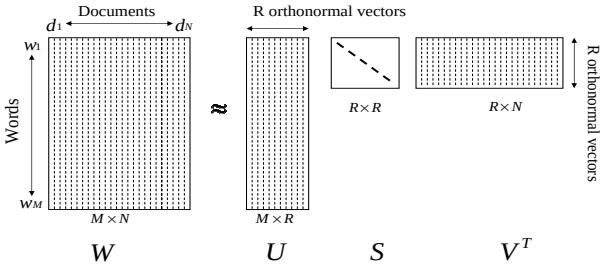

Figure 3: SVD of the Sparse Matrix W.

As Equ. (2) suggested, to induce semantic constraints in a straightforward way, one would proceed as follows: firstly, perform word semantic clustering with, say, their compact representations in the LSA-space; secondly, construct cluster generating dependencies by specifying the conditional distribution of $P(F|E)$; and finally, for each word pair, induce the semantic constraint by considering all possible semantic labeling schemes. We approximate this long process with simply finding word similarities defined by their cosine distance in the low dimension space:

$$Con(f, e) = \frac{1}{2}(\cos(u_f S, u_e S) + 1) \qquad (3)$$

The linear mapping above is introduced to avoid negative constraints and to set the maximum constraint value as 1.

In building word alignment models, a special "NULL" word is usually introduced to address target words that align to no source words. Since this physically non-existing word is not in the vocabulary of the bilingual LSA, we use the centroid of all source words as its vector representation in the LSA-space. The semantic constraints between "NULL" and any target words can be derived in the same way. However, this is chosen for mostly computational

convenience, and is not the only way to address the empty word issue.

2.2.2 Utilizing Word Alignment Statistics

While the simple bag-of-word model puts all source words and target words as rows in the matrix, another method of deriving semantic constraint constructs the sparse matrix by taking source words as rows and target words as columns and uses statistics from word alignment training to form word pair co-occurrence association.

More specifically, we regard each target word f as a "document" and each source word e as a "term". The number of occurrences of the source word e in the document f is defined as the expected number of times that f generates e in the parallel corpus under the word alignment model. This method requires training the baseline word alignment model in another direction by taking fs as source words and es as target words, which is often done for symmetric alignments, and then dumping out the soft counts when model converges. We threshold the minimum word-to-word translation probability to remove word pairs that have low co-occurrence counts.

Following the similarity induced semantic constraints in section 2.2.1, we need to find the distance between a term and a document. Let v_f be the projection of the document representing the target word f and u_e the projection of the term representing the source word e after performing SVD on the sparse matrix, we calculate the similarity between (f, e) and then find their semantic constraint to be

$$Con(f, e) = \frac{1}{2}(\cos(v_f S^{1/2}, u_e S^{1/2}) + 1) \qquad (4)$$

Unlike the method in section 2.2.1, there is no empty word issue here since we do have statistics of the "NULL" word as a source word generating e words and therefore there is a "document" assigned to it.

3 Experimental Results

We test our framework on the task of large vocabulary translation from dialectical (Iraqi) Arabic utterances into English. The task covers multiple domains including travel, emergency medical diagnosis, defense-oriented force protection, security and etc. To avoid impacts of speech recognition errors, we only report experiments from text to text translation.

The training corpus consists of 390K sentence pairs, with total 2.43M Arabic words and 3.38M English words. These sentences are in typical spoken transcription form, i.e., spelling errors, disfluencies, such as word or phrase repetition, and ungrammatical utterances are commonly observed. Arabic utterance length ranges from 3 to 70 words with the average of 6 words.

There are 25K entries in the English vocabulary and 90K in Arabic side. Data sparseness severely challenges word alignment model and consequently automatic phrase translation induction. There are 42K singletons in Arabic vocabulary, and 14K Arabic words with occurrence of twice each in the corpus. Since Arabic is a morphologically rich language where affixes are attached to stem words to indicate gender, tense, case and etc, in order to reduce vocabulary size and address out-of-vocabulary words, we split Arabic words into affix and root according to a rule-based segmentation scheme (Xiang et al., 2006) with the help from the Buckwalter analyzer (LDC, 2002) output. This reduces the size of Arabic vocabulary to 52K.

Our test data consists of 1294 sentence pairs. They are split into two parts: half of them is used as the development set, on which training parameters and decoding feature weights are tuned, the other half is for test.

3.1 Training and Translation Setup

Starting from the collection of parallel training sentences, we train word alignment models in two translation directions, from English to Iraqi Arabic and from Iraqi Arabic to English, and derive two sets of Viterbi alignments. By combining word alignments in two directions using heuristics (Och and Ney, 2003), a single set of static word alignments is then formed. All phrase pairs which respect to the word alignment boundary constraint are identified and pooled to build phrase translation tables with the Maximum Likelihood criterion. We prune phrase translation entries by their probabilities. The maximum number of tokens in Arabic phrases is set to 5 for all conditions.

Our decoder is a phrase-based multi-stack imple-

mentation of the log-linear model similar to Pharaoh (Koehn et al., 2003). Like other log-linear model based decoders, active features in our translation engine include translation models in two directions, lexicon weights in two directions, language model, distortion model, and sentence length penalty. These feature weights are tuned on the dev set to achieve optimal translation performance using downhill simplex method (Och and Ney, 2002). The language model is a statistical trigram model estimated with Modified Kneser-Ney smoothing (Chen and Goodman, 1996) using all English sentences in the parallel training data.

We measure translation performance by the BLEU score (Papineni et al., 2002) and Translation Error Rate (TER) (Snover et al., 2006) with one reference for each hypothesis. Word alignment models trained with different constraints are compared to show their effects on the resulting phrase translation tables and the final translation performance.

3.2 Translation Results

Our baseline word alignment model is the word-to-word Hidden Markov Model (Vogel et al., 1996). Basic models in two translation directions are trained simultaneously where statistics of two directions are shared to learn symmetric translation lexicon and word alignments with high precision motivated by (Zens et al., 2004) and (Liang et al., 2006). The baseline translation results (BLEU and TER) on the dev and test set are presented in the line "HMM" of Table 1. We also compare with results of IBM Model-4 word alignments implemented in GIZA++ toolkit (Och and Ney, 2003).

We study and compare two types of constraint and see how they affect word alignments and translation output. One is based on the entropy principle as described in Section 2.1, where α is set to 0.9; The other is based on bilingual latent semantic analysis.

For the simple bag-of-word bilingual LSA as described in Section 2.2.1, after SVD on the sparse matrix using the toolkit SVDPACK (Berry et al., 1993), all source and target words are projected into a low-dimensional ($R = 88$) LSA-space. Word pair semantic constrains are calculated based on their similarity as in Equ. 3 before word alignment training. Like the baseline, we perform 6 iterations of IBM Model-1 training and then 4 iteration of HMM training. The semantic constraints are used to guide word alignment model training for each iteration. The BLEU score and TER with this constraint are shown in the line "BiLSA-1" of Table 1.

To exploit word alignment statistics in bilingual LSA as described in Section 2.2.2, we dump out the statistics of the baseline word alignment model and use them to construct the sparse matrix. We find low-dimensional representation ($R = 67$) of English words and Arabic words and use their similarity to establish semantic constraints as in Equ. 4. The training procedure is the same as the baseline and "BiLSA-1". The translation results with these word alignments are shown as "BiLSA-2" in Table 1.

As Table 1 shows, when the entropy based constraints are applied, BLEU score improves 0.5 point on the test set. Clearly, when bilingual LSA constraints are applied, translation performance can be improved up to 1.6 BLEU points. We also observe that TER can drop 2.1 points with the "BiLSA-1" constraint.

While "BiLSA-1" constraint performs better on the test set, "BiLSA-2" constraint achieves slightly higher BLEU score on the dev set. We then try a simple combination of these two types of constraints, that is the geometric mean of $Con_{BiLSA-1}(f, e)$ and $Con_{BiLSA-2}(f, e)$, and find out that BLEU score can be improved a little bit further on both sets as the line "Mix" shows.

We notice that the relatively simpler HMM model can perform comparable or better than the sophisticated Model-4 when proper constraints are active in guiding word alignment model training. We also try to put constraints in Model-4. As the Equation 1 implies, when a word-to-word generative probability is needed, one should multiply corresponding lexicon entry in the t-table with the word pair constraint. We simply modify the GIZA++ toolkit (Och and Ney, 2003) by always weighting lexicon probabilities with soft constraints during iterative model training, and obtain 0.7% TER reduction on both sets and 0.4% BLEU improvement on the test set.

3.3 Analysis

To understand how prior knowledge encoded as soft constraints plays a role in guiding word alignment training, we compare statistics of different word alignment models. We find that our baseline HMM

Table 1: Translation Results with different word alignments.

Alignments	BLEU		TER	
	dev	test	dev	test
Model-4	0.310	0.296	0.528	0.530
+Mix	0.306	0.300	0.521	0.523
HMM	0.289	0.288	0.543	0.542
+Entropy	0.289	0.293	0.534	0.536
+BiLSA-1	0.294	0.300	0.531	0.521
+BiLSA-2	0.298	0.292	0.530	0.528
+Mix	0.302	0.304	0.532	0.524

generates 2.6% less number of total word links than that of Model-4. Part of the reason is that models of two directions in the baseline are trained simultaneously. The requirement of bi-directional evidence places a certain constraint on word alignments. When "BiLSA-1" constraints are applied in the baseline model, 2.7% less number of total word links are hypothesized, and consequently, less number of Arabic n-gram translations in the final phrase translation table are induced. The observation suggests that the constraints improve word alignment precision and accuracy of phrase translation tables as well.

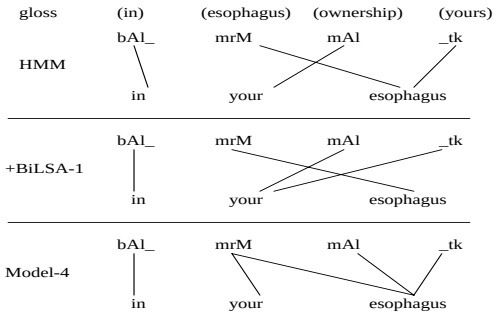

Figure 4: An example of word alignments under different models

Figure 4 shows example word alignments of a partial sentence pair. The complete English sentence is "have you ever had like any reflux diseases in your esophagus". We notice that the Arabic word "mrM" (means esophagus) appears only once in the corpus. Some of the word pair constraints are listed in Table 2. The example demos that due to reasonable constraints placed in word alignment training, the link to "_tK" is corrected and consequently we have accurate word translation for the Arabic singleton "mrM".

Table 2: Word pair constraint values

English e	Arabic f	$Con_{BiLSA-1}(f,e)$
esophagus	mrM	0.6424
	mAl	0.1819
	_tk	0.2897
your	mrM	0.6319
	mAl	0.4930
	_tk	0.9672

4 Related Work

Heuristics based on co-occurrence analysis, such as point-wise mutual information or Dice coefficients , have been shown to be indicative for word alignments (Zhang and Vogel, 2005; Melamed, 2000). The framework presented in this paper demonstrates the possibility of taking heuristics as constraints guiding statistical generative word alignment model training. Their effectiveness can be expected especially when data sparseness is severe.

Discriminative word alignment models, such as Ittycheriah and Roukos (2005); Moore (2005); Blunsom and Cohn (2006), have received great amount of study recently. They have proven that linguistic knowledge is useful in modeling word alignments under log-linear distributions as morphological, semantic or syntactic features. Our framework proposes to exploit these features differently by taking them as soft constraints of translation lexicon under a generative model.

While word alignments can help identifying semantic relations (van der Plas and Tiedemann, 2006), we proceed in the reverse direction. We investigate the impact of semantic constraints on statistical word alignment models as prior knowledge. In (Ma et al., 2004), bilingual semantic maps are constructed to guide word alignment. The framework we proposed seamlessly integrates derived semantic similarities into a statistical word alignment model. And we extended monolingual latent semantic analysis in bilingual applications.

Toutanova et al. (2002) augmented bilingual sentence pairs with part-of-speech tags as linguistic constraints for HMM-based word alignments. The constraints between tags are automatically learned in a parallel generative procedure along with lex-

icon. We have introduced hidden tags between a word pair to specialize their soft constraints, which serve as prior knowledge that will be used in guiding word alignment model training. Constraint between tags are embedded into the word to word generative process.

5 Conclusions and Future Work

We have presented a simple and effective framework to incorporate prior knowledge such as heuristics or linguistic features into statistical generative word alignment models. Prior knowledge serves as soft constraints that shall be placed on translation lexicon to guide word alignment model training and disambiguation during Viterbi alignment process. We studied two types of constraints that can be obtained automatically from data and showed improved performance (up to 1.6% absolute BLEU increase or 2.1% absolute TER reduction) in translating dialectical Arabic into English. Future work includes implementing the idea in alternative alignment models and also exploiting prior knowledge derived from such as manually-aligned data and pre-existing linguistic resources.

Abstract

We present a global discriminative statistical word order model for machine translation. Our model combines syntactic movement and surface movement information, and is discriminatively trained to choose among possible word orders. We show that combining discriminative training with features to detect these two different kinds of movement phenomena leads to substantial improvements in word ordering performance over strong baselines. Integrating this word order model in a baseline MT system results in a 2.4 points improvement in BLEU for English to Japanese translation.

1 Introduction

The machine translation task can be viewed as consisting of two subtasks: predicting the collection of words in a translation, and deciding the order of the predicted words. For some language pairs, such as English and Japanese, the ordering problem is especially hard, because the target word order differs significantly from the source word order.

Previous work has shown that it is useful to model target language order in terms of movement of syntactic constituents in constituency trees (Yamada and Knight, 2001; Galley et al., 2006) or dependency trees (Quirk et al., 2005), which are obtained using a parser trained to determine linguistic constituency. Alternatively, order is modelled in terms of movement of automatically induced hierarchical structure of sentences (Chiang, 2005; Wu, 1997).

The advantages of modeling how a target language syntax tree moves with respect to a source language syntax tree are that (*i*) we can capture the fact that constituents move as a whole and generally respect the phrasal cohesion constraints (Fox, 2002), and (*ii*) we can model broad syntactic reordering phenomena, such as subject-verb-object constructions translating into subject-object-verb ones, as is generally the case for English and Japanese.

On the other hand, there is also significant amount of information in the surface strings of the source and target and their alignment. Many state-of-the-art SMT systems do not use trees and base the ordering decisions on surface phrases (Och and Ney, 2004; Al-Onaizan and Papineni, 2006; Kuhn et al., 2006). In this paper we develop an order model for machine translation which makes use of both syntactic and surface information.

The framework for our statistical model is as follows. We assume the existence of a dependency tree for the source sentence, an unordered dependency tree for the target sentence, and a word alignment between the target and source sentences. Figure 1 (a) shows an example of aligned source and target dependency trees. Our task is to order the target dependency tree.

We train a statistical model to select the best order of the unordered target dependency tree. An important advantage of our model is that it is global, and does not decompose the task of ordering a target sentence into a series of local decisions, as in the recently proposed order models for Machine Transition (Al-Onaizan and Papineni, 2006; Xiong et al., 2006; Kuhn et al., 2006). Thus we are able to define features over complete target sentence orders, and avoid the independence assumptions made by these

models. Our model is discriminatively trained to select the best order (according to the BLEU measure) (Papineni et al., 2001) of an unordered target dependency tree from the space of possible orders.

Since the space of all possible orders of an unordered dependency tree is factorially large, we train our model on N-best lists of possible orders. These N-best lists are generated using approximate search and simpler models, as in the re-ranking approach of (Collins, 2000).

We first evaluate our model on the task of ordering target sentences, given correct (reference) unordered target dependency trees. Our results show that combining features derived from the source and target dependency trees, distortion surface order-based features (like the distortion used in Pharaoh (Koehn, 2004)) and language model-like features results in a model which significantly outperforms models using only some of the information sources.

We also evaluate the contribution of our model to the performance of an MT system. We integrate our order model in the MT system, by simply re-ordering the target translation sentences output by the system. The model resulted in an improvement from 33.6 to 35.4 BLEU points in English-to-Japanese translation on a computer domain.

2 Task Setup

The ordering problem in MT can be formulated as the task of ordering a target bag of words, given a source sentence and word alignments between target and source words. In this work we also assume a source dependency tree and an unordered target dependency tree are given. Figure 1(a) shows an example. We build a model that predicts an order of the target dependency tree, which induces an order on the target sentence words. The dependency tree constrains the possible orders of the target sentence only to the ones that are projective with respect to the tree. An order of the sentence is projective with respect to the tree if each word and its descendants form a contiguous subsequence in the ordered sentence. Figure 1(b) shows several orders of the sentence which violate this constraint.[1]

Previous studies have shown that if both the source and target dependency trees represent linguistic constituency, the alignment between subtrees in the two languages is very complex (Wellington et al., 2006). Thus such parallel trees would be difficult for MT systems to construct in translation. In this work only the source dependency trees are linguistically motivated and constructed by a parser trained to determine linguistic structure. The target dependency trees are obtained through projection of the source dependency trees, using the word alignment (we use GIZA++ (Och and Ney, 2004)), ensuring better parallelism of the source and target structures.

2.1 Obtaining Target Dependency Trees Through Projection

Our algorithm for obtaining target dependency trees by projection of the source trees via the word alignment is the one used in the MT system of (Quirk et al., 2005). We describe the algorithm schematically using the example in Figure 1. Projection of the dependency tree through alignments is not at all straightforward. One of the reasons of difficulty is that the alignment does not represent an isomorphism between the sentences, i.e. it is very often not a one-to-one and onto mapping.[2] If the alignment were one-to-one we could define the parent of a word w_t in the target to be the target word aligned to the parent of the source word s_i aligned to w_t. An additional difficulty is that such a definition could result in a non-projective target dependency tree. The projection algorithm of (Quirk et al., 2005) defines heuristics for each of these problems. In case of one-to-many alignments, for example, the case of "constraints" aligning to the Japanese words for "restriction" and "condition", the algorithm creates a

[1] For example, in the first order shown, the descendants of word 6 are not contiguous and thus this order violates the constraint.

[2] In an onto mapping, every word on the target side is associated with some word on the source side.

subtree in the target rooted at the rightmost of these words and attaches the other word(s) to it. In case of non-projectivity, the dependency tree is modified by re-attaching nodes higher up in the tree. Such a step is necessary for our example sentence, because the translations of the words "all" and "constraints" are not contiguous in the target even though they form a constituent in the source.

An important characteristic of the projection algorithm is that all of its heuristics use the *correct* target word order.[3] Thus the target dependency trees encode more information than is present in the source dependency trees and alignment.

2.2 Task Setup for Reference Sentences vs MT Output

Our model uses input of the same form when trained/tested on reference sentences and when used in machine translation: a source sentence with a dependency tree, an unordered target sentence with and unordered target dependency tree, and word alignments.

We train our model on reference sentences. In this setting, the given target dependency tree contains the correct bag of target words according to a reference translation, and is projective with respect to the correct word order of the reference by construction. We also evaluate our model in this setting; such an evaluation is useful because we can isolate the contribution of an order model, and develop it independently of an MT system.

When translating new sentences it is not possible to derive target dependency trees by the projection algorithm described above. In this setting, we use target dependency trees constructed by our baseline MT system (described in detail in 6.1). The system constructs dependency trees of the form shown in Figure 1 for each translation hypothesis. In this case the target dependency trees very often do not contain the correct target words and/or are not projective with respect to the best possible order.

[3]For example, checking which word is the rightmost for the heuristic for one-to-many mappings and checking whether the constructed tree is projective requires knowledge of the correct word order of the target.

3 Language Model with Syntactic Constraints: A Pilot Study

In this section we report the results of a pilot study to evaluate the difficulty of ordering a target sentence if we are given a target dependency tree as the one in Figure 1, versus if we are just given an unordered bag of target language words.

The difference between those two settings is that when ordering a target dependency tree, many of the orders of the sentence are not allowed, because they would be non-projective with respect to the tree. Figure 1 (b) shows some orders which violate the projectivity constraint. If the given target dependency tree is projective with respect to the correct word order, constraining the possible orders to the ones consistent with the tree can only help performance. In our experiments on reference sentences, the target dependency trees are projective by construction. If, however, the target dependency tree provided is not necessarily projective with respect to the best word order, the constraint may or may not be useful. This could happen in our experiments on ordering MT output sentences.

Thus in this section we aim to evaluate the usefulness of the constraint in both settings: reference sentences with projective dependency trees, and MT output sentences with possibly non-projective dependency trees. We also seek to establish a baseline for our task. Our methodology is to test a simple and effective order model, which is used by all state of the art SMT systems – a trigram language model – in the two settings: ordering an unordered bag of words, and ordering a target dependency tree.

Our experimental design is as follows. Given an unordered sentence t and an unordered target dependency tree $tree(t)$, we define two spaces of target sentence orders. These are the unconstrained space of all permutations, denoted by Permutations(t) and the space of all orders of t which are projective with respect to the target dependency tree, denoted by TargetProjective(t,$tree(t)$). For both spaces S, we apply a standard trigram target language model to select a most likely order from the space; i.e., we find a target order $order^*_S(t)$ such that: $order^*_S(t) = argmax_{order(t) \in S} Pr_{LM}(order(t))$. The operator which finds $order^*_S(t)$ is difficult to implement since the task is NP-hard in both set-

Reference Sentences		
Space	**BLEU**	**Avg. Size**
Permutations	58.8	2^{61}
TargetProjective	83.9	2^{29}
MT Output Sentences		
Space	**BLEU**	**Avg. Size**
Permutations	26.3	2^{56}
TargetProjective	31.7	2^{25}

Table 1: Performance of a tri-gram language model on ordering reference and MT output sentences: unconstrained or subject to target tree projectivity constraints.

tings, even for a bi-gram language model (Eisner and Tromble, 2006).[4] We implemented left-to-right beam A* search for the Permutations space, and a tree-based bottom up beam A* search for the TargetProjective space. To give an estimate of the search error in each case, we computed the number of times the correct order had a better language model score than the order returned by the search algorithm.[5] The lower bounds on search error were 4% for Permutations and 2% for TargetProjective, computed on reference sentences.

We compare the performance in BLEU of orders selected from both spaces. We evaluate the performance on reference sentences and on MT output sentences. Table 1 shows the results. In addition to BLEU scores, the table shows the median number of possible orders per sentence for the two spaces.

The highest achievable BLEU on reference sentences is 100, because we are given the correct bag of words. The highest achievable BLEU on MT output sentences is well below 100 (the BLEU score of the MT output sentences is 33). Table 3 describes the characteristics of the main data-sets used in the experiments in this paper; the test sets we use in the present pilot study are the reference test set (Ref-test) of 1K sentences and the MT test set (MT-test) of 1,000 sentences.

The results from our experiment show that the target tree projectivity constraint is extremely powerful on reference sentences, where the tree given is indeed projective. (Recall that in order to obtain the target dependency tree in this setting we have used information from the true order, which explains in part the large performance gain.)

[4]Even though the dependency tree constrains the space, the number of children of a node is not bounded by a constant.

[5]This is an underestimate of search error, because we don't know if there was another (non-reference) order which had a better score, but was not found.

The gain in BLEU due to the constraint was not as large on MT output sentences, but was still considerable. The reduction in search space size due to the constraint is enormous. There are about 2^{30} times fewer orders to consider in the space of target projective orders, compared to the space of all permutations. From these experiments we conclude that the constraints imposed by a projective target dependency tree are extremely informative. We also conclude that the constraints imposed by the target dependency trees constructed by our baseline MT system are very informative as well, even though the trees are not necessarily projective with respect to the best order. Thus the projectivity constraint with respect to a reasonably good target dependency tree is useful for addressing the search and modeling problems for MT ordering.

4 A Global Order Model for Target Dependency Trees

In the rest of the paper we present our new word order model and evaluate it on reference sentences and in machine translation. In line with previous work on NLP tasks such as parsing and recent work on machine translation, we develop a discriminative order model. An advantage of such a model is that we can easily combine different kinds of features (such as syntax-based and surface-based), and that we can optimize the parameters of our model directly for the evaluation measures of interest.

Additionally, we develop a globally normalized model, which avoids the independence assumptions in locally normalized conditional models.[6] We train a global log-linear model with a rich set of syntactic and surface features. Because the space of possible orders of an unordered dependency tree is factorially large, we use simpler models to generate N-best orders, which we then re-rank with a global model.

4.1 Generating N-best Orders

The simpler models which we use to generate N-best orders of the unordered target dependency trees are the standard trigram language model used in Section 3, and another statistical model, which we call a Local Tree Order Model (LTOM). The LTOM model

[6]Those models often assume that current decisions are independent of future observations.

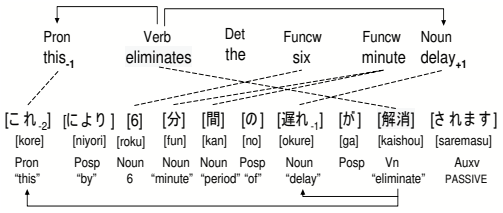

Figure 2: Dependency parse on the source (English) sentence, alignment and projected tree on the target (Japanese) sentence. Notice that the projected tree is only partial and is used to show the head-relative movement.

uses syntactic information from the source and target dependency trees, and orders each local tree of the target dependency tree independently. It follows the order model defined in (Quirk et al., 2005).

The model assigns a probability to the position of each target node (modifier) relative to its parent (head), based on information in both the source and target trees. The probability of an order of the complete target dependency tree decomposes into a product over probabilities of positions for each node in the tree as follows:

$$P(order(t)|s,t) = \prod_{n \in t} P(pos(n, parent(n))|s,t)$$

Here, position is modelled in terms of closeness to the head in the dependency tree. The closest pre-modifier of a given head has position -1; the closest post-modifier has a position 1. Figure 2 shows an example dependency tree pair annotated with head-relative positions. A small set of features is used to reflect local information in the dependency tree to model $P(pos(n, parent(n))|s,t)$: (*i*) lexical items of n and $parent(n)$, (*ii*) lexical items of the source nodes aligned to n and $parent(n)$, (*iii*) part-of-speech of the source nodes aligned to the node and its parent, and (*iv*) head-relative position of the source node aligned to the target node.

We train a log-linear model which uses these features on a training set of aligned sentences with source and target dependency trees in the form of Figure 2. The model is a local (non-sequence) classifier, because the decision on where to place each node does not depend on the placement of any other nodes.

Since the local tree order model learns to order whole subtrees of the target dependency tree, and since it uses syntactic information from the source, it provides an alternative view compared to the trigram language model. The example in Figure 2 shows that the head word "eliminates" takes a dependent "this" to the left (position -1), and on the Japanese side, the head word "kaishou" (corresponding to "eliminates") takes a dependent "kore" (corresponding to "this") to the left (position -2). The trigram language model would not capture the position of "kore" with respect to "kaishou", because the words are farther than three positions away.

We use the language model and the local tree order model to create N-best target dependency tree orders. In particular, we generate the N-best lists from a simple log-linear combination of the two models:

$$P(o(t)|s,t) \propto P_{LM}(o(t)|t) P_{LTOM}(o(t)|s,t)^{\lambda}$$

where $o(t)$ denotes an order of the target.[7] We used a bottom-up beam A* search to generate N-best orders. The performance of each of these two models and their combination, together with the 30-best oracle performance on reference sentences is shown in Table 2. As we can see, the 30-best oracle performance of the combined model (98.0) is much higher than the 1-best performance (92.6) and thus there is a lot of room for improvement.

4.2 Model

The log-linear reranking model is defined as follows. For each sentence pair sp_l ($l = 1, 2, ..., L$) in the training data, we have N candidate target word orders $o_{l,1}, o_{l,2}, ..., o_{l,N}$, which are the orders generated from the simpler models. Without loss of generality, we define $o_{l,1}$ to be the order with the highest BLEU score with respect to the correct order.[8]

We define a set of feature functions $f_m(o_{l,n}, sp_l)$ to describe a target word order $o_{l,n}$ of a given sentence pair sp_l. In the log-linear model, a corresponding weights vector λ is used to define the distribution over all possible candidate orders:

$$p(o_{l,n}|sp_l, \lambda) = \frac{e^{\lambda F(o_{l,n}, sp_l)}}{\sum_{n'} e^{\lambda F(o_{l,n'}, sp_l)}}$$

[7] We used the value $\lambda = .5$, which we selected on a development set to maximize BLEU.

[8] To avoid the problem that all orders could have a BLEU score of 0 if none of them contains a correct word four-gram, we define sentence-level k-gram BLEU, where k is the highest order, $k \leq 4$, for which there exists a correct k-gram in at least one of the N-Best orders.

We train the parameters λ by minimizing the negative log-likelihood of the training data plus a quadratic regularization term:

$L(\lambda) = -\sum_l \log p(o_{l,1}|sp_i, \lambda) + \frac{1}{2\sigma^2}\sum_m {\lambda_m}^2$

We also explored maximizing expected BLEU as our objective function, but since it is not convex, the performance was less stable and ultimately slightly worse, as compared to the log-likelihood objective.

4.3 Features

We design features to capture both the head-relative movement and the surface sequence movement of words in a sentence. We experiment with different combinations of features and show their contribution in Table 2 for reference sentences and Table 4 in machine translation. The notations used in the tables are defined as follows:

Baseline: **LTOM+LM** as described in Section 4.1

Word Bigram: Word bigrams of the target sentence. Examples from Figure 2: *"kore"+"niyori"*, *"niyori"+"roku"*.

DISP: Displacement feature. For each word position in the target sentence, we examine the alignment of the current word and the previous word, and categorize the possible patterns into 3 kinds: (a) parallel, (b) crossing, and (c) widening. Figure 3 shows how these three categories are defined.

Pharaoh DISP: Displacement as used in Pharaoh (Koehn, 2004). For each position in the sentence, the value of the feature is one less than the difference (absolute value) of the positions of the source words aligned to the current and the previous target word.

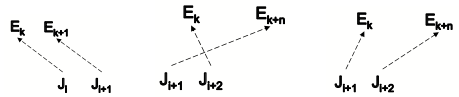
POSs and **POSt**: POS tags on the source and target sides. For Japanese, we have a set of 19 POS tags.

'+' means making conjunction of features and $prev()$ means using the information associated with the word from position -1.

In all explored models, we include the log-probability of an order according to the language model and the log-probability according to the local tree order model, the two features used by the baseline model.

5 Evaluation on Reference Sentences

Our experiments on ordering reference sentences use a set of 445K English sentences with their reference Japanese translations. This is a subset of the



(a) parallel (b) crossing (c) widening

Figure 3: Displacement feature: different alignment patterns of two contiguous words in the target sentence.

set MT-train in Table 3. The sentences were annotated with alignment (using GIZA++ (Och and Ney, 2004)) and syntactic dependency structures of the source and target, obtained as described in Section 2. Japanese POS tags were assigned by an automatic POS tagger, which is a local classifier not using tag sequence information.

We used 400K sentence pairs from the complete set to train the first pass models: the language model was trained on 400K sentences, and the local tree order model was trained on 100K of them. We generated N-best target tree orders for the rest of the data (45K sentence pairs), and used it for training and evaluating the re-ranking model. The re-ranking model was trained on 44K sentence pairs. All models were evaluated on the remaining 1,000 sentence pairs set, which is the set Ref-test in Table 3.

The top part of Table 2 presents the 1-best BLEU scores (actual performance) and 30-best oracle BLEU scores of the first-pass models and their log-linear combination, described in Section 4. We can see that the combination of the language model and the local tree order model outperformed either model by a large margin. This indicates that combining syntactic (from the LTOM model) and surface-based (from the language model) information is very effective even at this stage of selecting N-best orders for re-ranking. According to the 30-best oracle performance of the combined model LTOM+LM, 98.0 BLEU is the upper bound on performance of our re-ranking approach.

The bottom part of the table shows the performance of the global log-linear model, when features in addition to the scores from the two first-pass models are added to the model. Adding word-bigram features increased performance by about 0.6 BLEU points, indicating that training language-model like features discriminatively to optimize ordering performance, is indeed worthwhile. Next we compare

First-pass models		
Model	BLEU	
	1 best	30 best
Lang Model (Permutations)	58.8	71.2
Lang Model (TargetProjective)	83.9	95.0
Local Tree Order Model	75.8	87.3
Local Tree Order Model + Lang Model	92.6	98.0
Re-ranking Models		
Features	BLEU	
Baseline	92.60	
Word Bigram	93.19	
Pharaoh DISP	92.94	
DISP	93.57	
DISP+POSs	94.04	
DISP+POSs+POSt	94.14	
DISP+POSs+POSt, prev(DISP)+POSs+POSt	94.34	
DISP+POSs+POSt, prev(DISP)+POSs+POSt, WB	94.50	

Table 2: Performance of the first-pass order models and 30-best oracle performance, followed by performance of re-ranking model for different feature sets. Results are on reference sentences.

the Pharaoh displacement feature to the displacement feature we illustrated in Figure 3. We can see that the Pharaoh displacement feature improves performance of the baseline by .34 points, whereas our displacement feature improves performance by nearly 1 BLEU point. Concatenating the DISP feature with the POS tag of the source word aligned to the current word improved performance slightly.

The results show that surface movement features (i.e. the DISP feature) improve the performance of a model using syntactic-movement features (i.e. the LTOM model). Additionally, adding part-of-speech information from both languages in combination with displacement, and using a higher order on the displacement features was useful. The performance of our best model, which included all information sources, is 94.5 BLEU points, which is a 35% improvement over the fist-pass models, relative to the upper bound.

6 Evaluation in Machine Translation

We apply our model to machine translation by reordering the translation produced by a baseline MT system. Our baseline MT system constructs, for each target translation hypothesis, a target dependency tree. Thus we can apply our model to MT output in exactly the same way as for reference sentences, but using much noisier input: a source sentence with a dependency tree, word alignment and an unordered target dependency tree as the example shown in Figure 2. The difference is that the target dependency tree will likely not contain the correct target words and/or will not be projective with respect to the best possible order.

data set	num sent.	English		Japanese

6.1 Baseline MT System

Our baseline SMT system is the system of Quirk et al. (2005). It translates by first deriving a dependency tree for the source sentence and then translating the source dependency tree to a target dependency tree, using a set of probabilistic models. The translation is based on treelet pairs. A treelet is a connected subgraph of the source or target dependency tree. A treelet translation pair is a pair of word-aligned source and target treelets.

The baseline SMT model combines this treelet translation model with other feature functions — a target language model, a tree order model, lexical weighting features to smooth the translation probabilities, word count feature, and treelet-pairs count feature. These models are combined as feature functions in a (log)linear model for predicting a target sentence given a source sentence, in the framework proposed by (Och and Ney, 2002). The weights of this model are trained to maximize BLEU (Och and Ney, 2004). The SMT system is trained using the same form of data as our order model: parallel source and target dependency trees as in Figure 2.

Of particular interest are the components in the baseline SMT system contributing most to word order decisions. The SMT system uses the same target language trigram model and local tree order model, as we are using for generating N-best orders for reranking. Thus the baseline system already uses our first-pass order models and only lacks the additional information provided by our re-ranking order model.

6.2 Data and Experimental Results

The baseline MT system was trained on the MT-train dataset described in Table 3. The test set for the MT experiment is a 1K sentences set from the same domain (shown as MT-test in the table). The weights in the linear model used by the baseline SMT system were tuned on a separate development set.

Table 4 shows the performance of the first-pass models in the top part, and the performance of our

First-pass models		
Model	BLEU	
	1 best	30 best

Table 4: Performance of the first pass order models and 30-best oracle performance, followed by performance of re-ranking model for different feature sets. Results are in MT.

re-ranking model in the bottom part. The first row of the table shows the performance of the baseline MT system, which is a BLEU score of 33. Our first-pass and re-ranking models re-order the words of this 1-best output from the MT system. As for reference sentences, the combination of the two first-pass models outperforms the individual models. The 1-best performance of the combination is 33.6 and the 30-best oracle is 36.0. Thus the best we could do with our re-ranking model in this setting is 36 BLEU points.[9] Our best re-ranking model achieves 2.4 BLEU points improvement over the baseline MT system and 1.8 points improvement over the first-pass models, as shown in the table. The trends here are similar to the ones observed in our reference experiments, with the difference that target POS tags were less useful (perhaps due to ungrammatical candidates) and the displacement features were more useful. We can see that our re-ranking model almost reached the upper bound oracle performance, reducing the gap between the first-pass models performance (33.6) and the oracle (36.0) by 75%.

7 Conclusions and Future Work

We have presented a discriminative syntax-based order model for machine translation, trained to to select from the space of orders projective with respect to a target dependency tree. We investigated a combination of features modeling surface movement and syntactic movement phenomena and showed that these two information sources are complementary and their combination is powerful. Our results on ordering MT output and reference sentences were very encouraging. We obtained substantial improvement by the simple method of post-processing the 1-best MT output to re-order the proposed translation. In the future, we would like to explore tighter integration of our order model with the SMT system and to develop more accurate algorithms for constructing projective target dependency trees in translation.

[9] Notice that the combination of our two first-pass models outperforms the baseline MT system by half a point (33.6 versus 33.0). This is perhaps due to the fact that the MT system searches through a much larger space (possible word translations in addition to word orders), and thus could have a higher search error.

Abstract

Extracting tree transducer rules for syntactic MT systems can be hindered by word alignment errors that violate syntactic correspondences. We propose a novel model for unsupervised word alignment which explicitly takes into account target language constituent structure, while retaining the robustness and efficiency of the HMM alignment model. Our model's predictions improve the yield of a tree transducer extraction system, without sacrificing alignment quality. We also discuss the impact of various posterior-based methods of reconciling bidirectional alignments.

1 Introduction

Syntactic methods are an increasingly promising approach to statistical machine translation, being both algorithmically appealing (Melamed, 2004; Wu, 1997) and empirically successful (Chiang, 2005; Galley et al., 2006). However, despite recent progress, almost all syntactic MT systems, indeed statistical MT systems in general, build upon crude legacy models of word alignment. This dependence runs deep; for example, Galley et al. (2006) requires word alignments to project trees from the target language to the source, while Chiang (2005) requires alignments to induce grammar rules.

Word alignment models have not stood still in recent years. Unsupervised methods have seen substantial reductions in alignment error (Liang et al., 2006) as measured by the now much-maligned AER metric. A host of discriminative methods have been introduced (Taskar et al., 2005; Moore, 2005; Ayan and Dorr, 2006). However, few of these methods have explicitly addressed the tension between word alignments and the syntactic processes that employ them (Cherry and Lin, 2006; Daumé III and Marcu, 2005; Lopez and Resnik, 2005).

We are particularly motivated by systems like the one described in Galley et al. (2006), which constructs translations using tree-to-string transducer rules. These rules are extracted from a bitext annotated with both English (target side) parses and word alignments. Rules are extracted from target side constituents that can be projected onto contiguous spans of the source sentence via the word alignment. Constituents that project onto non-contiguous spans of the source sentence do not yield transducer rules themselves, and can only be incorporated into larger transducer rules. Thus, if the word alignment of a sentence pair does not respect the constituent structure of the target sentence, then the minimal translation units must span large tree fragments, which do not generalize well.

We present and evaluate an unsupervised word alignment model similar in character and computation to the HMM model (Ney and Vogel, 1996), but which incorporates a novel, syntax-aware distortion component which conditions on target language parse trees. These trees, while automatically generated and therefore imperfect, are nonetheless (1) a useful source of structural bias and (2) the same trees which constrain future stages of processing anyway. In our model, the trees do not *rule out* any alignments, but rather softly influence the probability of transitioning between alignment positions. In particular, transition probabilities condition upon paths through the target parse tree, allowing the model to prefer distortions which respect the tree structure.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 17–24,
Prague, Czech Republic, June 2007.

Our model generates word alignments that better respect the parse trees upon which they are conditioned, without sacrificing alignment quality. Using the joint training technique of Liang et al. (2006) to initialize the model parameters, we achieve an AER superior to the GIZA++ implementation of IBM model 4 (Och and Ney, 2003) and a reduction of 56.3% in aligned interior nodes, a measure of agreement between alignments and parses. As a result, our alignments yield more rules, which better match those we would extract had we used manual alignments.

2 Translation with Tree Transducers

In a tree transducer system, as in phrase-based systems, the coverage and generality of the transducer inventory is strongly related to the effectiveness of the translation model (Galley et al., 2006). We will demonstrate that this coverage, in turn, is related to the degree to which initial word alignments respect syntactic correspondences.

2.1 Rule Extraction

Galley et al. (2004) proposes a method for extracting tree transducer rules from a parallel corpus. Given a source language sentence s, a target language parse tree t of its translation, and a word-level alignment, their algorithm identifies the constituents in t which map onto contiguous substrings of s via the alignment. The root nodes of such constituents – denoted *frontier nodes* – serve as the roots and leaves of tree fragments that form *minimal* transducer rules.

Frontier nodes are distinguished by their compatibility with the word alignment. For a constituent c of t, we consider the set of source words s_c that are aligned to c. If none of the source words in the linear closure s_c^* (the words between the leftmost and rightmost members of s_c) aligns to a target word outside of c, then the root of c is a frontier node. The remaining *interior* nodes do not generate rules, but can play a secondary role in a translation system.[1] The roots of null-aligned constituents are not frontier nodes, but can attach productively to multiple minimal rules.

[1]Interior nodes can be used, for instance, in evaluating syntax-based language models. They also serve to differentiate transducer rules that have the same frontier nodes but different internal structure.

Two transducer rules, $t_1 \rightarrow s_1$ and $t_2 \rightarrow s_2$, can be combined to form larger translation units by composing t_1 and t_2 at a shared frontier node and appropriately concatenating s_1 and s_2. However, no technique has yet been shown to robustly extract smaller component rules from a large transducer rule. Thus, for the purpose of maximizing the coverage of the extracted translation model, we prefer to extract many small, minimal rules and generate larger rules via composition. Maximizing the number of frontier nodes supports this goal, while inducing many aligned interior nodes hinders it.

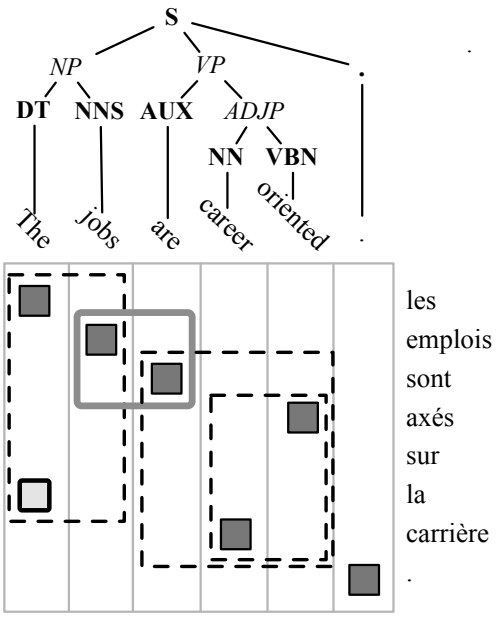
2.2 Word Alignment Interactions

We now turn to the interaction between word alignments and the transducer extraction algorithm. Consider the example sentence in figure 1A, which demonstrates how a particular type of alignment error prevents the extraction of many useful transducer rules. The mistaken link [*la* ⇒ *the*] intervenes between *axés* and *carrièr*, which both align within an English adjective phrase, while *la* aligns to a distant subspan of the English parse tree. In this way, the alignment violates the constituent structure of the English parse.

While alignment errors are undesirable in general, this error is particularly problematic for a syntax-based translation system. In a phrase-based system, this link would block extraction of the phrases [*axés sur la carrièr* ⇒ *career oriented*] and [*les emplois* ⇒ *the jobs*] because the error overlaps with both. However, the intervening phrase [*emplois sont* ⇒ *jobs are*] would still be extracted, at least capturing the transfer of subject-verb agreement. By contrast, the tree transducer extraction method fails to extract any of these fragments: the alignment error causes all non-terminal nodes in the parse tree to be interior nodes, excluding preterminals and the root. Figure 1B exposes the consequences: a wide array of desired rules are lost during extraction.

The degree to which a word alignment respects the constituent structure of a parse tree can be quantified by the frequency of interior nodes, which indicate alignment patterns that cross constituent boundaries. To achieve maximum coverage of the translation model, we hope to infer tree-violating alignments only when syntactic structures truly diverge.

(A)



Legend

(S (NP (DT[0] NNS[1]) VP[2] .[3]) → [0] [1] [2] [3]
(S (NP (DT[0] (NNS *jobs*)) VP[2] .[3]) → [0] *emplois* [2] [3]
(S (NP (DT[0] (NNS *jobs*)) (VP AUX[1] ADJV[2]) .[3]) → [0] *emplois* [1] [2] [3]
(S (NP (DT[0] (NNS *jobs*)) (VP (AUX *are*) ADJV[1]) .[2]) → [0] *emplois sont* [1] [2]

(ii)

(S (NP (DT[0] NNS[1]) (VP AUX[2] (ADJV NN[3] VBN[4]) .[5]) → [0] [1] [2] [3] [4] [5]
(S (NP (DT[0] (NNS *jobs*)) (VP AUX[1] (ADJV NN[2] VBN[3]) .[4]) → [0] *sont* [1] [2] [3] [4]
(S (NP (DT[0] (NNS *jobs*)) (VP (AUX *are*) (ADJV NN[1] VBN[2]) .[3]) → [0] *emplois sont* [1] [2] [3]

Figure 1: In this transducer extraction example, (A) shows a proposed alignment from our test set with an alignment error that violates the constituent structure of the English sentence. The resulting frontier nodes are printed in bold; all nodes would be frontier nodes under a correct alignment. (B) shows a small sample of the rules extracted under the proposed alignment, (ii), and the correct alignment, (i) and (ii). The single alignment error prevents the extraction of all rules in (i) and many more. This alignment pattern was observed in our test set and corrected by our model.

3 Unsupervised Word Alignment

To allow for this preference, we present a novel conditional alignment model of a foreign (source) sentence $\mathbf{f} = \{f_1, ..., f_J\}$ given an English (target) sentence $\mathbf{e} = \{e_1, ..., e_I\}$ and a target tree structure t. Like the classic IBM models (Brown et al., 1994), our model will introduce a latent alignment vector $\mathbf{a} = \{a_1, ..., a_J\}$ that specifies the position of an aligned target word for each source word. Formally, our model describes $p(\mathbf{a}, \mathbf{f}|\mathbf{e}, t)$, but otherwise borrows heavily from the HMM alignment model of Ney and Vogel (1996).

The HMM model captures the intuition that the alignment vector $\mathbf{a}$ will in general progress across the sentence $\mathbf{e}$ in a pattern which is mostly local, perhaps with a few large jumps. That is, alignments are locally monotonic more often than not.

Formally, the HMM model factors as:

$$p(\mathbf{a}, \mathbf{f}|\mathbf{e}) = \prod_{j=1}^{J} p_d(a_j|a_{j_-}, j) p_\ell(f_j|e_{a_j})$$

where j_- is the position of the last non-null-aligned source word before position j, p_ℓ is a lexical transfer model, and p_d is a local distortion model. As in all such models, the lexical component p_ℓ is a collection of unsmoothed multinomial distributions over

foreign words.

The distortion model $p_d(a_j|a_{j_-}, j)$ is a distribution over the signed distance $a_j - a_{j_-}$, typically parameterized as a multinomial, Gaussian or exponential distribution. The implementation that serves as our baseline uses a multinomial distribution with separate parameters for $j = 1$, $j = J$ and shared parameters for all $1 < j < J$. Null alignments have fixed probability at any position. Inference over **a** requires only the standard forward-backward algorithm.

3.1 Syntax-Sensitive Distortion

The broad and robust success of the HMM alignment model underscores the utility of its assumptions: that word-level translations can be usefully modeled via first-degree Markov transitions and independent lexical productions. However, its distortion model considers only string distance, disregarding the constituent structure of the English sentence.

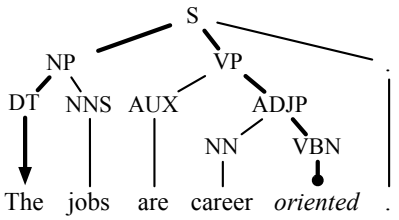
To allow syntax-sensitive distortion, we consider a new distortion model of the form $p_d(a_j|a_{j_-}, j, t)$. We condition on t via a generative process that transitions between two English positions by traversing the unique shortest path $\rho_{(a_{j_-}, a_j, t)}$ through t from a_{j_-} to a_j. We constrain ourselves to this shortest path using a staged generative process.

Stage 1 (POP$(\hat{n})$, STOP$(\hat{n})$): Starting in the leaf node at a_{j_-}, we choose whether to STOP or POP from child to parent, conditioning on the type of the parent node $\hat{n}$. Upon choosing STOP, we transition to stage 2.

Stage 2 (MOVE$(\hat{n}, d)$): Again, conditioning on the type of the parent $\hat{n}$ of the current node n, we choose a sibling $\bar{n}$ based on the signed distance $d = \phi_{\hat{n}}(n) - \phi_{\hat{n}}(\bar{n})$, where $\phi_{\hat{n}}(n)$ is the index of n in the child list of $\hat{n}$. Zero distance moves are disallowed. After exactly one MOVE, we transition to stage 3.

Stage 3 (PUSH$(n, \phi_n(\breve{n}))$): Given the current node n, we select one of its children $\breve{n}$, conditioning on the type of n and the position of the child $\phi_n(\breve{n})$. We continue to PUSH until reaching a leaf.

This process is a first-degree Markov walk through the tree, conditioning on the current node and its immediate surroundings at each step. We enforce the property that $\rho_{(a_{j_-}, a_j, t)}$ be unique by staging the process and disallowing zero distance moves in stage 2. Figure 2 gives an example sequence of tree transitions for a small parse tree.



Stage 1: { Pop(VBN), Pop(ADJP), Pop(VP), Stop(S) }
Stage 2: { Move(S, -1) }
Stage 3: { Push(NP, 1), Push(DT, 1) }

Figure 2: An example sequence of staged tree transitions implied by the unique shortest path from the word *oriented* ($a_{j_-} = 5$) to the word *the* ($a_j = 1$).

The parameterization of this distortion model follows directly from its generative process. Given a path $\rho_{(a_{j_-}, a_j, t)}$ with $r = k + m + 3$ nodes including the two leaves, the nearest common ancestor, k intervening nodes on the ascent and m on the descent, we express it as a triple of staged tree transitions that include k POPs, a STOP, a MOVE, and m PUSHes:

$$\begin{pmatrix} \{\text{POP}(n_2), ..., \text{POP}(n_{k+1}), \text{STOP}(n_{k+2})\} \\ \{\text{MOVE}\,(n_{k+2}, \phi(n_{k+3}) - \phi(n_{k+1}))\} \\ \{\text{PUSH}\,(n_{k+3}, \phi(n_{k+4}))\,, ..., \text{PUSH}\,(n_{r-1}, \phi(n_r))\} \end{pmatrix}$$

Next, we assign probabilities to each tree transition in each stage. In selecting these distributions, we aim to maintain the original HMM's sensitivity to target word order:

- Selecting POP or STOP is a simple Bernoulli distribution conditioned upon a node type.
- We model both MOVE and PUSH as multinomial distributions over the signed distance in positions (assuming a starting position of 0 for PUSH), echoing the parameterization popular in implementations of the HMM model.

This model reduces to the classic HMM distortion model given minimal English trees of only uniformly labeled pre-terminals and a root node. The classic 0-distance distortion would correspond to the

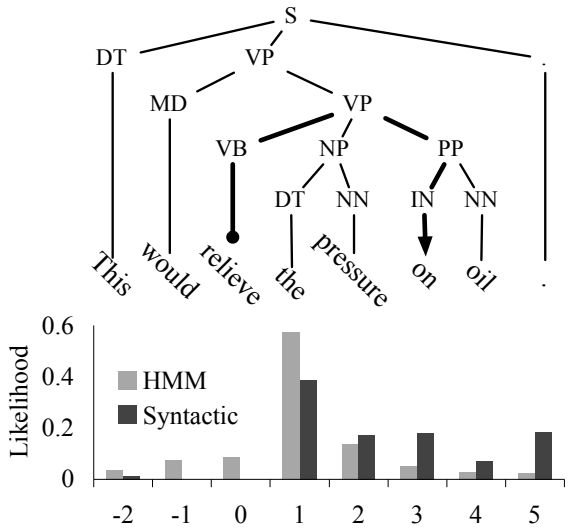


Figure 3: For this example sentence, the learned distortion distribution of $p_d(a_j|a_{j_-}, j, t)$ resembles its counterpart $p_d(a_j|a_{j_-}, j)$ of the HMM model but reflects the constituent structure of the English tree t. For instance, the short path from *relieve* to *on* gives a high transition likelihood.

STOP probability of the pre-terminal label; all other distances would correspond to MOVE probabilities conditioned on the root label, and the probability of transitioning to the terminal state would correspond to the POP probability of the root label.

As in a multinomial-distortion implementation of the classic HMM model, we must sometimes artificially normalize these distributions in the deficient case that certain jumps extend beyond the ends of the local rules. For this reason, MOVE and PUSH are actually parameterized by three values: a node type, a signed distance, and a range of options that dictates a normalization adjustment.

Once each tree transition generates a score, their product gives the probability of the entire path, and thereby the cost of the transition between string positions. Figure 3 shows an example learned distribution that reflects the structure of the given parse.

With these derivation steps in place, we must address a handful of special cases to complete the generative model. We require that the Markov walk from leaf to leaf of the English tree must start and end at the root, using the following assumptions.

1. Given no previous alignment, we forego stages 1 and 2 and begin with a series of PUSHes from the root of the tree to the desired leaf.

2. Given no subsequent alignments, we skip stages 2 and 3 after a series of POPs including a pop conditioned on the root node.

3. If the first choice in stage 1 is to STOP at the current leaf, then stage 2 and 3 are unnecessary. Hence, a choice to STOP immediately is a choice to emit another foreign word from the current English word.

4. We flatten unary transitions from the tree when computing distortion probabilities.

5. Null alignments are treated just as in the HMM model, incurring a fixed cost from any position.

This model can be simplified by removing all conditioning on node types. However, we found this variant to slightly underperform the full model described above. Intuitively, types carry information about cross-linguistic ordering preferences.

3.2 Training Approach

Because our model largely mirrors the generative process and structure of the original HMM model, we apply a nearly identical training procedure to fit the parameters to the training data via the Expectation-Maximization algorithm. Och and Ney (2003) gives a detailed exposition of the technique.

In the E-step, we employ the forward-backward algorithm and current parameters to find expected counts for each potential pair of links in each training pair. In this familiar dynamic programming approach, we must compute the distortion probabilities for each pair of English positions.

The minimal path between two leaves in a tree can be computed efficiently by first finding the path from the root to each leaf, then comparing those paths to find the nearest common ancestor and a path through it – requiring time linear in the height of the tree. Computing distortion costs independently for each pair of words in the sentence imposed a computational overhead of roughly 50% over the original HMM model. The bulk of this increase arises from the fact that distortion probabilities in this model must be computed for each unique tree, in contrast

to the original HMM which has the same distortion probabilities for all sentences of a given length.

In the M-step, we re-estimate the parameters of the model using the expected counts collected during the E-step. All of the component distributions of our lexical and distortion models are multinomials. Thus, upon assuming these expectations as values for the hidden alignment vectors, we maximize likelihood of the training data simply by computing relative frequencies for each component multinomial. For the distortion model, an expected count $c(a_j, a_{j\_})$ is allocated to all tree transitions along the path $\rho_{(a_{j\_},a_j,t)}$. These allocations are summed and normalized for each tree transition type to complete re-estimation. The method of re-estimating the lexical model remains unchanged.

Initialization of the lexical model affects performance dramatically. Using the simple but effective joint training technique of Liang et al. (2006), we initialized the model with lexical parameters from a jointly trained implementation of IBM Model 1.

3.3 Improved Posterior Inference

Liang et al. (2006) shows that thresholding the posterior probabilities of alignments improves AER relative to computing Viterbi alignments. That is, we choose a threshold τ (typically $\tau = 0.5$), and take

$$\mathbf{a} = \{(i, j) : p(a_j = i|\mathbf{f}, \mathbf{e}) > \tau\}.$$

Posterior thresholding provides computationally convenient ways to combine multiple alignments, and bidirectional combination often corrects for errors in individual directional alignment models. Liang et al. (2006) suggests a soft intersection of a model m with a reverse model r (foreign to English) that thresholds the product of their posteriors at each position:

$$\mathbf{a} = \{(i, j) : p_m(a_j = i|\mathbf{f}, \mathbf{e}) \cdot p_r(a_i = j|\mathbf{f}, \mathbf{e}) > \tau\}.$$

These intersected alignments can be quite sparse, boosting precision at the expense of recall. We explore a generalized version to this approach by varying the function c that combines p_m and p_r: $\mathbf{a} = \{(i, j) : c(p_m, p_r) > \tau\}$. If c is the $\max$ function, we recover the (hard) union of the forward and reverse posterior alignments. If c is the $\min$ function, we recover the (hard) intersection. A novel, high performing alternative is the soft union, which we evaluate in the next section:

$$c(p_m, p_r) = \frac{p_m(a_j = i|\mathbf{f}, \mathbf{e}) + p_r(a_i = j|\mathbf{f}, \mathbf{e})}{2}.$$

Syntax-alignment compatibility can be further promoted with a simple posterior decoding heuristic we call *competitive thresholding*. Given a threshold and a matrix c of combined weights for each possible link in an alignment, we include a link (i, j) only if its weight c_{ij} is above-threshold and it is connected to the maximum weighted link in both row i and column j. That is, only the maximum in each column and row and a contiguous enclosing span of above-threshold links are included in the alignment.

3.4 Related Work

This proposed model is not the first variant of the HMM model that incorporates syntax-based distortion. Lopez and Resnik (2005) considers a simpler tree distance distortion model. Daumé III and Marcu (2005) employs a syntax-aware distortion model for aligning summaries to documents, but condition upon the roots of the constituents that are jumped over during a transition, instead of those that are visited during a walk through the tree. In the case of syntactic machine translation, we want to condition on crossing constituent boundaries, even if no constituents are skipped in the process.

4 Experimental Results

To understand the behavior of this model, we computed the standard alignment error rate (AER) performance metric.[2] We also investigated extraction-specific metrics: the frequency of interior nodes – a measure of how often the alignments violate the constituent structure of English parses – and a variant of the CPER metric of Ayan and Dorr (2006).

We evaluated the performance of our model on both French-English and Chinese-English manually aligned data sets. For Chinese, we trained on the FBIS corpus and the LDC bilingual dictionary, then tested on 491 hand-aligned sentences from the 2002

[2]The hand-aligned test data has been annotated with both *sure* alignments S and *possible* alignments P, with $S \subseteq P$, according to the specifications described in Och and Ney (2003). With these alignments, we compute AER for a proposed alignment A as: $\left(1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|}\right) \times 100\%$.

French	Precision	Recall	AER
Classic HMM	93.9	**93.0**	6.5
Syntactic HMM	95.2	91.5	**6.4**
GIZA++	**96.0**	86.1	8.6
Chinese	Precision	Recall	AER
Classic HMM	81.6	78.8	**19.8**
Syntactic HMM	**82.2**	76.8	20.5
GIZA++*	61.9	**82.6**	29.7

Table 1: Alignment error rates (AER) for 100k training sentences. The evaluated alignments are a soft union for French and a hard union for Chinese, both using competitive thresholding decoding. *From Ayan and Dorr (2006), *grow-diag-final* heuristic.

NIST MT evaluation set. For French, we used the Hansards data from the NAACL 2003 Shared Task.[3] We trained on 100k sentences for each language.

4.1 Alignment Error Rate

We compared our model to the original HMM model, identical in implementation to our syntactic HMM model save the distortion component. Both models were initialized using the same jointly trained Model 1 parameters (5 iterations), then trained independently for 5 iterations. Both models were then combined with an independently trained HMM model in the opposite direction: $\mathbf{f} \rightarrow \mathbf{e}$.[4] Table 1 summarizes the results; the two models perform similarly. The main benefit of our model is the effect on rule extraction, discussed below.

We also compared our French results to the public baseline GIZA++ using the script published for the NAACL 2006 Machine Translation Workshop Shared Task.[5] Similarly, we compared our Chinese results to the GIZA++ results in Ayan and Dorr (2006). Our models substantially outperform GIZA++, confirming results in Liang et al. (2006).

Table 2 shows the effect on AER of competitive thresholding and different combination functions.

[3]Following previous work, we developed our system on the 37 provided validation sentences and the first 100 sentences of the corpus test set. We used the remainder as a test set.

[4]Null emission probabilities were fixed to $\frac{1}{|\mathbf{e}|}$, inversely proportional to the length of the English sentence. The decoding threshold was held fixed at $\tau = 0.5$.

[5]Training includes 16 iterations of various IBM models and a fixed null emission probability of .01. The output of running GIZA++ in both directions was combined via intersection.

French	w/o CT	with CT
Hard Intersection (Min)	8.4	8.4
Hard Union (Max)	12.3	7.7
Soft Intersection (Product)	6.9	7.1
Soft Union (Average)	**6.7**	**6.4**
Chinese	w/o CT	with CT
Hard Intersection (Min)	27.4	27.4
Hard Union (Max)	25.0	**20.5**
Soft Intersection (Product)	25.0	25.2
Soft Union (Average)	**21.1**	21.6

Table 2: Alignment error rates (AER) by decoding method for the syntactic HMM model. The competitive thresholding heuristic (CT) is particularly helpful for the hard union combination method.

The most dramatic effect of competitive thresholding is to improve alignment quality for hard unions. It also impacts rule extraction substantially.

4.2 Rule Extraction Results

While its competitive AER certainly speaks to the potential utility of our syntactic distortion model, we proposed the model for a different purpose: to minimize the particularly troubling alignment errors that cross constituent boundaries and violate the structure of English parse trees. We found that while the HMM and Syntactic models have very similar AER, they make substantially different errors.

To investigate the differences, we measured the degree to which each set of alignments violated the supplied parse trees, by counting the frequency of interior nodes that are not null aligned. Figure 4 summarizes the results of the experiment for French: the Syntactic distortion with competitive thresholding reduces tree violations substantially. Interior node frequency is reduced by 56% overall, with the most dramatic improvement observed for clausal constituents. We observed a similar 50% reduction for the Chinese data.

Additionally, we evaluated our model with the transducer analog to the consistent phrase error rate (CPER) metric of Ayan and Dorr (2006). This evaluation computes precision, recall, and F1 of the rules extracted under a proposed alignment, relative to the rules extracted under the gold-standard sure alignments. Table 3 shows improvements in F1 by using

	NP	VP	PP	S	SBAR	Non-Terminals	All
Reduction (percent)	54.1	46.3	52.4	77.5	58.0	53.1	56.3
Corpus Frequency	14.6	10.3	6.3	4.8	1.9	41.1	100.0

Figure 4: The syntactic distortion model with competitive thresholding decreases the frequency of interior nodes for each type and the whole corpus.

the syntactic HMM model and competitive thresholding together. Individually, each of these changes contributes substantially to this increase. Together, their benefits are partially, but not fully, additive.

5 Conclusion

In light of the need to reconcile word alignments with phrase structure trees for syntactic MT, we have proposed an HMM-like model whose distortion is sensitive to such trees. Our model substantially reduces the number of interior nodes in the aligned corpus and improves rule extraction while nearly retaining the speed and alignment accuracy of the HMM model. While it remains to be seen whether these improvements impact final translation accuracy, it is reasonable to hope that, all else equal, alignments which better respect syntactic correspondences will be superior for syntactic MT.

French	Prec.	Recall	F1
Classic HMM Baseline	40.9	17.6	24.6
Syntactic HMM + CT	33.9	22.4	27.0
Relative change	-17%	27%	10%

Chinese	Prec.	Recall	F1
HMM Baseline (hard)	**66.1**	14.5	23.7
HMM Baseline (soft)	36.7	39.1	37.8
Syntactic + CT (hard)	48.0	41.6	**44.6**
Syntactic + CT (soft)	32.9	**48.7**	39.2
*Relative change**	31%	6%	18%

Table 3: Relative to the classic HMM baseline, our syntactic distortion model with competitive thresholding improves the tradeoff between precision and recall of extracted transducer rules. Both French aligners were decoded using the best-performing soft union combiner. For Chinese, we show aligners under both soft and hard union combiners. *Denotes relative change from the second line to the third line.

Abstract

Statistical machine translation systems are usually trained on large amounts of bilingual text and monolingual text in the target language. In this paper we explore the use of transductive semi-supervised methods for the effective use of monolingual data from the source language in order to improve translation quality. We propose several algorithms with this aim, and present the strengths and weaknesses of each one. We present detailed experimental evaluations on the French–English EuroParl data set and on data from the NIST Chinese–English large-data track. We show a significant improvement in translation quality on both tasks.

1 Introduction

In statistical machine translation (SMT), translation is modeled as a decision process. The goal is to find the translation **t** of source sentence **s** which maximizes the posterior probability:

$$\arg\max_{\mathbf{t}} p(\mathbf{t} \mid \mathbf{s}) = \arg\max_{\mathbf{t}} p(\mathbf{s} \mid \mathbf{t}) \cdot p(\mathbf{t}) \qquad (1)$$

This decomposition of the probability yields two different statistical models which can be trained independently of each other: the translation model $p(\mathbf{s} \mid \mathbf{t})$ and the target language model $p(\mathbf{t})$.

State-of-the-art SMT systems are trained on large collections of text which consist of bilingual corpora (to learn the parameters of $p(\mathbf{s} \mid \mathbf{t})$), and of monolingual target language corpora (for $p(\mathbf{t})$). It has been shown that adding large amounts of target language text improves translation quality considerably. However, the availability of monolingual corpora in the source language does not help improve the system's performance. We will show how such corpora can be used to achieve higher translation quality.

Even if large amounts of bilingual text are given, the training of the statistical models usually suffers from sparse data. The number of possible events, i.e. phrase pairs or pairs of subtrees in the two languages, is too big to reliably estimate a probability distribution over such pairs. Another problem is that for many language pairs the amount of available bilingual text is very limited. In this work, we will address this problem and propose a general framework to solve it. Our hypothesis is that adding information from source language text can also provide improvements. Unlike adding target language text, this hypothesis is a natural semi-supervised learning problem. To tackle this problem, we propose algorithms for transductive semi-supervised learning. By transductive, we mean that we repeatedly translate sentences from the development set or test set and use the generated translations to improve the performance of the SMT system. Note that the evaluation step is still done just once at the end of our learning process. In this paper, we show that such an approach can lead to better translations despite the fact that the development and test data are typically much smaller in size than typical training data for SMT systems.

Transductive learning can be seen as a means to adapt the SMT system to a new type of text. Say a system trained on newswire is used to translate weblog texts. The proposed method adapts the trained models to the style and domain of the new input.

2 Baseline MT System

The SMT system we applied in our experiments is PORTAGE. This is a state-of-the-art phrase-based translation system which has been made available

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 25–32,
Prague, Czech Republic, June 2007.

to Canadian universities for research and education purposes. We provide a basic description here; for a detailed description see (Ueffing et al., 2007).

The models (or features) which are employed by the decoder are: (a) one or several phrase table(s), which model the translation direction $p(\mathbf{s} \mid \mathbf{t})$, (b) one or several n-gram language model(s) trained with the SRILM toolkit (Stolcke, 2002); in the experiments reported here, we used 4-gram models on the NIST data, and a trigram model on EuroParl, (c) a distortion model which assigns a penalty based on the number of source words which are skipped when generating a new target phrase, and (d) a word penalty. These different models are combined log-linearly. Their weights are optimized w.r.t. BLEU score using the algorithm described in (Och, 2003). This is done on a development corpus which we will call dev1 in this paper. The search algorithm implemented in the decoder is a dynamic-programming beam-search algorithm.

After the main decoding step, rescoring with additional models is performed. The system generates a 5,000-best list of alternative translations for each source sentence. These lists are rescored with the following models: (a) the different models used in the decoder which are described above, (b) two different features based on IBM Model 1 (Brown et al., 1993), (c) posterior probabilities for words, phrases, n-grams, and sentence length (Zens and Ney, 2006; Ueffing and Ney, 2007), all calculated over the N-best list and using the sentence probabilities which the baseline system assigns to the translation hypotheses. The weights of these additional models and of the decoder models are again optimized to maximize BLEU score. This is performed on a second development corpus, dev2.

3 The Framework

3.1 The Algorithm

Our transductive learning algorithm, Algorithm 1, is inspired by the Yarowsky algorithm (Yarowsky, 1995; Abney, 2004). The algorithm works as follows: First, the translation model is estimated based on the sentence pairs in the bilingual training data L. Then, a set of source language sentences, U, is translated based on the current model. A subset of good translations and their sources, T_i, is selected in each iteration and added to the training data. These selected sentence pairs are replaced in each iteration, and only the original bilingual training data, L, is kept fixed throughout the algorithm. The process of generating sentence pairs, selecting a subset of good sentence pairs, and updating the model is continued until a stopping condition is met. Note that we run this algorithm in a transductive setting which means that the set of sentences U is drawn either from a development set or the test set that will be used eventually to evaluate the SMT system or from additional data which is relevant to the development or test set. In Algorithm 1, changing the definition of **Estimate**, **Score** and **Select** will give us the different semi-supervised learning algorithms we will discuss in this paper.

Given the probability model $p(\mathbf{t} \mid \mathbf{s})$, consider the distribution over all possible valid translations **t** for a particular input sentence **s**. We can initialize this probability distribution to the uniform distribution for each sentence **s** in the unlabeled data U. Thus, this distribution over translations of sentences from U will have the maximum entropy. Under certain precise conditions, as described in (Abney, 2004), we can analyze Algorithm 1 as minimizing the entropy of the distribution over translations of U. However, this is true only when the functions **Estimate**, **Score** and **Select** have very prescribed definitions. In this paper, rather than analyze the convergence of Algorithm 1 we run it for a fixed number of iterations and instead focus on finding useful definitions for **Estimate**, **Score** and **Select** that can be experimentally shown to improve MT performance.

3.2 The Estimate Function

We consider the following different definitions for **Estimate** in Algorithm 1:

Full Re-training (of all translation models): If **Estimate**(L, T) estimates the model parameters based on $L \cup T$, then we have a semi-supervised algorithm that re-trains a model on the original training data L plus the sentences decoded in the last iteration. The size of L can be controlled by **filtering** the training data (see Section 3.5).

Additional Phrase Table: If, on the other hand, a new phrase translation table is learned on T only and then added as a new component in the log-linear model, we have an alternative to the full re-training

Algorithm 1 Transductive learning algorithm for statistical machine translation

Input: training set L of parallel sentence pairs. // Bilingual training data.
Input: unlabeled set U of source text. // Monolingual source language data.
Input: number of iterations R, and size of n-best list N.
$T_{-1} := \{\}$. // Additional bilingual training data.
$i := 0$. // Iteration counter.
repeat
  Training step: $\pi^{(i)} :=$ **Estimate**(L, T_{i-1}).
  $X_i := \{\}$. // The set of generated translations for this iteration.
  for sentence $\mathbf{s} \in U$ **do**
    Labeling step: Decode $\mathbf{s}$ using $\pi^{(i)}$ to obtain N best sentence pairs with their scores
    $X_i := X_i \cup \{(\mathbf{t}_n, \mathbf{s}, \pi^{(i)}(\mathbf{t}_n \,|\, \mathbf{s}))_{n=1}^{N}\}$
  end for
  Scoring step: $S_i :=$ **Score**(X_i) // Assign a score to sentence pairs $(\mathbf{t}, \mathbf{s})$ from X.
  Selection step: $T_i :=$ **Select**(X_i, S_i) // Choose a subset of *good* sentence pairs $(\mathbf{t}, \mathbf{s})$ from X.
  $i := i + 1$.
until $i > R$

of the model on labeled and unlabeled data which can be very expensive if L is very large (as on the Chinese–English data set). This additional phrase table is small and specific to the development or test set it is trained on. It overlaps with the original phrase tables, but also contains many new phrase pairs (Ueffing, 2006).

Mixture Model: Another alternative for **Estimate** is to create a mixture model of the phrase table probabilities with new phrase table probabilities

$$p(\mathbf{s} \,|\, \mathbf{t}) = \lambda \cdot L_p(\mathbf{s} \,|\, \mathbf{t}) + (1 - \lambda) \cdot T_p(\mathbf{s} \,|\, \mathbf{t}) \qquad (2)$$

where L_p and T_p are phrase table probabilities estimated on L and T, respectively. In cases where new phrase pairs are learned from T, they get added into the merged phrase table.

3.3 The Scoring Function

In Algorithm 1, the **Score** function assigns a score to each translation hypothesis **t**. We used the following scoring functions in our experiments:

Length-normalized Score: Each translated sentence pair $(\mathbf{t}, \mathbf{s})$ is scored according to the model probability $p(\mathbf{t} \,|\, \mathbf{s})$ normalized by the length $|\mathbf{t}|$ of the target sentence:

$$\textbf{Score}(\mathbf{t}, \mathbf{s}) \quad = \quad p(\mathbf{t} \,|\, \mathbf{s})^{\frac{1}{|\mathbf{t}|}} \qquad (3)$$

Confidence Estimation: The confidence estimation which we implemented follows the approaches suggested in (Blatz et al., 2003; Ueffing and Ney, 2007): The confidence score of a target sentence **t** is calculated as a log-linear combination of phrase posterior probabilities, Levenshtein-based word posterior probabilities, and a target language model score. The weights of the different scores are optimized w.r.t. classification error rate (CER).

The phrase posterior probabilities are determined by summing the sentence probabilities of all translation hypotheses in the N-best list which contain this phrase pair. The segmentation of the sentence into phrases is provided by the decoder. This sum is then normalized by the total probability mass of the N-best list. To obtain a score for the whole target sentence, the posterior probabilities of all target phrases are multiplied. The word posterior probabilities are calculated on basis of the Levenshtein alignment between the hypothesis under consideration and all other translations contained in the N-best list. For details, see (Ueffing and Ney, 2007). Again, the single values are multiplied to obtain a score for the whole sentence. For NIST, the language model score is determined using a 5-gram model trained on the English Gigaword corpus, and on French–English, we use the trigram model which was provided for the NAACL 2006 shared task.

3.4 The Selection Function

The **Select** function in Algorithm 1 is used to create the additional training data T_i which will be used in

the next iteration $i + 1$ by **Estimate** to augment the original bilingual training data. We use the following selection functions:

Importance Sampling: For each sentence **s** in the set of unlabeled sentences U, the Labeling step in Algorithm 1 generates an N-best list of translations, and the subsequent Scoring step assigns a score for each translation **t** in this list. The set of generated translations for all sentences in U is the event space and the scores are used to put a probability distribution over this space, simply by renormalizing the scores described in Section 3.3. We use importance sampling to select K translations from this distribution. Sampling is done with replacement which means that the same translation may be chosen several times. These K sampled translations and their associated source sentences make up the additional training data T_i.

Selection using a Threshold: This method compares the score of each single-best translation to a threshold. The translation is considered reliable and added to the set T_i if its score exceeds the threshold. Else it is discarded and not used in the additional training data. The threshold is optimized on the development beforehand. Since the scores of the translations change in each iteration, the size of T_i also changes.

Keep All: This method does not perform any filtering at all. It is simply assumed that all translations in the set X_i are reliable, and none of them are discarded. Thus, in each iteration, the result of the selection step will be $T_i = X_i$. This method was implemented mainly for comparison with other selection methods.

3.5 Filtering the Training Data

In general, having more training data improves the quality of the trained models. However, when it comes to the translation of a particular test set, the question is whether *all* of the available training data are relevant to the translation task or not. Moreover, working with large amounts of training data requires more computational power. So if we can identify a subset of training data which are relevant to the current task and use only this to re-train the models, we can reduce computational complexity significantly.

We propose to **Filter** the training data, either bilingual or monolingual text, to identify the parts which are relevant w.r.t. the test set. This filtering is based on n-gram coverage. For a source sentence **s** in the training data, its n-gram coverage over the sentences in the test set is computed. The average over several n-gram lengths is used as a measure of relevance of this training sentence w.r.t. the test corpus. Based on this, we select the top K source sentences or sentence pairs.

4 Experimental Results

4.1 Setting

We ran experiments on two different corpora: one is the French–English translation task from the EuroParl corpus, and the other one is Chinese–English translation as performed in the NIST MT evaluation (www.nist.gov/speech/tests/mt).

For the French–English translation task, we used the EuroParl corpus as distributed for the shared task in the NAACL 2006 workshop on statistical machine translation. The corpus statistics are shown in Table 1. Furthermore we filtered the EuroParl corpus, as explained in Section 3.5, to create two smaller bilingual corpora (train100k and train150k in Table 1). The development set is used to optimize the model weights in the decoder, and the evaluation is done on the test set provided for the NAACL 2006 shared task.

For the Chinese–English translation task, we used the corpora distributed for the large-data track in the

Table 3: Feasibility of settings for Algorithm 1

2006 NIST evaluation (see Table 2). We used the LDC segmenter for Chinese. The multiple translation corpora multi-p3 and multi-p4 were used as development corpora. Evaluation was performed on the 2004 and 2006 test sets. Note that the training data consists mainly of written text, whereas the test sets comprise three and four different genres: editorials, newswire and political speeches in the 2004 test set, and broadcast conversations, broadcast news, newsgroups and newswire in the 2006 test set. Most of these domains have characteristics which are different from those of the training data, e.g., broadcast conversations have characteristics of spontaneous speech, and the newsgroup data is comparatively unstructured.

Given the particular data sets described above, Table 3 shows the various options for the **Estimate**, **Score** and **Select** functions (see Section 3). The table provides a quick guide to the experiments we present in this paper vs. those we did not attempt due to computational infeasibility. We ran experiments corresponding to all entries marked with $*$ (see Section 4.2). For those marked $**$ the experiments produced only minimal improvement over the baseline and so we do not discuss them in this paper. The entries marked as † were not attempted because they are not feasible (e.g. full re-training on the NIST data). However, these were run on the smaller EuroParl corpus.

Evaluation Metrics

We evaluated the generated translations using three different evaluation metrics: BLEU score (Papineni et al., 2002), mWER (multi-reference word error rate), and mPER (multi-reference position-independent word error rate) (Nießen et al., 2000). Note that BLEU score measures quality, whereas mWER and mPER measure translation errors. We will present 95%-confidence intervals for the baseline system which are calculated using bootstrap resampling. The metrics are calculated w.r.t. one and four English references: the EuroParl data comes with one reference, the NIST 2004 evaluation set and the NIST section of the 2006 evaluation set are provided with four references each, whereas the GALE section of the 2006 evaluation set comes with one reference only. This results in much lower BLEU scores and higher error rates for the translations of the GALE set (see Section 4.2). Note that these values do not indicate lower translation quality, but are simply a result of using only one reference.

4.2 Results

EuroParl

We ran our initial experiments on EuroParl to explore the behavior of the transductive learning algorithm. In all experiments reported in this subsection, the test set was used as unlabeled data. The selection and scoring was carried out using importance sampling with normalized scores. In one set of experiments, we used the 100K and 150K training sentences filtered according to n-gram coverage over the test set. We fully re-trained the phrase tables on these data and 8,000 test sentence pairs sampled from 20-best lists in each iteration. The results on the test set can be seen in Figure 1. The BLEU score increases, although with slight variation, over the iterations. In total, it increases from 24.1 to 24.4 for the 100K filtered corpus, and from 24.5 to 24.8 for 150K, respectively. Moreover, we see that the BLEU score of the system using 100K training sentence pairs and transductive learning is the same as that of the one trained on 150K sentence pairs. So the information extracted from untranslated test sentences is equivalent to having an additional 50K sentence pairs.

In a second set of experiments, we used the whole EuroParl corpus and the sampled sentences for fully re-training the phrase tables in each iteration. We ran the algorithm for three iterations and the BLEU score increased from 25.3 to 25.6. Even though this

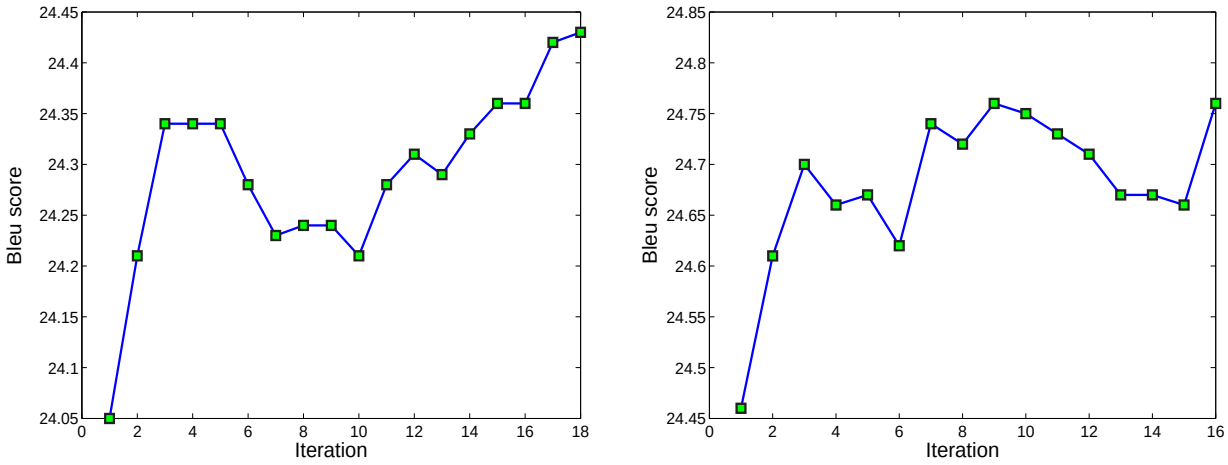

Figure 1: Translation quality for importance sampling with full re-training on train100k (left) and train150k (right). EuroParl French–English task.

is a small increase, it shows that the unlabeled data contains some information which can be explored in transductive learning.

In a third experiment, we applied the mixture model idea as explained in Section 3.2. The initially learned phrase table was merged with the learned phrase table in each iteration with a weight of $\lambda = 0.1$. This value for λ was found based on cross validation on a development set. We ran the algorithm for 20 iterations and BLEU score increased from 25.3 to 25.7. Since this is very similar to the result obtained with the previous method, but with an additional parameter λ to optimize, we did not use mixture models on NIST.

Note that the single improvements achieved here are slightly below the 95%-significance level. However, we observe them consistently in all settings.

NIST

Table 4 presents translation results on NIST with different versions of the scoring and selection methods introduced in Section 3. In these experiments, the unlabeled data U for Algorithm 1 is the development or test corpus. For this corpus U, 5,000-best lists were generated using the baseline SMT system. Since re-training the full phrase tables is not feasible here, a (small) additional phrase table, specific to U, was trained and plugged into the SMT system as an additional model. The decoder weights thus had to be optimized again to determine the appropriate weight for this new phrase table. This was done on the dev1 corpus, using the phrase table specific to dev1. Every time a new corpus is to be translated, an adapted phrase table is created using transductive learning and used with the weight which has been learned on dev1. In the first experiment presented in Table 4, all of the generated 1-best translations were kept and used for training the adapted phrase tables. This method yields slightly higher translation quality than the baseline system. The second approach we studied is the use of importance sampling (IS) over 20-best lists, based either on length-normalized sentence scores (norm.) or confidence scores (conf.). As the results in Table 4 show, both variants outperform the first method, with a consistent improvement over the baseline across all test corpora and evaluation metrics. The third method uses a threshold-based selection method. Combined with confidence estimation as scoring method, this yields the best results. All improvements over the baseline are significant at the 95%-level.

Table 5 shows the translation quality achieved on the NIST test sets when additional source language data from the Chinese Gigaword corpus comprising newswire text is used for transductive learning. These Chinese sentences were sorted according to their n-gram overlap (see Section 3.5) with the development corpus, and the top 5,000 Chinese sentences were used. The selection and scoring in Algorithm 1 were performed using confidence estimation with a threshold. Again, a new phrase table was trained on these data. As can be seen in Table 5, this

Table 4: Translation quality using an additional adapted phrase table trained on the dev/test sets. Different selection and scoring methods. NIST Chinese–English, best results printed in boldface.

system outperforms the baseline system on all test corpora. The error rates are significantly reduced in all three settings, and BLEU score increases in all cases. A comparison with Table 4 shows that transductive learning on the development set and test corpora, adapting the system to their domain and style, is more effective in improving the SMT system than the use of additional source language data.

In all experiments on NIST, Algorithm 1 was run for one iteration. We also investigated the use of an iterative procedure here, but this did not yield any improvement in translation quality.

5 Previous Work

Semi-supervised learning has been previously applied to improve word alignments. In (Callison-Burch et al., 2004), a generative model for word alignment is trained using unsupervised learning on parallel text. In addition, another model is trained on a small amount of hand-annotated word alignment data. A mixture model provides a probability for word alignment. Experiments showed that putting a large weight on the model trained on labeled data performs best. Along similar lines, (Fraser and Marcu, 2006) combine a generative model of word alignment with a log-linear discriminative model trained on a small set of hand aligned sentences. The word alignments are used to train a standard phrase-based SMT system, resulting in increased translation quality .

Table 5: Translation quality using an additional phrase table trained on monolingual Chinese news data. Selection step using threshold on confidence scores. NIST Chinese–English.

In (Callison-Burch, 2002) co-training is applied to MT. This approach requires several source languages which are sentence-aligned with each other and all translate into the same target language. One language pair creates data for another language pair and can be naturally used in a (Blum and Mitchell, 1998)-style co-training algorithm. Experiments on the EuroParl corpus show a decrease in WER. However, the selection algorithm applied there is actually supervised because it takes the reference translation into account. Moreover, when the algorithm is run long enough, large amounts of co-trained data injected too much noise and performance degraded.

Self-training for SMT was proposed in (Ueffing, 2006). An existing SMT system is used to translate the development or test corpus. Among the generated machine translations, the reliable ones are automatically identified using thresholding on confidence scores. The work which we presented here differs from (Ueffing, 2006) as follows:

- We investigated different ways of scoring and selecting the reliable translations and compared our method to this work. In addition to the con-

fidence estimation used there, we applied importance sampling and combined it with confidence estimation for transductive learning.

- We studied additional ways of exploring the newly created bilingual data, namely re-training the full phrase translation model or creating a mixture model.
- We proposed an iterative procedure which translates the monolingual source language data anew in each iteration and then re-trains the phrase translation model.
- We showed how additional monolingual source-language data can be used in transductive learning to improve the SMT system.

6 Discussion

It is not intuitively clear why the SMT system can learn something from its own output and is improved through semi-supervised learning. There are two main reasons for this improvement: Firstly, the selection step provides important feedback for the system. The confidence estimation, for example, discards translations with low language model scores or posterior probabilities. The selection step discards bad machine translations and reinforces phrases of high quality. As a result, the probabilities of low-quality phrase pairs, such as noise in the table or overly confident singletons, degrade. Our experiments comparing the various settings for transductive learning shows that selection clearly outperforms the method which keeps all generated translations as additional training data. The selection methods investigated here have been shown to be well-suited to boost the performance of semi-supervised learning for SMT.

Secondly, our algorithm constitutes a way of adapting the SMT system to a new domain or style without requiring bilingual training or development data. Those phrases in the existing phrase tables which are relevant for translating the new data are reinforced. The probability distribution over the phrase pairs thus gets more focused on the (reliable) parts which are relevant for the test data. For an analysis of the self-trained phrase tables, examples of translated sentences, and the phrases used in translation, see (Ueffing, 2006).

Abstract

Recent research presents conflicting evidence on whether word sense disambiguation (WSD) systems can help to improve the performance of statistical machine translation (MT) systems. In this paper, we successfully integrate a state-of-the-art WSD system into a state-of-the-art hierarchical phrase-based MT system, Hiero. We show for the first time that integrating a WSD system improves the performance of a state-of-the-art statistical MT system on an actual translation task. Furthermore, the improvement is statistically significant.

1 Introduction

Many words have multiple meanings, depending on the context in which they are used. Word sense disambiguation (WSD) is the task of determining the correct meaning or sense of a word in context. WSD is regarded as an important research problem and is assumed to be helpful for applications such as machine translation (MT) and information retrieval.

In translation, different senses of a word *w* in a source language may have different translations in a target language, depending on the particular meaning of *w* in context. Hence, the assumption is that in resolving sense ambiguity, a WSD system will be able to help an MT system to determine the correct translation for an ambiguous word. To determine the correct sense of a word, WSD systems typically use a wide array of features that are not limited to the local context of *w*, and some of these features may not be used by state-of-the-art statistical MT systems.

To perform translation, state-of-the-art MT systems use a statistical phrase-based approach (Marcu and Wong, 2002; Koehn et al., 2003; Och and Ney, 2004) by treating phrases as the basic units of translation. In this approach, a phrase can be any sequence of consecutive words and is not necessarily linguistically meaningful. Capitalizing on the strength of the phrase-based approach, Chiang (2005) introduced a *hierarchical* phrase-based statistical MT system, Hiero, which achieves significantly better translation performance than Pharaoh (Koehn, 2004a), which is a state-of-the-art phrase-based statistical MT system.

Recently, some researchers investigated whether performing WSD will help to improve the performance of an MT system. Carpuat and Wu (2005) integrated the translation predictions from a Chinese WSD system (Carpuat et al., 2004) into a Chinese-English word-based statistical MT system using the ISI ReWrite decoder (Germann, 2003). Though they acknowledged that directly using English translations as word senses would be ideal, they instead predicted the HowNet sense of a word and then used the English gloss of the HowNet sense as the WSD model's predicted translation. They did not incorporate their WSD model or its predictions into their translation model; rather, they used the WSD predictions either to constrain the options available to their decoder, or to postedit the output of their decoder. They reported the negative result that WSD decreased the performance of MT based on their experiments.

In another work (Vickrey et al., 2005), the WSD problem was recast as a *word translation* task. The

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 33–40,
Prague, Czech Republic, June 2007.

translation choices for a word *w* were defined as the set of words or phrases aligned to *w*, as gathered from a word-aligned parallel corpus. The authors showed that they were able to improve their model's accuracy on two simplified translation tasks: word translation and blank-filling.

Recently, Cabezas and Resnik (2005) experimented with incorporating WSD translations into Pharaoh, a state-of-the-art phrase-based MT system (Koehn et al., 2003). Their WSD system provided additional translations to the phrase table of Pharaoh, which fired a new model feature, so that the decoder could weigh the additional alternative translations against its own. However, they could not automatically tune the weight of this feature in the same way as the others. They obtained a relatively small improvement, and no statistical significance test was reported to determine if the improvement was statistically significant.

Note that the experiments in (Carpuat and Wu, 2005) did not use a state-of-the-art MT system, while the experiments in (Vickrey et al., 2005) were not done using a full-fledged MT system and the evaluation was not on how well each source sentence was translated as a whole. The relatively small improvement reported by Cabezas and Resnik (2005) without a statistical significance test appears to be inconclusive. Considering the conflicting results reported by prior work, it is not clear whether a WSD system can help to improve the performance of a state-of-the-art statistical MT system.

In this paper, we successfully integrate a state-of-the-art WSD system into the state-of-the-art hierarchical phrase-based MT system, Hiero (Chiang, 2005). The integration is accomplished by introducing two additional features into the MT model which operate on the existing rules of the grammar, without introducing competing rules. These features are treated, both in feature-weight tuning and in decoding, on the same footing as the rest of the model, allowing it to weigh the WSD model predictions against other pieces of evidence so as to optimize translation accuracy (as measured by BLEU). The contribution of our work lies in showing for the first time that integrating a WSD system significantly improves the performance of a state-of-the-art statistical MT system on an actual translation task.

In the next section, we describe our WSD system. Then, in Section 3, we describe the Hiero MT system and introduce the two new features used to integrate the WSD system into Hiero. In Section 4, we describe the training data used by the WSD system. In Section 5, we describe how the WSD translations provided are used by the decoder of the MT system. In Section 6 and 7, we present and analyze our experimental results, before concluding in Section 8.

2 Word Sense Disambiguation

Prior research has shown that using Support Vector Machines (SVM) as the learning algorithm for WSD achieves good results (Lee and Ng, 2002). For our experiments, we use the SVM implementation of (Chang and Lin, 2001) as it is able to work on multi-class problems to output the classification probability for each class.

Our implemented WSD classifier uses the knowledge sources of local collocations, parts-of-speech (POS), and surrounding words, following the successful approach of (Lee and Ng, 2002). For local collocations, we use 3 features, $w_{-1}w_{+1}$, w_{-1}, and w_{+1}, where w_{-1} (w_{+1}) is the token immediately to the left (right) of the current ambiguous word occurrence w. For parts-of-speech, we use 3 features, P_{-1}, P_0, and P_{+1}, where P_0 is the POS of w, and P_{-1} (P_{+1}) is the POS of w_{-1} (w_{+1}). For surrounding words, we consider all unigrams (single words) in the surrounding context of *w*. These unigrams can be in a different sentence from *w*. We perform feature selection on surrounding words by including a unigram only if it occurs 3 or more times in some sense of *w* in the training data.

To measure the accuracy of our WSD classifier, we evaluate it on the test data of SENSEVAL-3 Chinese lexical-sample task. We obtain accuracy that compares favorably to the best participating system in the task (Carpuat et al., 2004).

3 Hiero

Hiero (Chiang, 2005) is a hierarchical phrase-based model for statistical machine translation, based on weighted synchronous context-free grammar (CFG) (Lewis and Stearns, 1968). A synchronous CFG consists of rewrite rules such as the following:

$$\mathrm{X} \rightarrow \langle \gamma, \alpha \rangle \quad (1)$$

where X is a non-terminal symbol, γ (α) is a string of terminal and non-terminal symbols in the source (target) language, and there is a one-to-one correspondence between the non-terminals in γ and α indicated by co-indexation. Hence, γ and α always have the same number of non-terminal symbols. For instance, we could have the following grammar rule:

$$\text{X} \rightarrow \langle \text{每 月 到 X}_{\boxed{1}}, \text{go to X}_{\boxed{1}} \text{ every month to} \rangle \quad (2)$$

where boxed indices represent the correspondences between non-terminal symbols.

Hiero extracts the synchronous CFG rules automatically from a word-aligned parallel corpus. To translate a source sentence, the goal is to find its most probable derivation using the extracted grammar rules. Hiero uses a general log-linear model (Och and Ney, 2002) where the weight of a derivation D for a particular source sentence and its translation is

$$w(D) = \prod_i \phi_i(D)^{\lambda_i} \quad (3)$$

where ϕ_i is a feature function and λ_i is the weight for feature ϕ_i. To ensure efficient decoding, the ϕ_i are subject to certain locality restrictions. Essentially, they should be defined as products of functions defined on isolated synchronous CGF rules; however, it is possible to extend the domain of locality of the features somewhat. A *n*-gram language model adds a dependence on ($n-1$) neighboring target-side words (Wu, 1996; Chiang, 2007), making decoding much more difficult but still polynomial; in this paper, we add features that depend on the neighboring *source-side* words, which does not affect decoding complexity at all because the source string is fixed. In principle we could add features that depend on arbitrary source-side context.

3.1 New Features in Hiero for WSD

To incorporate WSD into Hiero, we use the translations proposed by the WSD system to help Hiero obtain a better or more probable derivation during the translation of each source sentence. To achieve this, when a grammar rule *R* is considered during decoding, and we recognize that some of the terminal symbols (words) in α are also chosen by the WSD system as translations for some terminal symbols (words) in γ, we compute the following features:

- $P_{wsd}(t \mid s)$ gives the contextual probability of the WSD classifier choosing t as a translation for s, where t (s) is some substring of terminal symbols in α (γ). Because this probability only applies to some rules, and we don't want to penalize those rules, we must add another feature,

- $Pty_{wsd} = \exp(-|t|)$, where t is the translation chosen by the WSD system. This feature, with a negative weight, rewards rules that use translations suggested by the WSD module.

Note that we can take the negative logarithm of the rule/derivation weights and think of them as costs rather than probabilities.

4 Gathering Training Examples for WSD

Our experiments were for Chinese to English translation. Hence, in the context of our work, a synchronous CFG grammar rule $\text{X} \rightarrow \langle \gamma, \alpha \rangle$ gathered by Hiero consists of a Chinese portion γ and a corresponding English portion α, where each portion is a sequence of words and non-terminal symbols.

Our WSD classifier suggests a list of English phrases (where each phrase consists of one or more English words) with associated contextual probabilities as possible translations for each particular Chinese phrase. In general, the Chinese phrase may consist of *k* Chinese words, where $k = 1, 2, 3, \ldots$. However, we limit k to 1 or 2 for experiments reported in this paper. Future work can explore enlarging *k*.

Whenever Hiero is about to extract a grammar rule where its Chinese portion is a phrase of one or two Chinese words with no non-terminal symbols, we note the location (sentence and token offset) in the Chinese half of the parallel corpus from which the Chinese portion of the rule is extracted. The actual sentence in the corpus containing the Chinese phrase, and the one sentence before and the one sentence after that actual sentence, will serve as the context for one training example for the Chinese phrase, with the corresponding English phrase of the grammar rule as its translation. Hence, unlike traditional WSD where the sense classes are tied to a specific sense inventory, our "senses" here consist of the English phrases extracted as translations for each Chinese phrase. Since the extracted training data may

be noisy, for each Chinese phrase, we remove English translations that occur only once. Furthermore, we only attempt WSD classification for those Chinese phrases with at least 10 training examples.

Using the WSD classifier described in Section 2, we classified the words in each Chinese source sentence to be translated. We first performed WSD on all single Chinese words which are either noun, verb, or adjective. Next, we classified the Chinese phrases consisting of 2 consecutive Chinese words by simply treating the phrase as *a single unit*. When performing classification, we give as output the set of English translations with associated context-dependent probabilities, which are the probabilities of a Chinese word (phrase) translating into each English phrase, depending on the context of the Chinese word (phrase). After WSD, the *i*th word c_i in every Chinese sentence may have up to 3 sets of associated translations provided by the WSD system: a set of translations for c_i as a single word, a second set of translations for $c_{i-1}c_i$ considered as a single unit, and a third set of translations for c_ic_{i+1} considered as a single unit.

5 Incorporating WSD during Decoding

The following tasks are done for each rule that is considered during decoding:

- identify Chinese words to suggest translations for
- match suggested translations against the English side of the rule
- compute features for the rule

The WSD system is able to predict translations only for a subset of Chinese words or phrases. Hence, we must first identify which parts of the Chinese side of the rule have suggested translations available. Here, we consider substrings of length up to two, and we give priority to longer substrings.

Next, we want to know, for each Chinese substring considered, whether the WSD system supports the Chinese-English translation represented by the rule. If the rule is finally chosen as part of the best derivation for translating the Chinese sentence, then all the words in the English side of the rule will appear in the translated English sentence. Hence, we need to match the translations suggested by the WSD system against the English side of the rule. It is for these matching rules that the WSD features will apply.

The translations proposed by the WSD system may be more than one word long. In order for a proposed translation to match the rule, we require two conditions. First, the proposed translation must be a substring of the English side of the rule. For example, the proposed translation "every to" would not match the chunk "every month to". Second, the match must contain at least one aligned Chinese-English word pair, but we do not make any other requirements about the alignment of the other Chinese or English words.[1] If there are multiple possible matches, we choose the longest proposed translation; in the case of a tie, we choose the proposed translation with the highest score according to the WSD model.

Define a *chunk* of a rule to be a maximal substring of terminal symbols on the English side of the rule. For example, in Rule (2), the chunks would be "go to" and "every month to". Whenever we find a matching WSD translation, we mark the whole chunk on the English side as consumed.

Finally, we compute the feature values for the rule. The feature $P_{wsd}(t \mid s)$ is the sum of the costs (according to the WSD model) of all the matched translations, and the feature Pty_{wsd} is the sum of the lengths of all the matched translations.

Figure 1 shows the pseudocode for the rule scoring algorithm in more detail, particularly with regards to resolving conflicts between overlapping matches. To illustrate the algorithm given in Figure 1, consider Rule (2). Hereafter, we will use symbols to represent the Chinese and English words in the rule: c_1, c_2, and c_3 will represent the Chinese words "每", "月", and "到" respectively. Similarly, e_1, e_2, e_3, e_4, and e_5 will represent the English words *go*, *to*, *every*, *month*, and *to* respectively. Hence, Rule (2) has two chunks: e_1e_2 and $e_3e_4e_5$. When the rule is extracted from the parallel corpus, it has these alignments between the words of its Chinese and English portion: $\{c_1$–e_3,c_2–e_4,c_3–e_1,c_3–e_2,c_3–$e_5\}$, which means that c_1 is aligned to e_3, c_2 is aligned to

[1] In order to check this requirement, we extended Hiero to make word alignment information available to the decoder.

Input: rule *R* considered during decoding with its own associated $cost_R$
L_c = list of symbols in Chinese portion of *R*
WSDcost = 0
i = 1
while i $\leq$ len(L_c):
    c_i = *i*th symbol in L_c
    if c_i is a Chinese word (i.e., not a non-terminal symbol):
        seenChunk = $\emptyset$ // seenChunk is a global variable and is passed by reference to matchWSD
        if (c_i is not the last symbol in L_c) and (c_{i+1} is a terminal symbol): then c_{i+1}=(*i*+1)th symbol in L_c, else c_{i+1} = NULL
        if (c_{i+1}!=NULL) and (c_i, c_{i+1}) as a *single unit* has WSD translations:
            WSD_c = set of WSD translations for (c_i, c_{i+1}) as a single unit with context-dependent probabilities
            WSDcost = WSDcost + matchWSD(c_i, WSD_c, seenChunk)
            WSDcost = WSDcost + matchWSD(c_{i+1}, WSD_c, seenChunk)
            i = i + 1
        else:
            WSD_c = set of WSD translations for c_i with context-dependent probabilities
            WSDcost = WSDcost + matchWSD(c_i, WSD_c, seenChunk)
    i = i + 1
$cost_R$ = $cost_R$ + WSDcost

matchWSD(*c*, WSD_c, seenChunk):
    // seenChunk is the set of chunks of *R* already examined for possible matching WSD translations
    cost = 0
    ChunkSet = set of chunks in *R* aligned to *c*
    for $chunk_j$ in ChunkSet:
        if $chunk_j$ not in seenChunk:
            seenChunk = seenChunk $\cup$ { $chunk_j$ }
            E_{chunk_j} = set of English words in $chunk_j$ aligned to *c*
            $Candidate_{wsd}$ = $\emptyset$
            for wsd_k in WSD_c:
                if (wsd_k is sub-sequence of $chunk_j$) and (wsd_k contains at least one word in E_{chunk_j})
                    $Candidate_{wsd}$ = $Candidate_{wsd}$ $\cup$ { wsd_k }
            wsd_{best} = *best matching* translation in $Candidate_{wsd}$ against $chunk_j$
            cost = cost + costByWSDfeatures(wsd_{best}) // costByWSDfeatures sums up the cost of the two WSD features
    return cost

Figure 1: WSD translations affecting the cost of a rule *R* considered during decoding.

e_4, and c_3 is aligned to e_1, e_2, and e_5. Although all words are aligned here, in general for a rule, some of its Chinese or English words may not be associated with any alignments.

In our experiment, c_1c_2 as a phrase has a list of translations proposed by the WSD system, including the English phrase "every month". *matchWSD* will first be invoked for c_1, which is aligned to only one chunk $e_3e_4e_5$ via its alignment with e_3. Since "every month" is a sub-sequence of the chunk and also contains the word e_3 ("every"), it is noted as a candidate translation. Later, it is determined that the most number of words any candidate translation has is two words. Since among all the 2-word candidate translations, the translation "every month" has the highest translation probability as assigned by the WSD classifier, it is chosen as the best matching translation for the chunk. *matchWSD* is then invoked for c_2, which is aligned to only one chunk $e_3e_4e_5$. However, since this chunk has already been examined by c_1 with which it is considered as a phrase, no further matching is done for c_2. Next, *matchWSD* is invoked for c_3, which is aligned to both chunks of *R*. The English phrases "go to" and "to" are among the list of translations proposed by the WSD system for c_3, and they are eventually chosen as the best matching translations for the chunks e_1e_2 and $e_3e_4e_5$, respectively.

6 Experiments

As mentioned, our experiments were on Chinese to English translation. Similar to (Chiang, 2005), we trained the Hiero system on the FBIS corpus, used the NIST MT 2002 evaluation test set as our development set to tune the feature weights, and the NIST MT 2003 evaluation test set as our test data. Using

System	BLEU-4	Individual *n*-gram precisions			
		1	2	3	4
Hiero	29.73	74.73	40.14	21.83	11.93
Hiero+WSD	30.30	74.82	40.40	22.45	12.42

Table 1: BLEU scores

System	Features									
	$P_{lm}(e)$	$P(\gamma\|\alpha)$	$P(\alpha\|\gamma)$	$P_w(\gamma\|\alpha)$	$P_w(\alpha\|\gamma)$	Pty_{phr}	$Glue$	Pty_{word}	$P_{wsd}(t\|s)$	Pty_{wsd}
Hiero	0.2337	0.0882	0.1666	0.0393	0.1357	0.0665	−0.0582	−0.4806	-	-
Hiero+WSD	0.1937	0.0770	0.1124	0.0487	0.0380	0.0988	−0.0305	−0.1747	0.1051	−0.1611

Table 2: Weights for each feature obtained by MERT training. The first eight features are those used by Hiero in (Chiang, 2005).

the English portion of the FBIS corpus and the Xinhua portion of the Gigaword corpus, we trained a trigram language model using the SRI Language Modelling Toolkit (Stolcke, 2002). Following (Chiang, 2005), we used the version 11a NIST BLEU script with its default settings to calculate the BLEU scores (Papineni et al., 2002) based on case-insensitive *n*-gram matching, where *n* is up to 4.

First, we performed word alignment on the FBIS parallel corpus using GIZA++ (Och and Ney, 2000) in both directions. The word alignments of both directions are then combined into a single set of alignments using the "diag-and" method of Koehn et al. (2003). Based on these alignments, synchronous CFG rules are then extracted from the corpus. While Hiero is extracting grammar rules, we gathered WSD training data by following the procedure described in section 4.

6.1 Hiero Results

Using the MT 2002 test set, we ran the minimum-error rate training (MERT) (Och, 2003) with the decoder to tune the weights for each feature. The weights obtained are shown in the row *Hiero* of Table 2. Using these weights, we run Hiero's decoder to perform the actual translation of the MT 2003 test sentences and obtained a BLEU score of 29.73, as shown in the row *Hiero* of Table 1. This is higher than the score of 28.77 reported in (Chiang, 2005), perhaps due to differences in word segmentation, etc. Note that comparing with the MT systems used in (Carpuat and Wu, 2005) and (Cabezas and Resnik, 2005), the Hiero system we are using represents a much stronger baseline MT system upon which the WSD system must improve.

6.2 Hiero+WSD Results

We then added the WSD features of Section 3.1 into Hiero and reran the experiment. The weights obtained by MERT are shown in the row *Hiero+WSD* of Table 2. We note that a negative weight is learnt for Pty_{wsd}. This means that in general, the model prefers grammar rules having chunks that matches WSD translations. This matches our intuition. Using the weights obtained, we translated the test sentences and obtained a BLEU score of **30.30**, as shown in the row *Hiero+WSD* of Table 1. The improvement of 0.57 is statistically significant at $p < 0.05$ using the sign-test as described by Collins et al. (2005), with 374 (+1), 318 (−1) and 227 (0). Using the bootstrap-sampling test described in (Koehn, 2004b), the improvement is statistically significant at $p < 0.05$. Though the improvement is modest, it is statistically significant and this positive result is important in view of the negative findings in (Carpuat and Wu, 2005) that WSD does not help MT. Furthermore, note that Hiero+WSD has higher *n*-gram precisions than Hiero.

7 Analysis

Ideally, the WSD system should be suggesting high-quality translations which are frequently part of the reference sentences. To determine this, we note the set of grammar rules used in the best derivation for translating each test sentence. From the rules of each test sentence, we tabulated the set of translations proposed by the WSD system and check whether they are found in the associated reference sentences.

On the entire set of NIST MT 2003 evaluation test sentences, an average of 10.36 translations proposed

No. of words in WSD translations	All test sentences		+1 from Collins sign-test	
	No. of WSD translations used	% match reference	No. of WSD translations used	% match reference
1	7087	77.31	3078	77.68
2	1930	66.11	861	64.92
3	371	43.13	171	48.54
4	124	26.61	52	28.85

Table 3: Number of WSD translations used and proportion that matches against respective reference sentences. WSD translations longer than 4 words are very sparse (less than 10 occurrences) and thus they are not shown.

by the WSD system were used for each sentence. When limited to the set of 374 sentences which were judged by the Collins sign-test to have better translations from Hiero+WSD than from Hiero, a higher number (11.14) of proposed translations were used on average. Further, for the entire set of test sentences, 73.01% of the proposed translations are found in the reference sentences. This increased to a proportion of 73.22% when limited to the set of 374 sentences. These figures show that having more, and higher-quality proposed translations contributed to the set of 374 sentences being better translations than their respective original translations from Hiero. Table 3 gives a detailed breakdown of these figures according to the number of words in each proposed translation. For instance, over all the test sentences, the WSD module gave 7087 translations of single-word length, and 77.31% of these translations match their respective reference sentences. We note that although the proportion of matching 2-word translations is slightly lower for the set of 374 sentences, the proportion increases for translations having more words.

After the experiments in Section 6 were completed, we visually inspected the translation output of Hiero and Hiero+WSD to categorize the ways in which integrating WSD contributes to better translations. The first way in which WSD helps is when it enables the integrated Hiero+WSD system to output extra appropriate English words. For example, the translations for the Chinese sentence "...或 其他 「恶劣 行为」， 将 无法 取得 更 多 援助 或 其他 让步 。" are as follows.

- Hiero: ... *or other bad behavior ", will be more aid and other concessions.*
- Hiero+WSD: ... *or other bad behavior ", will be unable to obtain more aid and other concessions.*

Here, the Chinese words "无法 取得" are not translated by Hiero at all. By providing the correct translation of "*unable to obtain*" for "无法 取得", the translation output of Hiero+WSD is more complete.

A second way in which WSD helps is by correcting a previously incorrect translation. For example, for the Chinese sentence "..., 在 全 国 各族 人 民， ...", the WSD system helps to correct Hiero's original translation by providing the correct translation of "*all ethnic groups*" for the Chinese phrase "各 族":

- Hiero: ..., *and people of all nationalities across the country, ...*
- Hiero+WSD: ..., *and people of all ethnic groups across the country, ...*

We also looked at the set of 318 sentences that were judged by the Collins sign-test to be worse translations. We found that in some situations, Hiero+WSD has provided extra appropriate English words, but those particular words are not used in the reference sentences. An interesting example is the translation of the Chinese sentence "澳洲 外长 指 北韩 行为 恶劣 将 无法 取得 更 多 援助".

- Hiero: *Australian foreign minister said that North Korea bad behavior will be more aid*
- Hiero+WSD: *Australian foreign minister said that North Korea bad behavior will be unable to obtain more aid*

This is similar to the example mentioned earlier. In this case however, those extra English words provided by Hiero+WSD, though appropriate, do not

result in more *n*-gram matches as the reference sentences used phrases such as "*will not gain*", "*will not get*", etc. Since the BLEU metric is precision based, the longer sentence translation by Hiero+WSD gets a lower BLEU score instead.

8 Conclusion

We have shown that WSD improves the translation performance of a state-of-the-art hierarchical phrase-based statistical MT system and this improvement is statistically significant. We have also demonstrated one way to integrate a WSD system into an MT system without introducing any rules that compete against existing rules, and where the feature-weight tuning and decoding place the WSD system on an equal footing with the other model components. For future work, an immediate step would be for the WSD classifier to provide translations for longer Chinese phrases. Also, different alternatives could be tried to match the translations provided by the WSD classifier against the chunks of rules. Finally, besides our proposed approach of integrating WSD into statistical MT via the introduction of two new features, we could explore other alternative ways of integration.

Abstract

We present a novel approach to the word sense disambiguation problem which makes use of corpus-based evidence combined with background knowledge. Employing an inductive logic programming algorithm, the approach generates expressive disambiguation rules which exploit several knowledge sources and can also model relations between them. The approach is evaluated in two tasks: identification of the correct translation for a set of highly ambiguous verbs in English-Portuguese translation and disambiguation of verbs from the Senseval-3 lexical sample task. The average accuracy obtained for the multilingual task outperforms the other machine learning techniques investigated. In the monolingual task, the approach performs as well as the state-of-the-art systems which reported results for the same set of verbs.

1 Introduction

Word Sense Disambiguation (WSD) is concerned with the identification of the meaning of ambiguous words in context. For example, among the possible senses of the verb "run" are "to move fast by using one's feet" and "to direct or control". WSD can be useful for many applications, including information retrieval, information extraction and machine translation. Sense ambiguity has been recognized as one of the most important obstacles to successful language understanding since the early 1960's and many techniques have been proposed to solve the problem. Recent approaches focus on the use of various lexical resources and corpus-based techniques in order to avoid the substantial effort required to codify linguistic knowledge. These approaches have shown good results; particularly those using supervised learning (see Mihalcea et al., 2004 for an overview of state-of-the-art systems). However, current approaches rely on limited knowledge representation and modeling techniques: traditional machine learning algorithms and attribute-value vectors to represent disambiguation instances. This has made it difficult to exploit deep knowledge sources in the generation of the disambiguation models, that is, knowledge that goes beyond simple features extracted directly from the corpus, like bags-of-words and collocations, or provided by shallow natural language tools like part-of-speech taggers.

In this paper we present a novel approach for WSD that follows a hybrid strategy, i.e. combines knowledge and corpus-based evidence, and employs a first-order formalism to allow the representation of deep knowledge about disambiguation examples together with a powerful modeling technique to induce theories based on the examples and background knowledge. This is achieved using Inductive Logic Programming (ILP) (Muggleton, 1991), which has not yet been applied to WSD.

Our hypothesis is that by using a very expressive representation formalism, a range of (shallow and deep) knowledge sources and ILP as learning technique, it is possible to generate models that, when compared to models produced by machine learning algorithms conventionally applied to

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 41–48,
Prague, Czech Republic, June 2007.

WSD, are both more accurate for fine-grained distinctions, and "interesting", from a knowledge acquisition point of view (i.e., convey potentially new knowledge that can be easily interpreted by humans).

WSD systems have generally been more successful in the disambiguation of nouns than other grammatical categories (Mihalcea et al., 2004). A common approach to the disambiguation of nouns has been to consider a wide context around the ambiguous word and treat it as a bag of words or limited set of collocates. However, disambiguation of verbs generally benefits from more specific knowledge sources, such as the verb's relation to other items in the sentence (for example, by analysing the semantic type of its subject and object). Consequently, we believe that the disambiguation of verbs is task to which ILP is particularly well-suited. Therefore, this paper focuses on the disambiguation of verbs, which is an interesting task since much of the previous work on WSD has concentrated on the disambiguation of nouns.

WSD is usually approached as an independent task, however, it has been argued that different applications may have specific requirements (Resnik and Yarowsky, 1997). For example, in machine translation, WSD, or *translation disambiguation*, is responsible for identifying the correct *translation* for an ambiguous source word. There is not always a direct relation between the possible senses for a word in a (monolingual) lexicon and its translations to a particular language, so this represents a different task to WSD against a (monolingual) lexicon (Hutchins and Somers, 1992). Although it has been argued that WSD does not yield better translation quality than a machine translation system alone, it has been recently shown that a WSD module that is developed following specific multilingual requirements can significantly improve the performance of a machine translation system (Carpuat et al., 2006).

This paper focuses on the application of our approach to the translation of verbs in English to Portuguese translation, specifically for a set of 10 mainly light and highly ambiguous verbs. We also experiment with a monolingual task by using the verbs from Senseval-3 lexical sample task. We explore knowledge from 12 syntactic, semantic and pragmatic sources. In principle, the proposed approach could also be applied to any lexical disambiguation task by customizing the sense repository and knowledge sources.

In the remainder of this paper we first present related approaches to WSD and discuss their limitations (Section 2). We then describe some basic concepts on ILP and our application of this technique to WSD (Section 3). Finally, we described our experiments and their results (Section 4).

2 Related Work

WSD approaches can be classified as (a) knowledge-based approaches, which make use of linguistic knowledge, manually coded or extracted from lexical resources (Agirre and Rigau, 1996; Lesk 1986); (b) corpus-based approaches, which make use of shallow knowledge automatically acquired from corpus and statistical or machine learning algorithms to induce disambiguation models (Yarowsky, 1995; Schütze 1998); and (c) hybrid approaches, which mix characteristics from the two other approaches to automatically acquire disambiguation models from corpus supported by linguistic knowledge (Ng and Lee 1996; Stevenson and Wilks, 2001).

Hybrid approaches can combine advantages from both strategies, potentially yielding accurate and comprehensive systems, particularly when deep knowledge is explored. Linguistic knowledge is available in electronic resources suitable for practical use, such as WordNet (Fellbaum, 1998), dictionaries and parsers. However, the use of this information has been hampered by the limitations of the modeling techniques that have been explored so far: using deep sources of domain knowledge is beyond the capabilities of such techniques, which are in general based on attribute-value vector representations.

Attribute-value vectors consist of a set of attributes intended to represent properties of the examples. Each attribute has a type (its name) and a single value for a given example. Therefore, attribute-value vectors have the same expressiveness as propositional formalisms, that is, they only allow the representation of atomic propositions and constants. These are the representations used by most of the machine learning algorithms conventionally employed to WSD, for example Naïve Bayes and decision-trees. First-order logic, a more expressive formalism which is employed by ILP, allows the representation of variables and n-ary predicates, i.e., relational knowledge.

In the hybrid approaches that have been explored so far, deep knowledge, like selectional preferences, is either pre-processed into a vector representation to accommodate machine learning algorithms, or used in previous steps to filter out possible senses e.g. (Stevenson and Wilks, 2001). This may cause information to be lost and, in addition, deep knowledge sources cannot interact in the learning process. As a consequence, the models produced reflect only the shallow knowledge that is provided to the learning algorithm.

Another limitation of attribute-value vectors is the need for a unique representation for all the examples: one attribute is created for every knowledge feature and the same structure is used to characterize all the examples. This usually results in a very sparse representation of the data, given that values for certain features will not be available for many examples. The problem of data sparseness increases as more knowledge is exploited and this can cause problems for the machine learning algorithms.

A final disadvantage of attribute-value vectors is that equivalent features may have to be bounded to distinct identifiers. An example of this occurs when the syntactic relations between words in a sentence are represented by attributes for each possible relation, sentences in which there is more than one instantiation for a particular grammatical role cannot be easily represented. For example, the sentence "John and Anna gave Mary a present." contains a coordinate subject and, since each feature requires a unique identifier, two are required ($subj_1$-$verb_1$, $subj_2$-$verb_1$). These will be treated as two independent pieces of knowledge by the learning algorithm.

First-order formalisms allow a generic predicate to be created for every possible syntactic role, relating two or more elements. For example *has_subject(verb, subject)*, which could then have two instantiations: *has_subject(give, john)* and *has_subject(give, anna)*. Since each example is represented independently from the others, the data sparseness problem is minimized. Therefore, ILP seems to provide the most general-purpose framework for dealing with such data: it does not suffer from the limitations mentioned above since there are explicit provisions made for the inclusion of background knowledge of any form, and the representation language is powerful enough to capture contextual relationships.

3 A hybrid relational approach to WSD

In what follows we provide an introduction to ILP and then outline how it is applied to WSD by presenting the sample corpus and knowledge sources used in our experiments.

3.1 Inductive Logic Programming

Inductive Logic Programming (Muggleton, 1991) employs techniques from Machine Learning and Logic Programming to build first-order theories from examples and background knowledge, which are also represented by first-order clauses. It allows the efficient representation of substantial knowledge about the problem, which is used during the learning process, and produces disambiguation models that can make use of this knowledge. The general approach underlying ILP can be outlined as follows:

Given:

- a set of positive and negative examples $\boldsymbol{E} = \boldsymbol{E}^+ \cup \boldsymbol{E}^-$

- a predicate $\boldsymbol{p}$ specifying the target relation to be learned

- knowledge $\boldsymbol{K}$ of the domain, described according to a language $\boldsymbol{L_k}$, which specifies which predicates $\boldsymbol{q_i}$ can be part of the definition of $\boldsymbol{p}$.

The goal is: to induce a hypothesis (or theory) $\boldsymbol{h}$ for $\boldsymbol{p}$, with relation to $\boldsymbol{E}$ and $\boldsymbol{K}$, which covers most of the $\boldsymbol{E}^+$, without covering the $\boldsymbol{E}^-$, i.e., $\boldsymbol{K} \wedge \boldsymbol{h} \models \boldsymbol{E}^+$ and $\boldsymbol{K} \wedge \boldsymbol{h} \not\models \boldsymbol{E}^-$.

We use the Aleph ILP system (Srinivasan, 2000), which provides a complete inference engine and can be customized in various ways. The default inference engine induces a theory iteratively using the following steps:

1. One instance is randomly selected to be generalized.

2. A more specific clause (the bottom clause) is built using inverse entailment (Muggleton, 1995), generally consisting of the representation of all the knowledge about that example.

3. A clause that is more generic than the bottom clause is searched for using a given search (e.g., best-first) and evaluation strategy (e.g., number of positive examples covered).

4. The best clause is added to the theory and the examples covered by that clause are removed from the sample set. Stop if there are more no examples in the training set, otherwise return to step 1.

3.2 Sample data

This approach was evaluated using two scenarios: (1) an English-Portuguese multilingual setting addressing 10 very frequent and problematic verbs selected in a previous study (Specia et. al., 2005); and (2) an English setting consisting of 32 verbs from Senseval-3 lexical sample task (Mihalcea et. al. 2004).

For the first scenario a corpus containing 500 sentences for each of the 10 verbs was constructed. The text was randomly selected from corpora of different domains and genres, including literary fiction, Bible, computer science dissertation abstracts, operational system user manuals, newspapers and European Parliament proceedings. This corpus was automatically annotated with the translation of the verb using a tagging system based on parallel corpus, statistical information and translation dictionaries (Specia et al., 2005), followed by a manual revision. For each verb, the sense repository was defined as the set of all the possible translations of that verb in the corpus. 80% of the corpus was randomly selected and used for training, with the remainder retained for testing. The 10 verbs, number of possible translations and the percentage of sentences for each verb which use the most frequent translation are shown in Table 1.

For the monolingual scenario, we use the sense tagged corpus and sense repositories provided for verbs in Senseval-3. There are 32 verbs with between 40 and 398 examples each. The number of senses varies between 3 and 10 and the average percentage of examples with the majority (most frequent) sense is 55%.

Verb	# Translations	Most frequent translation - %
ask	7	53
come	29	36
get	41	13
give	22	72
go	30	53
live	8	66
look	12	41
make	21	70
take	32	25
tell	8	66

Table 1. Verbs and possible senses in our corpus

Both corpora were lemmatized and part-of-speech (POS) tagged using Minipar (Lin, 1993) and Mxpost (Ratnaparkhi, 1996), respectivelly. Additionally, proper nouns identified by the tagger were replaced by a single identifier (*proper_noun*) and pronouns replaced by identifiers representing classes of pronouns (*relative_pronoun*, etc.).

3.3 Knowledge sources

We now describe the background knowledge sources used by the learning algorithm, having as an example sentence (1), in which the word "coming" is the target verb being disambiguated.

(1) "If there is such a thing as reincarnation, I would not mind **coming** back as a squirrel".

KS_1. Bag-of-words consisting of 5 words to the right and left of the verb (excluding stop words), represented using definitions of the form *has_bag*(*snt, word*):

has_bag(snt_1, *mind*).
has_bag(snt_1, *not*). …

KS_2. Frequent bigrams consisting of pairs of adjacent words in a sentence (other than the target verb) which occur more than 10 times in the corpus, represented by *has_bigram(snt, $word_1$, $word_2$)*:

has_bigram(snt_1, back, as).
has_bigram(snt_1, such, a). …

KS_3. Narrow context containing 5 content words to the right and left of the verb, identified using POS tags, represented by *has_narrow*(*snt, word_position, word*):

has_narrow(snt_1, 1st_word_left, mind).
has_narrow(snt_1, 1st_word_right, back). …

KS_4. POS tags of 5 words to the right and left of the verb, represented by *has_pos*(*snt, word_position, pos*):

has pos(snt_1, 1st_word_left, nn).
has pos(snt_1, 1^{st}_word_right, rb). …

KS_5. 11 collocations of the verb: 1st preposition to the right, 1st and 2nd words to the left and right, 1st noun, 1st adjective, and 1st verb to the left and right. These are represented using definitions of the form *has_collocation*(*snt, type, collocation*):

has_collocation(snt_1, *1st_prep_right, back*).
has_collocation(snt_1, *1st_noun_left, mind*).…

KS_6. Subject and object of the verb obtained using Minipar and represented by *has_rel*(*snt, type, word*):

has_rel(snt$_1$, subject, i).
has_rel(snt$_1$, object, nil). …

KS_7. Grammatical relations not including the target verb also identified using Minipar. The relations (verb-subject, verb-object, verb-modifier, subject-modifier, and object-modifier) occurring more than 10 times in the corpus are represented by *has_related_pair(snt, word$_1$, word$_2$)*:

has_related_pair(snt$_1$, there, be). …

KS_8. The sense with the highest count of overlapping words in its dictionary definition and in the sentence containing the target verb (excluding stop words) (Lesk, 1986), represented by *has_overlapping*(*sentence, translation*):

has_overlapping(snt$_1$, voltar).

KS_9. Selectional restrictions of the verbs defined using LDOCE (Procter, 1978). WordNet is used when the restrictions imposed by the verb are not part of the description of its arguments, but can be satisfied by synonyms or hyperonyms of those arguments. A hierarchy of feature types is used to account for restrictions established by the verb that are more generic than the features describing its arguments in the sentence. This information is represented by definitions of the form *satisfy_restriction*(*snt, rest_subject, rest_object*):

satisfy_restriction(*snt$_1$,* [*human*], *nil*).
satisfy_restriction(*snt$_1$,* [*animal, human*], *nil*).

KS_1-KS_9 can be applied to both multilingual and monolingual disambiguation tasks. The following knowledge sources were specifically designed for multilingual applications:

KS_{10}. Phrasal verbs in the sentence identified using a list extracted from various dictionaries. (This information was not used in the monolingual task because phrasal constructions are not considered verb senses in Senseval data.) These are represented by definitions of the form *has_expression*(*snt, verbal_expression*):

has_expression(snt$_1$, "come back").

KS_{11}. Five words to the right and left of the target verb in the Portuguese translation. This could be obtained using a machine translation system that would first translate the non-ambiguous words in the sentence. In our experiments it was extracted using a parallel corpus and represented using definitions of the form *has_bag_trns*(*snt, portuguese_word*):

has_bag_trns(snt$_1$, coelho).
has_bag_trns(snt$_1$, reincarnação). …

KS_{12}. Narrow context consisting of 5 collocations of the verb in the Portuguese translation, which take into account the positions of the words, represented by *has_narrow_trns*(*snt, word_position, portuguese_word*):

has_narrow_trns(*snt*$_1$, *1st_word_right, como*).
has_narrow_trns(*snt*$_1$, *2nd_word_right, um*). …

In addition to background knowledge, the system learns from a set of examples. Since all knowledge about them is expressed as background knowledge, their representation is very simple, containing only the sentence identifier and the sense of the verb in that sentence, i.e. *sense(snt, sense)*:

sense(snt$_1$,voltar).
sense(snt$_2$,ir). …

Based on the examples, background knowledge and a series of settings specifying the predicate to be learned (i.e., the heads of the rules), the predicates that can be in the conditional part of the rules, how the arguments can be shared among different predicates and several other parameters, the inference engine produces a set of symbolic rules. Figure 1 shows examples of the rules induced for the verb "to come" in the multilingual task.

Rule_1. sense(A, voltar) :-
  has_collocation(A, 1st_prep_right, back).
Rule_2. sense(A, chegar) :-
  has_rel(A, subj, B), has_bigram(A, today, B),
  has_bag_trans(A, hoje).
Rule_3. sense(A, chegar) :-
  satisfy_restriction(A, [animal, human], [concrete]);
  has_expression(A, 'come at').
Rule_4. sense(A, vir) :-
  satisfy_restriction(A, [animate], nil);
  (has_rel(A, subj, B),
  (has_pos(A, B, nnp); has_pos(A, B, prp))).

Figure 1. Examples of rules produced for the verb "come" in the multilingual task

Models learned with ILP are symbolic and can be easily interpreted. Additionally, innovative knowledge about the problem can emerge from the rules learned by the system. Although some rules simply test shallow features such as collocates, others pose conditions on sets of knowledge sources, including relational sources, and allow non-instantiated arguments to be shared amongst them by means of variables. For example, in Figure 1, **Rule_1** states that the translation of the verb in a sentence *A* will be "voltar" (*return*) if the first preposition to the right of the verb in that sentence is "back". **Rule_2** states that the translation of the verb will be "chegar" (*arrive*) if it has a certain subject *B*, which occurs frequently with the word "today" as a bigram, and if the partially translated sentence contains the word "hoje" (the translation of "today"). **Rule_3** says that the translation of the verb will be "chegar" (*reach*) if the subject of the verb has the features "animal" or "human" and the object has the feature "concrete", or if the verb occurs in the expression "come at". **Rule_4** states that the translation of the verb will be "vir" (*move toward*) if the subject of the verb has the feature "animate" and there is no object, or if the verb has a subject *B* that is a proper noun (*nnp*) or a personal pronoun (*prp*).

4 Experiments and results

To assess the performance of the approach the model produced for each verb was tested on the corresponding set of test cases by applying the rules in a decision-list like approach, i.e., retaining the order in which they were produced and backing off to the most frequent sense in the training set to classify cases that were not covered by any of the rules. All the knowledge sources were made available to be used by the inference engine, since previous experiments showed that they are all relevant (Specia, 2006). In what follows we present the results and discuss each task.

4.1 Multilingual task

Table 2 shows the accuracies (in terms of percentage of corpus instances which were correctly disambiguated) obtained by the Aleph models. Results are compared against the accuracy that would be obtained by using the most frequent translation in the training set to classify all the examples of the test set (in the column labeled "Majority sense"). For comparison, we ran experiments with three learning algorithms frequently used for WSD, which rely on knowledge represented as attribute-value vectors: C4.5 (decision-trees), Naive Bayes and Support Vector Machine (SVM)[1]. In order to represent all knowledge sources in attribute-value vectors, KS_2, KS_7, KS_9 and KS_{10} had to be pre-processed to be transformed into binary attributes. For example, in the case of selectional restrictions (KS_9), one attribute was created for each possible sense of the verb and a true/false value was assigned to it depending on whether the arguments of the verb satisfied any restrictions referring to that sense. Results for each of these algorithms are also shown in Table 2.

As we can see in Table 2, the accuracy of the ILP approach is considerably better than the most frequent sense baseline and also outperforms the other learning algorithms. This improvement is statistically significant (paired t-test; $p < 0.05$). As expected, accuracy is generally higher for verbs with fewer possible translations.

The models produced by Aleph for all the verbs are reasonably compact, containing 50 to 96 rules. In those models the various knowledge sources appear in different rules and all are used. This demonstrates that they are all useful for the disambiguation of verbs.

Verb	Majority sense	C4.5	Naïve Bayes	SVM	Aleph
ask	0.68	0.68	0.82	0.88	0.92
come	0.46	0.57	0.61	0.68	0.73
get	0.03	0.25	0.46	0.47	0.49
give	0.72	0.71	0.74	0.74	0.74
go	0.49	0.61	0.66	0.66	0.66
live	0.71	0.72	0.64	0.73	0.87
look	0.48	0.69	0.81	0.83	0.93
make	0.64	0.62	0.60	0.64	0.68
take	0.14	0.41	0.50	0.51	0.59
tell	0.65	0.67	0.66	0.68	0.82
Average	**0.50**	**0.59**	**0.65**	**0.68**	**0.74**

Table 2. Accuracies obtained by Aleph and other learning algorithms in the multilingual task

These results are very positive, particularly if we consider the characteristics of the multilingual scenario: (1) the verbs addressed are highly ambiguous; (2) the corpus was automatically tagged and thus distinct synonym translations were sometimes

[1] The implementations provided by Weka were used. Weka is available from http://www.cs.waikato.ac.nz/ml/weka/

used to annotate different examples (these count as different senses for the inference engine); and (3) certain translations occur very infrequently (just 1 or 2 examples in the whole corpus). It is likely that a less strict evaluation regime, such as one which takes account of synonym translations, would result in higher accuracies.

It is worth noticing that we experimented with a few relevant parameters for both Aleph and the other learning algorithms. Values that yielded the best average predictive accuracy in the training sets were assumed to be optimal and used to evaluate the test sets.

4.2 Monolingual task

Table 3 shows the average accuracy obtained by Aleph in the monolingual task (Senseval-3 verbs with fine-grained sense distinctions and using the evaluation system provided by Senseval). It also shows the average accuracy of the most frequent sense and accuracies reported on the same set of verbs by the best systems submitted by the sites which participated in this task. Syntalex-3 (Mohammad and Pedersen, 2004) is based on an ensemble of bagged decision trees with narrow context part-of-speech features and bigrams. CLaC1 (Lamjiri et al., 2004) uses a Naive Bayes algorithm with a dynamically adjusted context window around the target word. Finally, MC-WSD (Ciaramita and Johnson, 2004) is a multi-class averaged perceptron classifier using syntactic and narrow context features, with one component trained on the data provided by Senseval and other trained on WordNet glosses.

System	% Average accuracy
Majority sense	0.56
Syntalex-3	0.67
CLaC1	0.67
MC-WSD	0.72
Aleph	0.72

Table 3. Accuracies obtained by Aleph and other approaches in the monolingual task

As we can see in Table 3, results are very encouraging: even without being particularly customized for this monolingual task, the ILP approach significantly outperforms the majority sense baseline and performs as well as the state-of-the-art system reporting results for the same set of verbs. As with the multilingual task, the models produced contain a small number of rules (from 6, for verbs with a few examples, to 88) and all knowledge sources are used across different rules and verbs.

In general, results from both multilingual and monolingual tasks demonstrate that the hypothesis put forward in Section 1, that ILP's ability to generate expressive rules which combine and integrate a wide range of knowledge sources is beneficial for WSD systems, is correct.

5 Conclusion

We have introduced a new hybrid approach to WSD which uses ILP to combine deep and shallow knowledge sources. ILP induces expressive disambiguation models which include relations between knowledge sources. It is an interesting approach to learning which has been considered promising for several applications in natural language processing and has been explored for a few of them, namely POS-tagging, grammar acquisition and semantic parsing (Cussens et al., 1997; Mooney, 1997). This paper has demonstrated that ILP also yields good results for WSD, in particular for the disambiguation of verbs.

We plan to further evaluate our approach for other sets of words, including other parts-of-speech to allow further comparisons with other approaches. For example, Dang and Palmer (2005) also use a rich set of features with a traditional learning algorithm (maximum entropy). Currently, we are evaluating the role of the WSD models for the 10 verbs of the multilingual task in an English-Portuguese statistical machine translation system.

Abstract

When a word sense disambiguation (WSD) system is trained on one domain but applied to a different domain, a drop in accuracy is frequently observed. This highlights the importance of domain adaptation for word sense disambiguation. In this paper, we first show that an active learning approach can be successfully used to perform domain adaptation of WSD systems. Then, by using the predominant sense predicted by expectation-maximization (EM) and adopting a count-merging technique, we improve the effectiveness of the original adaptation process achieved by the basic active learning approach.

1 Introduction

In natural language, a word often assumes different meanings, and the task of determining the correct meaning, or sense, of a word in different contexts is known as word sense disambiguation (WSD). To date, the best performing systems in WSD use a corpus-based, supervised learning approach. With this approach, one would need to collect a text corpus, in which each ambiguous word occurrence is first tagged with its correct sense to serve as training data.

The reliance of supervised WSD systems on annotated corpus raises the important issue of domain dependence. To investigate this, Escudero et al. (2000) and Martinez and Agirre (2000) conducted experiments using the DSO corpus, which contains sentences from two different corpora, namely Brown Corpus (BC) and Wall Street Journal (WSJ). They found that training a WSD system on one part (BC or WSJ) of the DSO corpus, and applying it to the other, can result in an accuracy drop of more than 10%, highlighting the need to perform domain adaptation of WSD systems to new domains. Escudero et al. (2000) pointed out that one of the reasons for the drop in accuracy is the difference in sense priors (i.e., the proportions of the different senses of a word) between BC and WSJ. When the authors assumed they knew the sense priors of each word in BC and WSJ, and adjusted these two datasets such that the proportions of the different senses of each word were the same between BC and WSJ, accuracy improved by 9%.

In this paper, we explore domain adaptation of WSD systems, by adding training examples from the new domain as additional training data to a WSD system. To reduce the effort required to adapt a WSD system to a new domain, we employ an active learning strategy (Lewis and Gale, 1994) to select examples to annotate from the new domain of interest. To our knowledge, our work is the first to use active learning for domain adaptation for WSD. A similar work is the recent research by Chen et al. (2006), where active learning was used successfully to reduce the annotation effort for WSD of 5 English verbs using *coarse-grained* evaluation. In that work, the authors only used active learning to reduce the annotation effort and did not deal with the porting of a WSD system to a new domain.

Domain adaptation is necessary when the training and target domains are different. In this paper,

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 49–56,
Prague, Czech Republic, June 2007.

we perform domain adaptation for WSD of a set of nouns using *fine-grained* evaluation. The contribution of our work is not only in showing that active learning can be successfully employed to reduce the annotation effort required for domain adaptation in a *fine-grained* WSD setting. More importantly, our main focus and contribution is in showing how we can improve the effectiveness of a basic active learning approach when it is used for domain adaptation. In particular, we explore the issue of different sense priors across different domains. Using the sense priors estimated by expectation-maximization (EM), the predominant sense in the new domain is predicted. Using this predicted predominant sense and adopting a count-merging technique, we *improve* the effectiveness of the adaptation process.

In the next section, we discuss the choice of corpus and nouns used in our experiments. We then introduce active learning for domain adaptation, followed by count-merging. Next, we describe an EM-based algorithm to estimate the sense priors in the new domain. Performance of domain adaptation using active learning and count-merging is then presented. Next, we show that by using the predominant sense of the target domain as predicted by the EM-based algorithm, we improve the effectiveness of the adaptation process. Our empirical results show that for the set of nouns which have different predominant senses between the training and target domains, we are able to reduce the annotation effort by 71%.

2 Experimental Setting

In this section, we discuss the motivations for choosing the particular corpus and the set of nouns to conduct our domain adaptation experiments.

2.1 Choice of Corpus

The DSO corpus (Ng and Lee, 1996) contains 192,800 annotated examples for 121 nouns and 70 verbs, drawn from BC and WSJ. While the BC is built as a balanced corpus, containing texts in various categories such as religion, politics, humanities, fiction, etc, the WSJ corpus consists primarily of business and financial news. Exploiting the difference in coverage between these two corpora, Escudero et al. (2000) separated the DSO corpus into its BC and WSJ parts to investigate the domain dependence of several WSD algorithms. Following the setup of (Escudero et al., 2000), we similarly made use of the DSO corpus to perform our experiments on domain adaptation.

Among the few currently available manually sense-annotated corpora for WSD, the SEMCOR (SC) corpus (Miller et al., 1994) is the most widely used. SEMCOR is a subset of BC which is sense-annotated. Since BC is a balanced corpus, and since performing adaptation from a general corpus to a more specific corpus is a natural scenario, we focus on adapting a WSD system trained on BC to WSJ in this paper. Henceforth, out-of-domain data will refer to BC examples, and in-domain data will refer to WSJ examples.

2.2 Choice of Nouns

The WordNet Domains resource (Magnini and Cavaglia, 2000) assigns domain labels to synsets in WordNet. Since the focus of the WSJ corpus is on business and financial news, we can make use of WordNet Domains to select the set of nouns having at least one synset labeled with a business or finance related domain label. This is similar to the approach taken in (Koeling et al., 2005) where they focus on determining the predominant sense of words in corpora drawn from finance versus sports domains.[1] Hence, we select the subset of DSO nouns that have at least one synset labeled with any of these domain labels: *commerce*, *enterprise*, *money*, *finance*, *banking*, and *economy*. This gives a set of 21 nouns: *book*, *business*, *center*, *community*, *condition*, *field*, *figure*, *house*, *interest*, *land*, *line*, *money*, *need*, *number*, *order*, *part*, *power*, *society*, *term*, *use*, *value*.[2]

For each noun, all the BC examples are used as out-of-domain training data. One-third of the WSJ examples for each noun are set aside as evaluation

[1] Note however that the coverage of the WordNet Domains resource is not comprehensive, as about 31% of the synsets are simply labeled with "factotum", indicating that the synset does not belong to a specific domain.

[2] 25 nouns have at least one synset labeled with the listed domain labels. In our experiments, 4 out of these 25 nouns have an accuracy of more than 90% before adaptation (i.e., training on just the BC examples) and accuracy improvement is less than 1% after all the available WSJ adaptation examples are added as additional training data. To obtain a clearer picture of the adaptation process, we discard these 4 nouns, leaving a set of 21 nouns.

Dataset	No. of senses		MFS acc. (%)	No. of training examples	No. of adaptation examples
	BC	WSJ			
21 nouns	6.7	6.8	61.1	310	406
9 nouns	7.9	8.6	65.8	276	416

Table 1: The average number of senses in BC and WSJ, average MFS accuracy, average number of BC training, and WSJ adaptation examples per noun.

data, and the rest of the WSJ examples are designated as in-domain adaptation data. The row *21 nouns* in Table 1 shows some information about these 21 nouns. For instance, these nouns have an average of 6.7 senses in BC and 6.8 senses in WSJ. This is slightly higher than the 5.8 senses per verb in (Chen et al., 2006), where the experiments were conducted using coarse-grained evaluation. Assuming we have access to an "oracle" which determines the predominant sense, or most frequent sense (MFS), of each noun in our WSJ test data perfectly, and we assign this most frequent sense to each noun in the test data, we will have achieved an accuracy of 61.1% as shown in the column *MFS accuracy* of Table 1. Finally, we note that we have an average of 310 BC training examples and 406 WSJ adaptation examples per noun.

3 Active Learning

For our experiments, we use naive Bayes as the learning algorithm. The knowledge sources we use include parts-of-speech, local collocations, and surrounding words. These knowledge sources were effectively used to build a state-of-the-art WSD program in one of our prior work (Lee and Ng, 2002). In performing WSD with a naive Bayes classifier, the sense s assigned to an example with features $f_1, \ldots, f_n$ is chosen so as to maximize:

$$p(s) \prod_{j=1}^{n} p(f_j|s)$$

In our domain adaptation study, we start with a WSD system built using training examples drawn from BC. We then investigate the utility of adding additional in-domain training data from WSJ. In the baseline approach, the additional WSJ examples are randomly selected. With active learning (Lewis and Gale, 1994), we use *uncertainty sampling* as shown in Figure 1. In each iteration, we train a WSD system on the available training data and apply it on the WSJ adaptation examples. Among these WSJ examples, the example predicted with the lowest confidence is selected and removed from the adaptation data. The correct label is then supplied for this example and it is added to the training data.

$D_T \leftarrow$ the set of BC training examples
$D_A \leftarrow$ the set of untagged WSJ adaptation examples
$\Gamma \leftarrow$ WSD system trained on D_T
repeat
  $p_{min} \leftarrow \infty$
  for each $d \in D_A$ do
    $\widehat{s} \leftarrow$ word sense prediction for d using Γ
    $p \leftarrow$ confidence of prediction $\widehat{s}$
    if $p < p_{min}$ then
      $p_{min} \leftarrow p$, $d_{min} \leftarrow d$
    end
  end
  $D_A \leftarrow D_A - d_{min}$
  provide correct sense s for d_{min} and add d_{min} to D_T
  $\Gamma \leftarrow$ WSD system trained on new D_T
end

Figure 1: Active learning

Note that in the experiments reported in this paper, all the adaptation examples are already pre-annotated before the experiments start, since all the WSJ adaptation examples come from the DSO corpus which have already been sense-annotated. Hence, the annotation of an example needed during each adaptation iteration is simulated by performing a lookup without any manual annotation.

4 Count-merging

We also employ a technique known as *count-merging* in our domain adaptation study. Count-merging assigns different weights to different examples to better reflect their relative importance. Roark and Bacchiani (2003) showed that weighted count-merging is a special case of maximum a posteriori (MAP) estimation, and successfully used it for probabilistic context-free grammar domain adaptation (Roark and Bacchiani, 2003) and language model adaptation (Bacchiani and Roark, 2003).

Count-merging can be regarded as scaling of counts obtained from different data sets. We let $\widetilde{c}$ denote the counts from out-of-domain training data, $\bar{c}$ denote the counts from in-domain adaptation data, and $\widehat{p}$ denote the probability estimate by

count-merging. We can scale the out-of-domain and in-domain counts with different factors, or just use a single weight parameter β:

$$\widehat{p}(f_j|s_i) = \frac{\widetilde{c}(f_j, s_i) + \beta\bar{c}(f_j, s_i)}{\widetilde{c}(s_i) + \beta\bar{c}(s_i)} \quad (1)$$

Similarly,

$$\widehat{p}(s_i) = \frac{\widetilde{c}(s_i) + \beta\bar{c}(s_i)}{\widetilde{c} + \beta\bar{c}} \quad (2)$$

Obtaining an optimum value for β is not the focus of this work. Instead, we are interested to see if assigning a higher weight to the in-domain WSJ adaptation examples, as compared to the out-of-domain BC examples, will improve the adaptation process. Hence, we just use a β value of 3 in our experiments involving count-merging.

5 Estimating Sense Priors

In this section, we describe an EM-based algorithm that was introduced by Saerens et al. (2002), which can be used to estimate the sense priors, or a priori probabilities of the different senses in a new dataset. We have recently shown that this algorithm is effective in estimating the sense priors of a set of nouns (Chan and Ng, 2005).

Most of this section is based on (Saerens et al., 2002). Assume we have a set of labeled data D_L with *n* classes and a set of *N* independent instances $(\mathbf{x}_1, \ldots, \mathbf{x}_N)$ from a new data set. The likelihood of these *N* instances can be defined as:

$$\begin{aligned} L(\mathbf{x}_1, \ldots, \mathbf{x}_N) &= \prod_{k=1}^{N} p(\mathbf{x}_k) \\ &= \prod_{k=1}^{N} \left[\sum_{i=1}^{n} p(\mathbf{x}_k, \omega_i) \right] \\ &= \prod_{k=1}^{N} \left[\sum_{i=1}^{n} p(\mathbf{x}_k|\omega_i) p(\omega_i) \right] \quad (3) \end{aligned}$$

Assuming the within-class densities $p(\mathbf{x}_k|\omega_i)$, i.e., the probabilities of observing $\mathbf{x}_k$ given the class ω_i, do not change from the training set D_L to the new data set, we can define: $p(\mathbf{x}_k|\omega_i) = p_L(\mathbf{x}_k|\omega_i)$. To determine the a priori probability estimates $\widehat{p}(\omega_i)$ of the new data set that will maximize the likelihood of (3) with respect to $p(\omega_i)$, we can apply the iterative procedure of the EM algorithm. In effect, through maximizing the likelihood of (3), we obtain the a priori probability estimates as a by-product.

Let us now define some notations. When we apply a classifier trained on D_L on an instance $\mathbf{x}_k$ drawn from the new data set D_U, we get $\widehat{p}_L(\omega_i|\mathbf{x}_k)$, which we define as the probability of instance $\mathbf{x}_k$ being classified as class ω_i by the classifier trained on D_L. Further, let us define $\widehat{p}_L(\omega_i)$ as the a priori probability of class ω_i in D_L. This can be estimated by the class frequency of ω_i in D_L. We also define $\widehat{p}^{(s)}(\omega_i)$ and $\widehat{p}^{(s)}(\omega_i|\mathbf{x}_k)$ as estimates of the new a priori and a posteriori probabilities at step *s* of the iterative EM procedure. Assuming we initialize $\widehat{p}^{(0)}(\omega_i) = \widehat{p}_L(\omega_i)$, then for each instance $\mathbf{x}_k$ in D_U and each class ω_i, the EM algorithm provides the following iterative steps:

$$\widehat{p}^{(s)}(\omega_i|\mathbf{x}_k) = \frac{\widehat{p}_L(\omega_i|\mathbf{x}_k)\frac{\widehat{p}^{(s)}(\omega_i)}{\widehat{p}_L(\omega_i)}}{\sum_{j=1}^{n} \widehat{p}_L(\omega_j|\mathbf{x}_k)\frac{\widehat{p}^{(s)}(\omega_j)}{\widehat{p}_L(\omega_j)}} \quad (4)$$

$$\widehat{p}^{(s+1)}(\omega_i) = \frac{1}{N}\sum_{k=1}^{N} \widehat{p}^{(s)}(\omega_i|\mathbf{x}_k) \quad (5)$$

where Equation (4) represents the expectation E-step, Equation (5) represents the maximization M-step, and *N* represents the number of instances in D_U. Note that the probabilities $\widehat{p}_L(\omega_i|\mathbf{x}_k)$ and $\widehat{p}_L(\omega_i)$ in Equation (4) will stay the same throughout the iterations for each particular instance $\mathbf{x}_k$ and class ω_i. The new a posteriori probabilities $\widehat{p}^{(s)}(\omega_i|\mathbf{x}_k)$ at step *s* in Equation (4) are simply the a posteriori probabilities in the conditions of the labeled data, $\widehat{p}_L(\omega_i|\mathbf{x}_k)$, weighted by the ratio of the new priors $\widehat{p}^{(s)}(\omega_i)$ to the old priors $\widehat{p}_L(\omega_i)$. The denominator in Equation (4) is simply a normalizing factor.

The a posteriori $\widehat{p}^{(s)}(\omega_i|\mathbf{x}_k)$ and a priori probabilities $\widehat{p}^{(s)}(\omega_i)$ are re-estimated sequentially during each iteration *s* for each new instance $\mathbf{x}_k$ and each class ω_i, until the convergence of the estimated probabilities $\widehat{p}^{(s)}(\omega_i)$, which will be our estimated sense priors. This iterative procedure will increase the likelihood of (3) at each step.

6 Experimental Results

For each adaptation experiment, we start off with a classifier built from an initial training set consisting

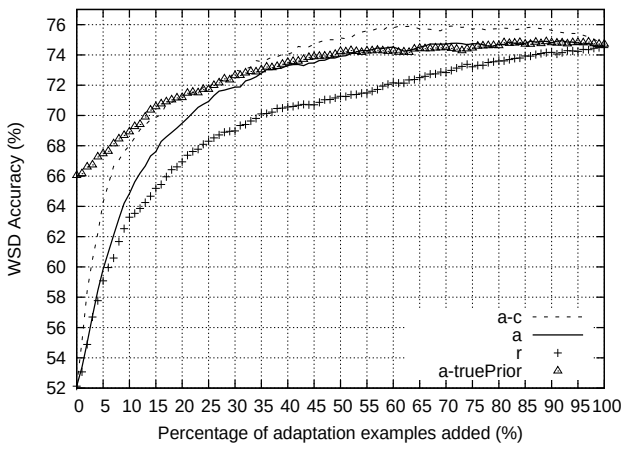

Figure 2: Adaptation process for all 21 nouns.

of the BC training examples. At each adaptation iteration, WSJ adaptation examples are selected *one at a time* and added to the training set. The adaptation process continues until all the adaptation examples are added. Classification accuracies averaged over 3 random trials on the WSJ test examples at each iteration are calculated. Since the number of WSJ adaptation examples differs for each of the 21 nouns, the learning curves we will show in the various figures are plotted in terms of different percentage of adaptation examples added, varying from 0 to 100 percent in steps of 1 percent. To obtain these curves, we first calculate for each noun, the WSD accuracy when different percentages of adaptation examples are added. Then, for each percentage, we calculate the macro-average WSD accuracy over all the nouns to obtain a single learning curve representing all the nouns.

6.1 Utility of Active Learning and Count-merging

In Figure 2, the curve *r* represents the adaptation process of the baseline approach, where additional WSJ examples are randomly selected during each adaptation iteration. The adaptation process using active learning is represented by the curve *a*, while applying count-merging with active learning is represented by the curve *a-c*. Note that random selection *r* achieves its highest WSD accuracy after *all* the adaptation examples are added. To reach the same accuracy, the *a* approach requires the addition of only 57% of adaptation examples. The *a-c* approach is even more effective and requires only 42% of adaptation examples. This demonstrates the effectiveness of count-merging in further reducing the annotation effort, when compared to using only active learning. To reach the MFS accuracy of 61.1% as shown earlier in Table 1, *a-c* requires just 4% of the adaptation examples.

To determine the utility of the out-of-domain BC examples, we have also conducted three active learning runs using only WSJ adaptation examples. Using 10%, 20%, and 30% of WSJ adaptation examples to build a classifier, the accuracy of these runs is lower than the active learning *a* curve and paired t-tests show that the difference is statistically significant at the level of significance 0.01.

6.2 Using Sense Priors Information

As mentioned in section 1, research in (Escudero et al., 2000) noted an improvement in accuracy when they adjusted the BC and WSJ datasets such that the proportions of the different senses of each word were the same between BC and WSJ. We can similarly choose BC examples such that the sense priors in the BC training data adhere to the sense priors in the WSJ evaluation data. To gauge the effectiveness of this approach, we first assume that we know the *true* sense priors of each noun in the WSJ evaluation data. We then gather BC training examples for a noun to adhere as much as possible to the sense priors in WSJ. Assume sense s_i is the predominant sense in the WSJ evaluation data, s_i has a sense prior of p_i in the WSJ data and has n_i BC training examples. Taking n_i examples to represent a sense prior of p_i, we proportionally determine the number of BC examples to gather for other senses s according to their respective sense priors in WSJ. If there are insufficient training examples in BC for some sense s, whatever available examples of s are used.

This approach gives an average of 195 BC training examples for the 21 nouns. With this new set of training examples, we perform adaptation using active learning and obtain the *a-truePrior* curve in Figure 2. The *a-truePrior* curve shows that by ensuring that the sense priors in the BC training data adhere as much as possible to the sense priors in the WSJ data, we start off with a higher WSD accuracy. However, the performance is no different from the *a*

curve after 35% of adaptation examples are added. A possible reason might be that by strictly adhering to the sense priors in the WSJ data, we have removed too many BC training examples, from an average of 310 examples per noun as shown in Table 1, to an average of 195 examples.

6.3 Using Predominant Sense Information

Research by McCarthy et al. (2004) and Koeling et al. (2005) pointed out that a change of predominant sense is often indicative of a change in domain. For example, the predominant sense of the noun *interest* in the BC part of the DSO corpus has the meaning "a sense of concern with and curiosity about someone or something". In the WSJ part of the DSO corpus, the noun *interest* has a different predominant sense with the meaning "a fixed charge for borrowing money", which is reflective of the business and finance focus of the WSJ corpus.

Instead of restricting the BC training data to adhere strictly to the sense priors in WSJ, another alternative is just to ensure that the predominant sense in BC is the same as that of WSJ. Out of the 21 nouns, 12 nouns have the same predominant sense in both BC and WSJ. The remaining 9 nouns that have different predominant senses in the BC and WSJ data are: *center, field, figure, interest, line, need, order, term, value*. The row *9 nouns* in Table 1 gives some information for this set of 9 nouns. To gauge the utility of this approach, we conduct experiments on these nouns by first assuming that we know the *true* predominant sense in the WSJ data. Assume that the WSJ predominant sense of a noun is s_i and s_i has n_i examples in the BC data. We then gather BC examples for a noun to adhere to this WSJ predominant sense, by gathering only up to n_i BC examples for each sense of this noun. This approach gives an average of 190 BC examples for the 9 nouns. This is higher than an average of 83 BC examples for these 9 nouns if BC examples are selected to follow the sense priors of WSJ evaluation data as described in the last subsection 6.2.

For these 9 nouns, the average KL-divergence between the sense priors of the original BC data and WSJ evaluation data is 0.81. This drops to 0.51 after ensuring that the predominant sense in BC is the same as that of WSJ, confirming that the sense priors in the newly gathered BC data more closely follow

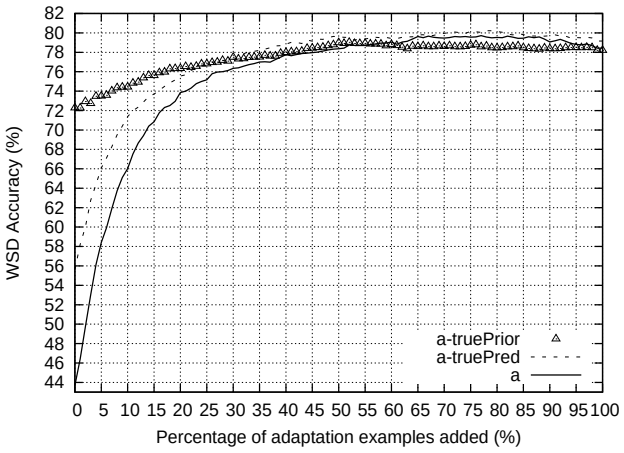

Figure 3: Using true predominant sense for the 9 nouns.

the sense priors in WSJ. Using this new set of training examples, we perform domain adaptation using active learning to obtain the curve *a-truePred* in Figure 3. For comparison, we also plot the curves *a* and *a-truePrior* for this set of 9 nouns in Figure 3. Results in Figure 3 show that *a-truePred* starts off at a higher accuracy and performs consistently better than the *a* curve. In contrast, though *a-truePrior* starts at a high accuracy, its performance is lower than *a-truePred* and *a* after 50% of adaptation examples are added. The approach represented by *a-truePred* is a compromise between ensuring that the sense priors in the training data follow as closely as possible the sense priors in the evaluation data, while retaining enough training examples. These results highlight the importance of striking a balance between these two goals.

In (McCarthy et al., 2004), a method was presented to determine the predominant sense of a word in a corpus. However, in (Chan and Ng, 2005), we showed that in a supervised setting where one has access to some annotated training data, the EM-based method in section 5 estimates the sense priors more effectively than the method described in (McCarthy et al., 2004). Hence, we use the EM-based algorithm to estimate the sense priors in the WSJ evaluation data for each of the 21 nouns. The sense with the highest estimated sense prior is taken as the predominant sense of the noun.

For the set of 12 nouns where the predominant

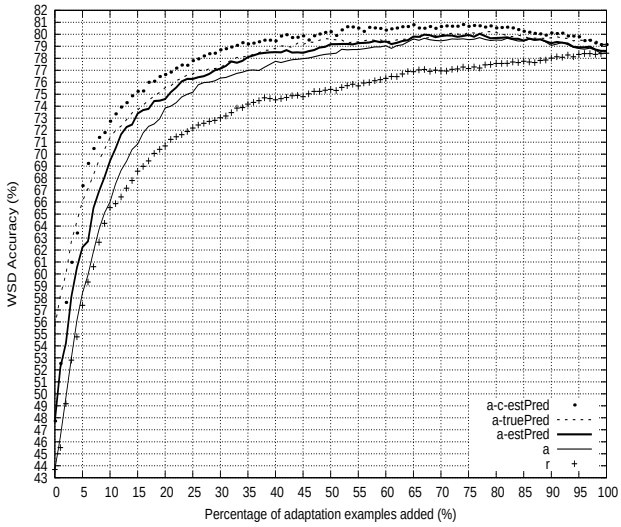

Figure 4: Using estimated predominant sense for the 9 nouns.

Accuracy	% adaptation examples needed			
	r	a	a-estPred	a-c-estPred
50%: 61.1	8	7 (0.88)	5 (0.63)	4 (0.50)
60%: 64.5	10	9 (0.90)	7 (0.70)	5 (0.50)
70%: 68.0	15	12 (0.80)	9 (0.60)	6 (0.40)
80%: 71.5	23	16 (0.70)	12 (0.52)	9 (0.39)
90%: 74.9	46	24 (0.52)	21 (0.46)	15 (0.33)
100%: 78.4	100	51 (0.51)	38 (0.38)	29 (0.29)

Table 2: Annotation savings and percentage of adaptation examples needed to reach various accuracies.

sense remains unchanged between BC and WSJ, the EM-based algorithm is able to predict that the predominant sense remains unchanged for *all* 12 nouns. Hence, we will focus on the 9 nouns which have different predominant senses between BC and WSJ for our remaining adaptation experiments. For these 9 nouns, the EM-based algorithm correctly predicts the WSJ predominant sense for 6 nouns. Hence, the algorithm is able to predict the correct predominant sense for 18 out of 21 nouns overall, representing an accuracy of 86%.

Figure 4 plots the curve *a-estPred*, which is similar to *a-truePred*, except that the predominant sense is now estimated by the EM-based algorithm. Employing count-merging with *a-estPred* produces the curve *a-c-estPred*. For comparison, the curves *r*, *a*, and *a-truePred* are also plotted. The results show that *a-estPred* performs consistently better than *a*, and *a-c-estPred* in turn performs better than *a-estPred*. Hence, employing the predicted predominant sense and count-merging, we further improve the effectiveness of the active learning-based adaptation process.

With reference to Figure 4, the WSD accuracies of the *r* and *a* curves before and after adaptation are 43.7% and 78.4% respectively. Starting from the mid-point 61.1% accuracy, which represents a 50% accuracy increase from 43.7%, we show in Table 2 the percentage of adaptation examples required by the various approaches to reach certain levels of WSD accuracies. For instance, to reach the final accuracy of 78.4%, *r*, *a*, *a-estPred*, and *a-c-estPred* require the addition of 100%, 51%, 38%, and 29% adaptation examples respectively. The numbers in brackets give the ratio of adaptation examples needed by *a*, *a-estPred*, and *a-c-estPred* versus random selection *r*. For instance, to reach a WSD accuracy of 78.4%, *a-c-estPred* needs only 29% adaptation examples, representing a ratio of 0.29 and an annotation saving of 71%. Note that this represents a more effective adaptation process than the basic active learning *a* approach, which requires 51% adaptation examples. Hence, besides showing that active learning can be used to reduce the annotation effort required for domain adaptation, we have further improved the effectiveness of the adaptation process by using the predicted predominant sense of the new domain and adopting the count-merging technique.

7 Related Work

In applying active learning for domain adaptation, Zhang et al. (2003) presented work on sentence boundary detection using generalized Winnow, while Tur et al. (2004) performed language model adaptation of automatic speech recognition systems. In both papers, out-of-domain and in-domain data were simply mixed together without MAP estimation such as count-merging. For WSD, Fujii et al. (1998) used selective sampling for a Japanese language WSD system, Chen et al. (2006) used active learning for 5 verbs using coarse-grained evaluation, and H. T. Dang (2004) employed active learning for another set of 5 verbs. However, their work only investigated the use of active learning to reduce the annotation effort necessary for WSD, but

did not deal with the porting of a WSD system to a different domain. Escudero et al. (2000) used the DSO corpus to highlight the importance of the issue of domain dependence of WSD systems, but did not propose methods such as active learning or count-merging to address the specific problem of how to perform domain adaptation for WSD.

8 Conclusion

Domain adaptation is important to ensure the general applicability of WSD systems across different domains. In this paper, we have shown that active learning is effective in reducing the annotation effort required in porting a WSD system to a new domain. Also, we have successfully used an EM-based algorithm to detect a change in predominant sense between the training and new domain. With this information on the predominant sense of the new domain and incorporating count-merging, we have shown that we are able to improve the effectiveness of the original adaptation process achieved by the basic active learning approach.

Abstract

Human categorization is neither a binary nor a context-free process. Rather, some concepts are better examples of a category than others, while the criteria for category membership may be satisfied to different degrees by different concepts in different contexts. In light of these empirical facts, WordNet's static category structure appears both excessively rigid and unduly fragile for processing real texts. In this paper we describe a syntagmatic, corpus-based approach to redefining WordNet's categories in a functional, gradable and context-sensitive fashion. We describe how the diagnostic properties for these definitions are automatically acquired from the web, and how the increased flexibility in categorization that arises from these redefinitions offers a robust account of metaphor comprehension in the mold of Glucksberg's (2001) theory of category-inclusion. Furthermore, we demonstrate how this competence with figurative categorization can effectively be governed by automatically-generated ontological constraints, also acquired from the web.

1 Introduction

Linguistic variation across contexts is often symptomatic of ontological differences between contexts. These observable variations can serve as valuable clues not just to the specific senses of words in context (e.g., see Pustejovsky, Hanks and Rumshisky, 2004) but to the underlying ontological structure itself (see Cimiano, Hotho and Staab, 2005). The most revealing variations are syntagmatic in nature, which is to say, they look beyond individual word forms to larger patterns of contiguous usage (Hanks, 2004). In most contexts, the similarity between chocolate, say, and a narcotic like heroin will meagerly reflect the simple ontological fact that both are kinds of substances; certainly, taxonomic measures of similarity as discussed in Budanitsky and Hirst (2006) will capture little more than this commonality. However, in a context in which the addictive properties of chocolate are very salient (e.g., an online dieting forum), chocolate is more likely to be categorized as a drug and thus be considered more similar to heroin. Look, for instance, at the similar ways in which these words can be used: one can be ”chocolate-crazed” or ”chocolate-addicted” and suffer ”chocolate-induced” symptoms (e.g., each of these uses can be found in the pages of Wikipedia). In a context that gives rise to these expressions, it is unsurprising that chocolate should appear altogether more similar to a harmful narcotic.

In this paper we computationally model this idea that language use reflects category structure. As noted by De Leenheer and de Moor (2005), ontologies are lexical representations of concepts, so we can expect the effects of context on language use to closely reflect the effects of context on ontological structure. An understanding of the linguistic effects of context, as expressed through syntagmatic patterns of word usage, should lead therefore to the design of more flexible lexical ontologies that naturally adapt to their contexts of use. WordNet (Fell-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 57–64,
Prague, Czech Republic, June 2007.

baum, 1998) is just one such lexical ontology that can benefit greatly from the added flexibility that context-sensitivity can bring. Though comprehensive in scale and widely used, WordNet suffers from an obvious structural rigidity in which concepts are either entirely within a category or entirely outside a category: no gradation of category membership is allowed, and no contextual factors are brought to bear on criteria for membership. Thus, a gun is always a weapon in WordNet while an axe is never so, despite the uses (sporting or murderous) to which each can be put.

In section two we describe a computational framework for giving WordNet senses a functional, context-sensitive form. These functional forms simultaneously represent i) an intensional definition for each word sense; ii) a structured query capable of retrieving instances of the corresponding category from a context-specific corpus; and iii) a membership function that assigns gradated scores to these instances based on available syntagmatic evidence. In section three we describe how the knowledge required to automate this functional re-definition is acquired from the web and linked to WordNet. In section four we describe how these re-definitions can produce a robust model of metaphor, before we evaluate the descriptive sufficiency of this approach in section five, comparing it to the knowledge already available within WordNet. We conclude with some final remarks in section six.

2 Functional Context-Sensitive Categories

We take a wholly textual view of context and assume that a given context can be implicitly characterized by a representative text corpus. This corpus can be as large as a text archive or an encyclopedia (e.g., the complete text of Wikipedia), or as small as a single document, a sentence or even a single noun-phrase. For instance, the micro-context "alcoholic apple-juice" is enough to implicate the category Liquor, rather than Juice, as a semantic head, while "lovable snake" can be enough of a context to locally categorize Snake as a kind of Pet. There is a range of syntagmatic patterns that one can exploit to glean category insights from a text. For instance, the "X kills" pattern is enough to categorize X as a kind of Killer, "hunts X" is enough to categorize X as a kind of Prey, while "X-covered", "X-dipped" and "X-frosted" all indicate that X is a kind of Covering. Likewise, "army of X" suggests that a context views X as a kind of Soldier, while "barrage of X" suggests that X should be seen as a kind of Projectile.

We operationalize the collocation-type of adjective and noun via the function (*attr ADJ NOUN*), which returns a number in the range 0...1; this represents the extent to which ADJ is used to modify NOUN in the context-defining corpus. Dice's coefficient (e.g., see Cimiano *et al*., 2005) is used to implement this measure. A context-sensitive category membership function can be defined, as in that for Fundamentalist in Figure 1:

```
(define Fundamentalist.0 (arg0)
    (*  (max
            (%isa arg0 Person.0)
            (%isa arg0 Group.0))
        (min
            (max
                (attr political arg0)
                (attr religious arg0))
            (max
                (attr extreme arg0)
                (attr violent arg0)
                (attr radical arg0)))))
```

Figure 1. A functional re-definition of the category Fundamentalist.

The function of Figure 1 takes, as a single argument $\mathbf{arg}_0$, a putative member of the category Fundamentalist.0 (note how the sense tag, 0, is used to identify a specific WordNet sense of "fundamentalist"), and returns a membership score in the range 0...1 for this term. This score reflects the syntagmatic evidence for considering $\mathbf{arg}_0$ to be political or religious, as well as extreme or violent or radical. The function *(%isa* $\mathbf{arg}_0$ *CAT)* returns a value of 1.0 if some sense of $\mathbf{arg}_0$ is a descendent of CAT (here Person.0 or Group.0), otherwise 0. This safeguards ontological coherence and ensures that only kinds of people or groups can ever be considered as fundamentalists.

The example of Figure 1 is hand-crafted, but a functional form can be assigned automatically to many of the synsets in WordNet by heuristic means.

For instance, those of Figure 2 are automatically derived from WordNet's morpho-semantic links:

*(define Fraternity.0 (**arg**$_0$)*
((%sim **arg**$_0$ Fraternity.0)*
(max
*(attr fraternal **arg**$_0$)*
*(attr brotherly **arg**$_0$))))*

*(define Orgasm.0 (**arg**$_0$)*
((%sim **arg**$_0$ Orgasm.0)*
(max
*(attr climactic **arg**$_0$)*
*(attr orgasmic **arg**$_0$))))*

Figure 2. Exploiting the WordNet links between nouns and their adjectival forms.

The function *(%sim **arg**$_0$ CAT)* reflects the perceived similarity between the putative member arg_0 and a synset CAT in WordNet, using one of the standard formulations described in Budanitsky and Hirst (2006). Thus, any kind of group (e.g., a glee club, a Masonic lodge, or a barbershop quartet) described in a text as "fraternal" or "brotherly" (both occupy the same WordNet synset) can be considered a Fraternity to the corresponding degree, tempered by its *a priori* similarity to a Fraternity; likewise, any climactic event can be categorized as an Orgasm to a more or less degree.

Alternately, the function of Figure 3 is automatically obtained for the lexical concept Espresso by shallow parsing its WordNet gloss: "strong black coffee brewed by forcing steam under pressure through powdered coffee beans".

*(define Espresso.0 (**arg**$_0$)*
((%sim **arg**$_0$ Espresso.0)*
(min
*(attr strong **arg**$_0$)*
*(attr black **arg**$_0$))))*

Figure 3. A functional re-definition of the category Espresso based on its WordNet gloss.

It follows that any substance (e.g., oil or tea) described locally as "black" and "strong" with a non-zero taxonomic similarity to coffee can be considered a kind of Espresso.

Combining the contents of WordNet 1.6 and WordNet 2.1, 27,732 different glosses (shared by 51,035 unique word senses) can be shallow parsed to yield a definition of the kind shown in Figure 3. Of these, 4525 glosses yield two or more properties that can be given functional form via *attr*. However, one can question whether these features are sufficient, and more importantly, whether they are truly diagnostic of the categories they are used to define. In the next section we consider another source of diagnostic properties, explicit similes on the web, before, in section 5, comparing the quality of these properties to those available from WordNet.

3 Diagnostic Properties on the Web

We employ the *Google* search engine as a retrieval mechanism for acquiring the diagnostic properties of categories from the web, since the *Google* API and its support for the wildcard term * allows this process to be fully automated. The guiding intuition here is that looking for explicit similes of the form "X is as P as Y" is the surest way of finding the most salient properties of a term Y; with other syntagmatic patterns, such as adjective:noun collocations, one cannot be sure that the adjective is central to the noun.

Since we expect that explicit similes will tend to exploit properties that occupy an exemplary point on a scale, we first extract a list of antonymous adjectives, such as "hot" or "cold", from WordNet. For every adjective ADJ on this list, we send the query *"as ADJ as *"* to Google and scan the first 200 snippets returned to extract different noun values for the wildcard *. From each set of snippets we can also ascertain the relative frequencies of different noun values for ADJ. The complete set of nouns extracted in this way is then used to drive a second phase of the search, in which the query template *"as * as a NOUN"* is used to acquire similes that may have lain beyond the 200-snippet horizon of the original search, or that may hinge on adjectives not included on the original list. Together, both phases collect a wide-ranging series of core samples (of 200 hits each) from across the web, yielding a set of 74,704 simile instances (of 42,618 unique types) relating

3769 different adjectives to 9286 different nouns

3.1 Property Filtering

Unfortunately, many of these similes are not sufficiently well-formed to identify salient properties. In many cases, the noun value forms part of a larger noun phrase: it may be the modifier of a compound noun (as in "bread lover"), or the head of complex noun phrase (such as "gang of thieves" or "wound that refuses to heal"). In the former case, the compound is used if it corresponds to a compound term in WordNet and thus constitutes a single lexical unit; if not, or if the latter case, the simile is rejected. Other similes are simply too contextual or underspecified to function well in a null context, so if one must read the original document to make sense of the simile, it is rejected. More surprisingly, perhaps, a substantial number of the retrieved similes are ironic, in which the literal meaning of the simile is contrary to the meaning dictated by common sense. For instance, "as hairy as a bowling ball" (found once) is an ironic way of saying "as hairless as a bowling ball" (also found just once). Many ironies can only be recognized using world knowledge, such as "as sober as a Kennedy" and "as tanned as an Irishman".

Given the creativity involved in these constructions, one cannot imagine a reliable automatic filter to safely identify bona-fide similes. For this reason, the filtering task is performed by a human judge, who annotated 30,991 of these simile instances (for 12,259 unique adjective/noun pairings) as non-ironic and meaningful in a null context; these similes relate a set of 2635 adjectives to a set of 4061 different nouns. In addition, the judge also annotated 4685 simile instances (of 2798 types) as ironic; these similes relate a set of 936 adjectives to a set of 1417 nouns. Perhaps surprisingly, ironic pairings account for over 13% of all annotated simile instances and over 20% of all annotated types.

3.2 Linking to WordNet Senses

To create functional WordNet definitions from these adjective:noun pairings, we first need to identify the WordNet sense of each noun. For instance, "as stiff as a zombie" might refer either to a re-animated corpse or to an alcoholic cocktail (both are senses of "zombie" in WordNet, and drinks can be "stiff" too). Disambiguation is trivial for nouns with just a single sense in WordNet. For nouns with two or more fine-grained senses that are all taxonomically close, such as "gladiator" (two senses: a boxer and a combatant), we consider each sense to be a suitable target. In some cases, the WordNet gloss for as particular sense will literally mention the adjective of the simile, and so this sense is chosen. In all other cases, we employ a strategy of mutual disambiguation to relate the noun vehicle in each simile to a specific sense in WordNet. Two similes "as A as N_1" and "as A as N_2" are mutually disambiguating if N_1 and N_2 are synonyms in WordNet, or if some sense of N_1 is a hypernym or hyponym of some sense of N_2 in WordNet. For instance, the adjective "scary" is used to describe both the noun "rattler" and the noun "rattlesnake" in bona-fide (non-ironic) similes; since these nouns share a sense, we can assume that the intended sense of "rattler" is that of a dangerous snake rather than a child's toy. Similarly, the adjective "brittle" is used to describe both saltines and crackers, suggesting that it is the bread sense of "cracker" rather than the hacker, firework or hillbilly senses (all in WordNet) that is intended.

These heuristics allow us to automatically disambiguate 10,378 bona-fide simile types (85%), yielding a mapping of 2124 adjectives to 3778 different WordNet senses. Likewise, 77% (or 2164) of the simile types annotated as ironic are disambiguated automatically. A remarkable stability is observed in the alignment of noun vehicles to WordNet senses: 100% of the ironic vehicles always denote the same sense, no matter the adjective involved, while 96% of bona-fide vehicles always denote the same sense. This stability suggests two conclusions: the disambiguation process is consistent and accurate; but more intriguingly, only one coarse-grained sense of any word is likely to be sufficiently exemplary of some property to be useful in a simile.

4 From Similes to Category Functions

As noted in section 3, the filtered web data yields 12,259 bona-fide similes describing 4061 target nouns in terms of 2635 different adjectival properties. Word-sense disambiguation allows 3778 synsets in WordNet to be given a functional redefinition in terms of 2124 diagnostic properties, as

in the definition of Gladiator in Figure 4:

*(define Gladiator.0 (**arg**$_0$)*
((%isa **arg**$_0$ Person.0)*
((%sim **arg**$_0$ Gladiator.0)*
(combine
*(attr strong **arg**$_0$)*
*(attr violent **arg**$_0$)*
*(attr manly **arg**$_0$)))))*

Figure 4. A web-based definition of Gladiator.

Since we cannot ascertain from the web data which properties are necessary and which are collectively sufficient, we use the function *combine* to aggregate the available evidence. This function implements a naïve probabilistic *or*, in which each piece of syntagmatic evidence is naively assumed to be independent, as follows:

(combine $e_0\, e_1$) = e_0 + $e_1(1 - e_0)$
(combine $e_0\, e_{1 \ldots} e_n$) = (combine e_0 (combine $e_{1 \ldots} e_n$))

Thus, any combatant or competitor (such as a sportsman) that is described as *strong*, *violent* or *manly* in a corpus can be categorized as a Gladiator in that context; the more properties that hold, and the greater the degree to which they hold, the greater the membership score that is assigned.

The source of the hard taxonomic constraint *(%isa* arg_0 *Person.0)* is explained in the next section. For now, note how the use of *%sim* in the functions of Figures 2, 3 and 4 means that these membership functions readily admit both literal and metaphoric members. Since the line between literal and metaphoric uses of a category is often impossible to draw, the best one can do is to accept metaphor as a gradable phenomenon (see Hanks, 2006). The incorporation of taxonomic similarity via *%sim* ensures that literal members will tend to receive higher membership scores, and that the most tenuous metaphors will receive the lowest membership scores (close to 0.0).

4.1 Constrained Category Inclusion

Simile and metaphor involve quite different conceptual mechanisms. For instance, anything that is particularly strong or black might meaningfully be called ”as black as espresso” or ”as strong as espresso”, yet few such things can meaningfully be called just ”espresso”. While simile is a mechanism for highlighting inter-concept similarity, metaphor is at heart a mechanism of category inclusion (see Glucksberg, 2001). As the espresso example demonstrates, category inclusion is more than a matter of shared properties: humans have strong intuitions about the structure of categories and the extent to which they can be stretched to include new members. So while it is sensible to apply the category Espresso to other substances, preferably liquids, it seems nonsensical to apply the category to animals, artifacts, places and so on.

Much as the salient properties of categories can be acquired form the web (see section 3), so too can the intuitions governing inclusion amongst categories. For instance, an attested web-usage of the phrase ”Espresso-like CAT” tells us that sub-types of CAT are allowable targets of categorization by the category Espresso. Thus, since the query ”espresso-like substance” returns 3 hits via Google, types of substance (oil, etc.) can be described as Espresso if they are contextually strong and black. In contrast, the query ”espresso-like person” returns 0 hits, so no instance of person can be described as Espresso, no matter how black or how strong. While this is clearly a heuristic approach to a complex cognitive problem, it does allow us to tap into the tacit knowledge that humans employ in categorization. More generally, a concept X can be included in a category C if X exhibits salient properties of C and, for some hypernym H of X in WordNet, we can find an attested use of ”C-like H” on the web.

If we can pre-fetch all possible ”C-like H” from the web, this will allow comprehension to proceed without having to resort to web analysis in mid-categorization. While there are too many possible values of H to make full pre-fetching a practical reality, we *can* generalize the problem somewhat, by selecting a range of values for H from the middle-layer of WordNet, such as *Person*, *Substance*, *Animal*, *Tool*, *Plant*, *Structure*, *Event*, *Vehicle*, *Idea* and *Place*, and by pre-fetching the query ”C-like H” for all 4061 nouns collected in section 3, combined with this limited set of H values. For every noun in our database then, we precompile a vector of possible category inclusions.

For instance, ”lattice” yields the following vector:

{*structure(1620), substance(8), container(1), vehicle(1)*}

where numbers in parentheses indicate the web-frequency of the corresponding ”Lattice-like H” query. Thus, the category Lattice can be used to describe (and metaphorically include) other kinds of structure (like crystals), types of substance (e.g., crystalline substances), containers (like honeycombs) and even vehicles (e.g., those with many compartments). Likewise, the noun ”snake” yields the following vector of possibilities:

{*structure(125), animal(122), person(56), vehicle(17), tool(9)*}

(note, the frequency for ”person” includes the frequency for ”man” and ”woman”). The category Snake can also be used to describe and include structures (like tunnels), other animals (like eels), people (e.g., the dishonest variety), vehicles (e.g., articulated trucks, trains) and tools (e.g., hoses). The noun ”gladiator” yields a vector of just one element, {*person(1)*}, from which the simple constraint *(%isa* arg_0 *Person.0)* in Figure 4 is derived. In contrast, ”snake” is now given the definition of Figure 5:

```
(define Snake.0 (arg0)
      (*  (max
            (%isa arg0 Structure.0)
            (%isa arg0 Animal.0)
            (%isa arg0 Person.0)
            (%isa arg0 Vehicle.0))
          (* (%sim arg0 Snake.0)
             (combine
                 (attr cunning arg0)
                 (attr slippery arg0)
                 (attr flexible arg0)
                 (attr slim arg0)
                 (attr sinuous arg0)
                 (attr crooked arg0)
                 (attr deadly arg0)
                 (attr poised arg0)))))
```

Figure 5. A membership function for Snake using web-derived category-inclusion constraints.

Glucksberg (2001) notes that the same category, used figuratively, can exhibit different qualities in different metaphors. For instance, Snake might describe a kind of crooked person in one metaphor, a poised killer in another metaphor, and a kind of flexible tool in yet another. The use of *combine* in Figure 5 means that a single category definition can give rise to each of these perspectives in the appropriate contexts. We therefore do not need a different category definition for each metaphoric use of Snake.

To illustrate the high-level workings of category-inclusion, Table 1 generalizes over the set of 3778 disambiguated nouns from section 3 to estimate the propensity for one semantic category, like Person, to include members of another category, like Animal, in X-like Y constructs.

X-like Y	*P*	*A*	*Sub*	*T*	*Str*
(P)erson	.66	.05	.03	.04	.09
(A)nimal	.36	.27	.04	.05	.15
(Sub)stance	.14	.03	.37	.05	.32
(T)ool	.08	.03	.07	.22	.34
(Str)ucture	.04	.03	.03	.03	.43

Table 1. The Likelihood of a category X accommodating a category Y.

Table 1 reveals that 36% of ”ANIMAL-like” patterns on the web describe a kind of Person, while only 5% of ”PERSON-like” patterns on the web describe a kind of Animal. Category inclusion appears here to be a conservative mechanism, with like describing like in most cases; thus, types of Person are most often used to describe other kinds of Person (comprising 66% of ”PERSON-like” patterns), types of substance to describe other substances, and so on. The clear exception is Animal, with ”ANIMAL-like” phrases more often used to describe people (36%) than other kinds of animal (27%). The anthropomorphic uses of this category demonstrate the importance of folk-knowledge in figurative categorization, of the kind one is more likely to find in real text, and on the web (as in section 3), rather than in resources like WordNet.

5 Empirical Evaluation

The simile gathering process of section 3, abetted by Google's practice of ranking pages according to popularity, should reveal the most frequently-used comparative nouns, and thus, the most useful categories to capture in a general-purpose ontology like WordNet. But the descriptive sufficiency of these categories is not guaranteed unless the defining properties ascribed to each can be shown to be collectively rich enough, and individually salient enough, to predict how each category is perceived and applied by a language user.

If similes are indeed a good basis for mining the most salient and diagnostic properties of categories, we should expect the set of properties for each category to accurately predict how the category is perceived as a whole. For instance, humans – unlike computers – do not generally adopt a dispassionate view of ideas, but rather tend to associate certain positive or negative feelings, or affective values, with particular ideas. Unsavoury activities, people and substances generally possess a negative affect, while pleasant activities and people possess a positive affect. Whissell (1989) reduces the notion of affect to a single numeric dimension, to produce a *dictionary of affect* that associates a numeric value in the range 1.0 (most unpleasant) to 3.0 (most pleasant) with over 8000 words in a range of syntactic categories (including adjectives, verbs and nouns). So to the extent that the adjectival properties yielded by processing similes paint an accurate picture of each category / noun-sense, we should be able to predict the affective rating of each vehicle via a weighted average of the affective ratings of the adjectival properties ascribed to these nouns (i.e., where the affect rating of each adjective contributes to the estimated rating of a noun in proportion to its frequency of co-occurrence with that noun in our simile data). More specifically, we should expect that ratings estimated via these simile-derived properties should correlate well with the independent ratings contained in Whissell's dictionary.

To determine whether similes do offer the clearest perspective on a category's most salient properties, we calculate and compare this correlation using the following data sets:

A. Adjectives derived from annotated bona-fide (non-ironic) similes only.

B. Adjectives derived from all annotated similes (both ironic and non-ironic).

C. Adjectives derived from ironic similes only.

D. All adjectives used to modify a given noun in a large corpus. We use over 2-gigabytes of text from the online encyclopaedia Wikipedia as our corpus.

E. The set of 63,935 unique property-of-noun pairings extracted via shallow-parsing from WordNet glosses in section 2, e.g., *strong* and *black* for Espresso.

Predictions of affective rating were made from each of these data sources and then correlated with the ratings reported in Whissell's dictionary of affect using a two-tailed Pearson test ($p < 0.01$). As expected, property sets derived from bona-fide similes only (A) yielded the best correlation (+0.514) while properties derived from ironic similes only (C) yielded the worst (-0.243); a middling correlation coefficient of 0.347 was found for all similes together, demonstrating the fact that bona-fide similes outnumber ironic similes by a ratio of 4 to 1. A weaker correlation of 0.15 was found using the corpus-derived adjectival modifiers for each noun (D); while this data provides quite large property sets for each noun, these properties merely reflect potential rather than intrinsic properties of each noun and so do not reveal what is most diagnostic about a category. More surprisingly, property sets derived from WordNet glosses (E) are also poorly predictive, yielding a correlation with Whissell's affect ratings of just 0.278. This suggests that the properties used to define categories in hand-crafted resources like WordNet are not always those that actually reflect how humans think of these categories.

6 Concluding Remarks

Much of what we understand about different categories is based on tacit and defeasible knowledge of the outside world, knowledge that cannot easily be shoe-horned into the rigid *is-a* structure of an ontology like WordNet. This already-complex picture

is complicated even further by the often metaphoric relationship between words and the categories they denote, and by the fact that the metaphor/literal distinction is not binary but gradable. Furthermore, the gradability of category membership is clearly influenced by context: in a corpus describing the exploits of Vikings, an axe will most likely be seen as a kind of weapon, but in a corpus dedicated to forestry, it will likely describe a tool. A resource like WordNet, in which *is-a* links are reserved for category relationships that are always true, in any context, is going to be inherently limited when dealing with real text.

We have described an approach that can be seen as a functional equivalent to the CPA (Corpus Pattern Analysis) approach of Pustejovsky *et al*. (2004), in which our goal is not that of automated induction of word senses in context (as it is in CPA) but the automated induction of flexible, context-sensitive category structures. As such, our goal is primarily ontological rather than lexicographic, though both approaches are complementary since each views syntagmatic evidence as the key to understanding the use of lexical concepts in context. By defining category membership in terms of syntagmatic expectations, we establish a functional and gradable basis for determining whether one lexical concept (or synset) in WordNet deserves to be seen as a descendant of another in a particular corpus and context. Augmented with ontological constraints derived from the usage of "X-like Y" patterns on the web, we also show how these membership functions can implement Glucksberg's (2001) theory of category inclusion.

We have focused on just one syntagmatic pattern here – adjectival modification of nouns – but categorization can be inferred from a wide range of productive patterns in text, particularly those concerning verbs and their case-fillers. For instance, verb-centred similes of the form "to V+*inf* like a|an N" and "to be V+*past* like a|an N" reveal insights into the diagnostic behaviour of entities (e.g., that predators hunt, that prey is hunted, that eagles soar and bombs explode). Taken together, adjective-based properties and verb-based behaviours can paint an even more comprehensive picture of each lexical concept, so that e.g., political agents that kill can be categorized as assassins, loyal entities that fight can be categorized as soldiers, and so on. An important next step, then, is to mine these behaviours from the web and incorporate the corresponding syntagmatic expectations into our category definitions. The symbolic nature of the resulting definitions means these can serve not just as mathematical membership functions, but as "active glosses", capable of recruiting their own members in a particular context while demonstrating a flexibility with categorization and a genuine competence with metaphor.

A Bayesian Model for Discovering Typological Implications

Abstract

A standard form of analysis for linguistic typology is the universal implication. These implications state facts about the range of extant languages, such as "if objects come after verbs, then adjectives come after nouns." Such implications are typically discovered by painstaking hand analysis over a small sample of languages. We propose a computational model for assisting at this process. Our model is able to discover both well-known implications as well as some novel implications that deserve further study. Moreover, through a careful application of hierarchical analysis, we are able to cope with the well-known sampling problem: languages are not independent.

1 Introduction

Linguistic typology aims to distinguish between logically possible languages and actually observed languages. A fundamental building block for such an understanding is the *universal implication* (Greenberg, 1963). These are short statements that restrict the space of languages in a concrete way (for instance "object-verb ordering implies adjective-noun ordering"); Croft (2003), Hawkins (1983) and Song (2001) provide excellent introductions to linguistic typology. We present a statistical model for automatically discovering such implications from a large typological database (Haspelmath et al., 2005).

Analyses of universal implications are typically performed by linguists, inspecting an array of 30-100 languages and a few pairs of features. Looking at all pairs of features (typically several hundred) is virtually impossible by hand. Moreover, it is insufficient to simply look at counts. For instance, results presented in the form "verb precedes object implies prepositions in 16/19 languages" are nonconclusive. While compelling, this is not enough evidence to decide if this is a statistically well-founded implication. For one, maybe 99% of languages have prepositions: then the fact that we've achieved a rate of 84% actually seems really bad. Moreover, if the 16 languages are highly related historically or areally (geographically), and the other 3 are not, then we may have only learned something about geography.

In this work, we propose a statistical model that deals cleanly with these difficulties. By building a computational model, it is possible to apply it to a very large typological database and search over many thousands of pairs of features. Our model hinges on two novel components: a statistical noise model a hierarchical inference over language families. To our knowledge, there is no prior work directly in this area. The closest work is represented by the books *Possible and Probable Languages* (Newmeyer, 2005) and *Language Classification by Numbers* (McMahon and McMahon, 2005), but the focus of these books is on automatically discovering phylogenetic trees for languages based on Indo-European cognate sets (Dyen et al., 1992).

2 Data

The database on which we perform our analysis is the *World Atlas of Language Structures* (Haspelmath et al., 2005). This database contains information about 2150 languages (sampled from across the world; Figure 1 depicts the locations of lan-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 65–72,
Prague, Czech Republic, June 2007.

Language	Numeral Classifiers	Rel/N Order	O/V Order	Glottalized Consonants	Tone	Number of Genders
English	Absent	NRel	VO	None	None	Three
Hindi	Absent	RelN	OV	None	None	Two
Mandarin	Obligatory	RelN	VO	None	Complex	None
Russian	Absent	NRel	VO	None	None	Three
Tukang Besi	Absent	?	Either	Implosives	None	Three
Zulu	Absent	NRel	VO	Ejectives	Simple	Five+

Table 1: Example database entries for a selection of diverse languages and features.

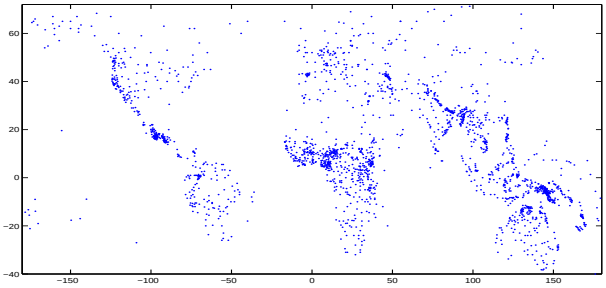

Figure 1: Map of the 2150 languages in the database.

guages). There are 139 *features* in this database, broken down into categories such as "Nominal Categories," "Simple Clauses," "Phonology," "Word Order," etc. The database is *sparse*: for many language/feature pairs, the feature value is unknown. In fact, only about 16% of all possible language/feature pairs are known. A sample of five languages and six features from the database are shown in Table 1.

Importantly, the density of samples is not random. For certain languages (eg., English, Chinese, Russian), nearly all features are known, whereas other languages (eg., Asturian, Omagua, Frisian) that have fewer than five feature values known. Furthermore, some features are known for many languages. This is due to the fact that certain features take less effort to identify than others. Identifying, for instance, if a language has a particular set of phonological features (such as glottalized consonants) requires only listening to speakers. Other features, such as determining the order of relative clauses and nouns require understanding much more of the language.

3 Models

In this section, we propose two models for automatically uncovering universal implications from noisy, sparse data. First, note that even well attested implications are not always exceptionless. A common example is that verbs preceding objects ("VO") implies adjectives following nouns ("NA"). This implication (VO $\supset$ NA) has one glaring exception: English. This is one particular form of noise. Another source of noise stems from transcription. WALS contains data about languages documented by field linguists as early as the 1900s. Much of this older data was collected before there was significant agreement in documentation style. Different field linguists often had different dimensions along which they segmented language features into classes. This leads to noise in the properties of individual languages.

Another difficulty stems from the *sampling problem*. This is a well-documented issue (see, eg., (Croft, 2003)) stemming from the fact that any set of languages is not sampled uniformly from the space of all probable languages. Politically interesting languages (eg., Indo-European) and typologically unusual languages (eg., Dyirbal) are better documented than others. Moreover, languages are not independent: German and Dutch are more similar than German and Hindi due to history and geography.

The first model, FLAT, treats each language as independent. It is thus susceptible to sampling problems. For instance, the WALS database contains a half dozen versions of German. The FLAT model considers these versions of German just as statistically independent as, say, German and Hindi. To cope with this problem, we then augment the FLAT model into a HIERarchical model that takes advantage of known hierarchies in linguistic phylogenetics. The HIER model explicitly models the fact that individual languages are *not* independent and exhibit strong familial dependencies. In both models, we initially restrict our attention to pairs of features. We will describe our models as if all features are binary. We expand any multi-valued feature with K values into K binary features in a "one versus rest" manner.

3.1 The FLAT Model

In the FLAT model, we consider a $2 \times N$ matrix of feature values. The N corresponds to the number of languages, while the 2 corresponds to the two features currently under consideration (eg., object/verb order and noun/adjective order). The order of the

two features is important: f_1 implies f_2 is logically different from f_2 implies f_1. Some of the entries in the matrix will be unknown. We may safely remove all languages from consideration for which *both* are unknown, but we do *not* remove languages for which only one is unknown. We do so because our model needs to capture the fact that if f_2 is *always* true, then $f_1 \supset f_2$ is uninteresting.

The statistical model is set up as follows. There is a single variable (we will denote this variable "m") corresponding to whether the implication holds. Thus, $m = 1$ means that f_1 implies f_2 and $m = 0$ means that it does not. Independent of m, we specify two feature priors, π_1 and π_2 for f_1 and f_2 respectively. π_1 specifies the prior probability that f_1 will be true, and π_2 specifies the prior probability that f_2 will be true. One can then put the model together naïvely as follows. If $m = 0$ (i.e., the implication does not hold), then the entire data matrix is generated by choosing values for f_1 (resp., f_2) independently according to the prior probability π_1 (resp., π_2). On the other hand, if $m = 1$ (i.e., the implication *does* hold), then the first column of the data matrix is generated by choosing values for f_1 independently by π_1, but the second column is generated differently. In particular, if for a particular language, we have that f_1 is true, then the fact that the implication holds means that f_2 *must* be true. On the other hand, if f_1 is false for a particular language, then we may generate f_2 according to the prior probability π_2. Thus, having $m = 1$ means that the model is significantly more constrained. In equations:

$$p(f_1 \mid \pi_1) = \pi_1^{f_1}(1-\pi_1)^{1-f_1}$$

$$p(f_2 \mid f_1, \pi_2, m) = \begin{cases} f_2 & m = f_1 = 1 \\ \pi_2^{f_2}(1-\pi_2)^{1-f_2} & \text{otherwise} \end{cases}$$

The problem with this naïve model is that it does not take into account the fact that there is "noise" in the data. (By noise, we refer either to mis-annotations, or to "strange" languages like English.) To account for this, we introduce a simple noise model. There are several options for parameterizing the noise, depending on what independence assumptions we wish to make. One could simply specify a noise rate for the entire data set. One could alternatively specify a language-specific noise rate. Or one could specify a feature-specific noise rate. We opt for a blend between the first and second option. We assume an underlying noise rate for the entire data set, but that, conditioned on this underlying rate, there is a language-specific noise level. We believe this to be an appropriate noise model because it models the fact that the majority of information for a single language is from a single source. Thus, if there is an error in the database, it is more likely that other errors will be for the same languages.

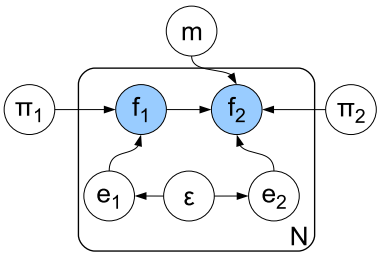

Figure 2: Graphical model for the FLAT model.

In order to model this statistically, we assume that there are latent variables $e_{1,n}$ and $e_{2,n}$ for each language n. If $e_{1,n} = 1$, then the first feature for language n is wrong. Similarly, if $e_{2,n} = 1$, then the second feature for language n is wrong. Given this model, the probabilities are exactly as in the naïve model, with the exception that instead of using f_1 (resp., f_2), we use the exclusive-or[1] $f_1 \otimes e_1$ (resp., $f_2 \otimes e_2$) so that the feature values are flipped whenever the noise model suggests an error.

The graphical model for the FLAT model is shown in Figure 2. Circular nodes denote random variables and arrows denote conditional dependencies. The rectangular plate denotes the fact that the elements contained within it are replicated N times (N is the number of languages). In this model, there are four "root" nodes: the implication value m; the two feature prior probabilities π_1 and π_2; and the language-specific error rate ϵ. On all of these nodes we place Bayesian priors. Since m is a binary random variable, we place a Bernoulli prior on it. The πs are Bernoulli random variables, so they are given independent Beta priors. Finally, the noise rate ϵ is also given a Beta prior. For the two Beta parameters governing the error rate (i.e., a_ϵ and b_ϵ) we set these by hand so that the mean expected error rate is 5% and the probability of the error rate being between 0% and 10% is 50% (this number is based on an expert opinion of the noise-rate in the data). For the rest of

[1]The exclusive-or of a and b, written $a \otimes b$, is true exactly when either a or b is true but not both.

the parameters we use uniform priors.

3.2 The HIER Model

A significant difficulty in working with any large typological database is that the languages will be sampled *non*uniformly. In our case, this means that implications that seem true in the FLAT model may only be true for, say, Indo-European, and the remaining languages are considered noise. While this may be interesting in its own right, we are more interested in discovering implications that are truly universal.

We model this using a hierarchical Bayesian model. In essence, we take the FLAT model and build a notion of language relatedness into it. In particular, we enforce a hierarchy on the m implication variables. For simplicity, suppose that our "hierarchy" of languages is nearly flat. Of the N languages, half of them are Indo-European and the other half are Austronesian. We will use a nearly identical model to the FLAT model, but instead of having a single m variable, we have three: one for IE, one for Austronesian and one for "all languages."

For a general tree, we assign one implication variable for each node (including the root and leaves). The goal of the inference is to infer the value of the m variable corresponding to the root of the tree.

All that is left to specify the full HIER model is to specify the probability distribution of the m random variables. We do this as follows. We place a zero mean Gaussian prior with (unknown) variance σ^2 on the root m. Then, for a non-root node, we use a Gaussian with mean equal to the "m" value of the parent and tied variance σ^2. In our three-node example, this means that the root is distributed $\mathcal{N}or(0, \sigma^2)$ and each child is distributed $\mathcal{N}or(m_{\text{root}}, \sigma^2)$, where m_{root} is the random variable corresponding to the root. Finally, the leaves (corresponding to the languages themselves) are distributed *logistic-binomial*. Thus, the m random variable corresponding to a leaf (language) is distributed $\mathcal{B}in(s(m_{\text{par}}))$, where m_{par} is the m value for the parent (internal) node and s is the sigmoid function $s(x) = [1 + exp(-x)]^{-1}$.

The intuition behind this model is that the m value at each node in the tree (where a node is either "all languages" or a specific language family or an individual language) specifies the extent to which the implication under consideration holds for that node. A large positive m means that the implication is very likely to hold. A large negative value means it is very likely to not hold. The normal distributions across edges in the tree indicate that we expect the m values not to change too much across the tree. At the leaves (i.e., individual languages), the logistic-binomial simply transforms the real-valued ms into the range $[0, 1]$ so as to make an appropriate input to the binomial distribution.

4 Statistical Inference

In this section, we describe how we use Markov chain Monte Carlo methods to perform inference in the statistical models described in the previous section; Andrieu et al. (2003) provide an excellent introduction to MCMC techniques. The key idea behind MCMC techniques is to approximate intractable expectations by drawing random samples from the probability distribution of interest. The expectation can then be approximated by an empirical expectation over these sample.

For the FLAT model, we use a combination of Gibbs sampling with rejection sampling as a subroutine. Essentially, all sampling steps are standard Gibbs steps, except for sampling the error rates e. The Gibbs step is not available analytically for these. Hence, we use rejection sampling (drawing from the Beta prior and accepting according to the posterior).

The sampling procedure for the HIER model is only slightly more complicated. Instead of performing a simple Gibbs sample for m in Step (4), we first sample the m values for the internal nodes using simple Gibbs updates. For the leaf nodes, we use rejection sampling. For this rejection, we draw proposal values from the Gaussian specified by the parent m, and compute acceptance probabilities.

In all cases, we run the outer Gibbs sampler for 1000 iterations and each rejection sampler for 20 iterations. We compute the marginal values for the m implication variables by averaging the sampled values after dropping 200 "burn-in" iterations.

5 Data Preprocessing and Search

After extracting the raw data from the WALS electronic database (Haspelmath et al., 2005)[2], we perform a minor amount of preprocessing. Essentially, we have manually removed certain feature

[2]This is nontrivial—we are currently exploring the possibility of freely sharing these data.

values from the database because they are underrepresented. For instance, the "Glottalized Consonants" feature has eight possible values (one for "none" and seven for different varieties of glottalized consonants). We reduce this to simply two values "has" or "has not." 313 languages have no glottalized consonants and 139 have some variety of glottalized consonant. We have done something similar with approximately twenty of the features.

For the HIER model, we obtain the hierarchy in one of two ways. The first hierarchy we use is the "linguistic hierarchy" specified as part of the WALS data. This hierarchy divides languages into families and subfamilies. This leads to a tree with the leaves at depth four. The root has 38 immediate children (corresponding to the major families), and there are a total of 314 internal nodes. The second hierarchy we use is an areal hierarchy obtained by clustering languages according to their latitude and longitude. For the clustering we first cluster all the languages into 6 "macro-clusters." We then cluster each macro-cluster individually into 25 "micro-clusters." These micro-clusters then have the languages at their leaves. This yields a tree with 31 internal nodes.

Given the database (which contains approximately 140 features), performing a raw search even over all possible *pairs* of features would lead to over $19,000$ computations. In order to reduce this space to a more manageable number, we filter:

- There must be at least 250 languages for which *both* features are known.
- There must be at least 15 languages for which both feature values hold simultaneously.
- Whenever f_1 is true, at least half of the languages also have f_2 true.

Performing all these filtration steps reduces the number of pairs under consideration to 3442. While this remains a computationally expensive procedure, we were able to perform all the implication computations for these 3442 possible pairs in about a week on a single modern machine (in Matlab).

6 Results

The task of discovering universal implications is, at its heart, a data-mining task. As such, it is difficult to evaluate, since we often do not know the correct answers! If our model only found well-documented implications, this would be interesting but useless from the perspective of aiding linguists focus their energies on new, plausible implications. In this section, we present the results of our method, together with both a quantitative and qualitative evaluation.

6.1 Quantitative Evaluation

In this section, we perform a quantitative evaluation of the results based on *predictive power*. That is, one generally would prefer a system that finds implications that hold with high probability across the data. The word "generally" is important: this quality is neither necessary nor sufficient for the model to be good. For instance, finding 1000 implications of the form $A_1 \supset X, A_2 \supset X, \ldots, A_{1000} \supset X$ is completely uninteresting if X is true in 99% of the cases. Similarly, suppose that a model can find 1000 implications of the form $X \supset A_1, \ldots, X \supset A_{1000}$, but X is only true in five languages. In both of these cases, according to a "predictive power" measure, these would be ideal systems. But they are both somewhat uninteresting.

Despite these difficulties with a predictive power-based evaluation, we feel that it is a good way to understand the relative merits of our different models. Thus, we compare the following systems: FLAT (our proposed flat model), LINGHIER (our model using the phylogenetic hierarchy), DISTHIER (our model using the areal hierarchy) and RANDOM (a model that ranks implications—that meet the three qualifications from the previous section—randomly).

The models are scored as follows. We take the entire WALS data set and "hide" a random 10% of the entries. We then perform full inference and ask the inferred model to predict the missing values. The accuracy of the model is the accuracy of its predictions. To obtain a sense of the quality of the ranking, we perform this computation on the top k ranked implications provided by each model; $k \in \{2, 4, 8, \ldots, 512, 1024\}$.

The results of this quantitative evaluation are shown in Figure 3 (on a log-scale for the x-axis). The two best-performing models are the two hierarchical models. The flat model does significantly worse and the random model does terribly. The vertical lines are a standard deviation over 100 folds of the experiment (hiding a different 10% each time). The difference between the two hierarchical models is typically not statistically significant. At the top of the ranking, the model based on phylogenetic

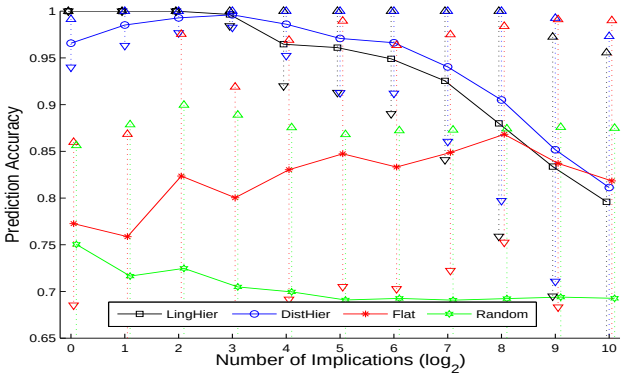

Figure 3: Results of quantitative (predictive) evaluation. Top curves are the hierarchical models; middle is the flat model; bottom is the random baseline.

information performs marginally better; at the bottom of the ranking, the order flips. Comparing the hierarchical models to the flat model, we see that adequately modeling the *a priori* similarity between languages is quite important.

6.2 Cross-model Comparison

The results in the previous section support the conclusion that the two hierarchical models are doing something significantly different (and better) than the flat model. This clearly must be the case. The results, however, do not say whether the two hierarchies are substantially different. Moreover, are the results that they produce substantially different. The answer to these two questions is "yes."

We first address the issue of tree similarity. We consider all pairs of languages which are at distance 0 in the areal tree (i.e., have the same parent). We then look at the mean tree-distance between those languages in the phylogenetic tree. We do this for all distances in the areal tree (because of its construction, there are only three: 0, 2 and 4). The mean distances in the phylogenetic tree corresponding to these three distances in the areal tree are: 2.9, 3.5 and 4.0, respectively. This means that languages that are "nearby" in the areal tree are quite often very far apart in the phylogenetic tree.

To answer the issue of whether the results obtained by the two trees are similar, we employ Kendall's τ statistic. Given two ordered lists, the τ statistic computes how correlated they are. τ is always between 0 and 1, with 1 indicating identical ordering and 0 indicated completely reversed ordering. The results are as follows. Comparing FLAT to LINGHIER yield $\tau = 0.4144$, a very low correlation. Between FLAT and DISTHIER, $\tau = 0.5213$, also very low. These two are as expected. Finally, between LINGHIER and DISTHIER, we obtain $\tau = 0.5369$, a very low correlation, considering that both perform well predictively.

6.3 Qualitative Analysis

For the purpose of a qualitative analysis, we reproduce the top 30 implications discovered by the LINGHIER model in Table 2 (see the final page).[3] Each implication is numbered, then the actual implication is presented. For instance, #7 says that any language that has adjectives preceding their governing nouns also has numerals preceding their nouns. We additionally provide an "analysis" of many of these discovered implications. Many of them (eg., #7) are well known in the typological literature. These are simply numbered according to well-known references. For instance our #7 is implication #18 from Greenberg, reproduced by Song (2001). Those that reference Hawkins (eg., #11) are based on implications described by Hawkins (1983); those that reference Lehmann are references to the principles decided by Lehmann (1981) in Ch 4 & 8.

Some of the implications our model discovers are obtained by composition of well-known implications. For instance, our #3 (namely, OV $\supset$ Genitive-Noun) can be obtained by combining Greenberg #4 (OV $\supset$ Postpositions) and Greenberg #2a (Postpositions $\supset$ Genitive-Noun). It is quite encouraging that 14 of our top 21 discovered implications are well-known in the literature (and this, not even considering the tautalogically true implications)! This strongly suggests that our model is doing something reasonable and that there is true structure in the data.

In addition to many of the known implications found by our model, there are many that are "unknown." Space precludes attempting explanations of them all, so we focus on a few. Some are easy. Consider #8 (Strongly suffixing $\supset$ Tense-aspect suffixes): this is quite plausible—if you have a lan-

[3] In truth, our model discovers several tautalogical implications that we have removed by hand before presentation. These are examples like "SVO $\supset$ VO" or "No unusual consonants $\supset$ no glottalized consonants." It is, of course, good that our model discovers these, since they are obviously true. However, to save space, we have withheld them from presentation here. The 30th implication presented here is actually the 83rd in our full list.

guage that tends to have suffixes, it will probably have suffixes for tense/aspect. Similarly, #10 states that languages with verb morphology for questions lack question particles; again, this can be easily explained by an appeal to economy.

Some of the discovered implications require a more involved explanation. One such example is #20: labial-velars implies no uvulars.[4] It turns out that labial-velars are most common in Africa just north of the equator, which is also a place that has very few uvulars (there are a handful of other examples, mostly in Papua New Guinea). While this implication has not been previously investigated, it makes some sense: if a language has one form of rare consonant, it is unlikely to have another.

As another example, consider #28: Obligatory suffix pronouns implies no possessive affixes. This means is that in languages (like English) for which pro-drop is impossible, possession is not marked morphologically on the head noun (like English, "book" appears the same regarless of if it is "his book" or "the book"). This also makes sense: if you cannot drop pronouns, then one usually will mark possession on the pronoun, not the head noun. Thus, you do not need marking on the head noun.

Finally, consider #25: High and mid front vowels (i.e., / u/, etc.) implies large vowel inventory ($\geq$ 7 vowels). This is supported by typological evidence that high and mid front vowels are the "last" vowels to be added to a language's repertoire. Thus, in order to get them, you must also have many other types of vowels already, leading to a large vowel inventory.

Not all examples admit a simple explanation and are worthy of further thought. Some of which (like the ones predicated on "SV") may just be peculiarities of the annotation style: the subject verb order changes frequently between transitive and intransitive usages in many languages, and the annotation reflects just one. Some others are bizzarre: why not having fricatives should mean that you don't have tones (#27) is not a priori clear.

6.4 Multi-conditional Implications

Many implications in the literature have multiple implicants. For instance, much research has gone into looking at which implications hold, considering only "VO" languages, or considering only languages with prepositions. It is straightforward to modify our model so that it searches over triples of features, conditioning on two and predicting the third. Space precludes an in-depth discussion of these results, but we present the top examples in Table 3 (after removing the tautalogically true examples, which are more numerous in this case, as well as examples that are directly obtainable from Table 2). It is encouraging that in the top 1000 multi-conditional implications found, the most frequently used were "OV" (176 times) "Postpositions" (157 times) and "Adjective-Noun" (89 times). This result agrees with intuition.

Implicants		Implicand
Postpositions Adjective-Noun	$\supset$	Demonstrative-Noun
Posessive prefixes Tense-aspect suffixes	$\supset$	Genitive-Noun
Case suffixes Plural suffix	$\supset$	Genitive-Noun
Adjective-Noun Genitive-Noun	$\supset$	OV
High cons/vowel ratio No front-rounded vowels	$\supset$	No tones
Negative affix Genitive-Noun	$\supset$	OV
No front-rounded vowels Labial velars	$\supset$	Large vowel quality inventory
Subordinating suffix Tense-aspect suffixes	$\supset$	Postpositions
No case affixes Prepositions	$\supset$	Initial subordinator word
Strongly suffixing Plural suffix	$\supset$	Genitive-Noun

Table 3: Top implications discovered by the LINGHIER multi-conditional model.

7 Discussion

We have presented a Bayesian model for discovering universal linguistic implications from a typological database. Our model is able to account for noise in a linguistically plausible manner. Our hierarchical models deal with the sampling issue in a unique way, by using prior knowledge about language families to "group" related languages. Quantitatively, the hierarchical information turns out to be quite useful, regardless of whether it is phylogenetically- or areally-based. Qualitatively, our model can recover many well-known implications as well as many more potential implications that can be the object of future linguistic study. We believe that our model is suf-

[4] Labial-velars and uvulars are rare consonants (order 100 languages). Labial-velars are joined sounds like /kp/ and /gb/ (to English speakers, sounding like chicken noises); uvulars sounds are made in the back of the throat, like snoring.

Table 2: Top 30 implications discovered by the LINGHIER model.

ficiently general that it could be applied to many different typological databases — we attempted not to "overfit" it to WALS. Our hope is that the automatic discovery of such implications not only aid typologically-inclined linguists, but also other groups. For instance, well-attested universal implications have the potential to reduce the amount of data field linguists need to collect. They have also been used computationally to aid in the learning of unsupervised part of speech taggers (Schone and Jurafsky, 2001). Many extensions are possible to this model; for instance attempting to uncover typologically hierarchies and other higher-order structures. We have made the full output of all models available at `http://hal3.name/WALS`.

Abstract

In this paper, we propose a novel discriminative language model, which can be applied quite generally. Compared to the well known N-gram language models, discriminative language models can achieve more accurate discrimination because they can employ overlapping features and non-local information. However, discriminative language models have been used only for re-ranking in specific applications because negative examples are not available. We propose sampling pseudo-negative examples taken from probabilistic language models. However, this approach requires prohibitive computational cost if we are dealing with quite a few features and training samples. We tackle the problem by estimating the latent information in sentences using a semi-Markov class model, and then extracting features from them. We also use an online margin-based algorithm with efficient kernel computation. Experimental results show that pseudo-negative examples can be treated as real negative examples and our model can classify these sentences correctly.

1 Introduction

Language models (LMs) are fundamental tools for many applications, such as speech recognition, machine translation and spelling correction. The goal of LMs is to determine whether a sentence is correct or incorrect in terms of grammars and pragmatics.

The most widely used LM is a probabilistic language model (PLM), which assigns a probability to a sentence or a word sequence. In particular, N-grams with maximum likelihood estimation (NLMs) are often used. Although NLMs are simple, they are effective for many applications.

However, NLMs cannot determine correctness of a sentence independently because the probability depends on the length of the sentence and the global frequencies of each word in it. For example, $p(S_1) < p(S_2)$, where $p(S)$ is the probability of a sentence S given by an NLM, does not always mean that S_2 is more correct, but instead could occur when S_2 is shorter than S_1, or if S_2 has more common words than S_1. Another problem is that NLMs cannot handle overlapping information or non-local information easily, which is important for more accurate sentence classification. For example, a NLM could assign a high probability to a sentence even if it does not have a verb.

Discriminative language models (DLMs) have been proposed to classify sentences directly as correct or incorrect (Gao et al., 2005; Roark et al., 2007), and these models can handle both non-local and overlapping information. However DLMs in previous studies have been restricted to specific applications. Therefore the model cannot be used for other applications. If we had negative examples available, the models could be trained directly by discriminating between correct and incorrect sentences.

In this paper, we propose a generic DLM, which can be used not only for specific applications, but also more generally, similar to PLMs. To achieve

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 73–80,
Prague, Czech Republic, June 2007.

this goal, we need to solve two problems. The first is that since we cannot obtain negative examples (incorrect sentences), we need to generate them. The second is the prohibitive computational cost because the number of features and examples is very large. In previous studies this problem did not arise because the amount of training data was limited and they did not use a combination of features, and thus the computational cost was negligible.

To solve the first problem, we propose sampling incorrect sentences taken from a PLM and then training a model to discriminate between correct and incorrect sentences. We call these examples Pseudo-Negative because they are not actually negative sentences. We call this method DLM-PN (DLM with Pseudo-Negative samples).

To deal with the second problem, we employ an online margin-based learning algorithm with fast kernel computation. This enables us to employ combinations of features, which are important for discrimination between correct and incorrect sentences. We also estimate the latent information in sentences by using a semi-Markov class model to extract features. Although there are substantially fewer latent features than explicit features such as words or phrases, latent features contain essential information for sentence classification.

Experimental results show that these pseudo-negative samples can be treated as incorrect examples, and that DLM-PN can learn to correctly discriminate between correct and incorrect sentences and can therefore classify these sentences correctly.

2 Previous work

Probabilistic language models (PLMs) estimate the probability of word strings or sentences. Among these models, N-gram language models (NLMs) are widely used. NLMs approximate the probability by conditioning only on the preceding $N-1$ words. For example, let S denote a sentence of t words, $S := w_1, w_2, \ldots, w_t$. Then, by the chain rule of probability and the approximation, we have

$$\begin{aligned} P(S) &= P(w_1, w_2, \ldots, w_t) \\ &= \prod_{i=1\ldots t} P(w_i | w_{i-N+1}, \ldots, w_{i-1}). \quad (1) \end{aligned}$$

The parameters can be estimated using the maximum likelihood method.

Since the number of parameters in NLM is still large, several smoothing methods are used (Chen and Goodman, 1998) to produce more accurate probabilities, and to assign nonzero probabilities to any word string.

However, since the probabilities in NLMs depend on the length of the sentence, two sentences of different length cannot be compared directly.

Recently, Whole Sentence Maximum Entropy Models (Rosenfeld et al., 2001) (WSMEs) have been introduced. They assign a probability to each sentence using a maximum entropy model. Although WSMEs can encode all features of a sentence including non-local ones, they are only slightly superior to NLMs, in that they have the disadvantage of being computationally expensive, and not all relevant features can be included.

A discriminative language model (DLM) assigns a score $f(S)$ to a sentence S, measuring the correctness of a sentence in terms of grammar and pragmatics, so that $f(S) > 0$ implies S is correct and $f(S) < 0$ implies S is incorrect. A PLM can be considered as a special case of a DLM by defining f using $P(S)$. For example, we can take $f(S) = P(S)/|S| - \alpha$, where α is some threshold, and $|S|$ is the length of S.

Given a sentence S, we extract a feature vector ($\phi(S)$) from it using a pre-defined set of feature functions $\{\phi_j\}_{j=1}^m$. The form of the function f we use is

$$f(S) = \mathbf{w} \cdot \phi(S), \quad (2)$$

where $\mathbf{w}$ is a feature weighting vector.

Since there is no restriction in designing $\phi(S)$, DLMs can make use of both over-lapping and non-local information in S. We estimate $\mathbf{w}$ using training samples $\{(S_i, y_i)\}$ for $i = 1...t$, where $y_i = 1$ if S_i is correct and $y_i = -1$ if S_i is incorrect.

However, it is hard to obtain incorrect sentences because only correct sentences are available from the corpus. This problem was not an issue for previous studies because they were concerned with specific applications and therefore were able to obtain real negative examples easily. For example, Roark (2007) proposed a discriminative language model, in which a model is trained so that a correct sentence should have higher score than others. The difference between their approach and ours is that we do not assume just one application. Moreover, they had

```
For i=1,2,...
   Choose a word w_i at random
    according to the distribution
    P(w_i|w_{i-N+1},...,w_{i-1})
   If w_i = "end of a sentence"
      Break
   End End
```

Figure 1: Sample procedure for pseudo-negative examples taken from N-gram language models.

training sets consisting of one correct sentence and many incorrect sentences, which were very similar because they were generated by the same input. Our framework does not assume any such training sets, and we treat correct or incorrect examples independently in training.

3 Discriminative Language Model with Pseudo-Negative samples

We propose a novel discriminative language model; a Discriminative Language Model with Pseudo-Negative samples (DLM-PN). In this model, pseudo-negative examples, which are all assumed to be incorrect, are sampled from PLMs.

First a PLM is built using training data and then examples, which are almost all negative, are sampled independently from PLMs. DLMs are trained using correct sentences from a corpus and negative examples from a Pseudo-Negative generator.

An advantage of sampling is that as many negative examples can be collected as correct ones, and a distinction can be clearly made between truly correct sentences and incorrect sentences, even though the latter might be correct in a local sense.

For sampling, any PLMs can be used as long as the model supports a sentence sampling procedure. In this research we used NLMs with interpolated smoothing because such models support efficient sentence sampling. Figure 1 describes the sampling procedure and figure 2 shows an example of a pseudo-negative sentence.

Since the focus is on discriminating between correct sentences from a corpus and incorrect sentences sampled from the NLM, DLM-PN may not able to classify incorrect sentences that are not generated from the NLM. However, this does not result in a serious problem, because these sentences, if they exist, can be filtered out by NLMs.

4 Online margin-based learning with fast kernel computation

The DLM-PN can be trained by using any binary classification learning methods. However, since the number of training examples is very large, batch training has suffered from prohibitively large computational cost in terms of time and memory. Therefore we make use of an online learning algorithm proposed by (Crammer et al., 2006), which has a much smaller computational cost. We follow the definition in (Crammer et al., 2006).

The initiation vector $\mathbf{w}_1$ is initialized to $\mathbf{0}$ and for each round the algorithm observes a training example $\mathbf{x}_i := \phi(S_i)$ and predicts its label y_i' to be either $+1$ or -1. After the prediction is made, the true label y_i is revealed and the algorithm suffers an *instantaneous hinge-loss* $l(\mathbf{w}; (\mathbf{x}_i, y_i)) = 1 - y_i(\mathbf{w}_i \cdot \mathbf{x}_i)$ which reflects the degree to which its prediction was wrong. If the prediction was wrong, the parameter

$\mathbf{w}$ is updated as

$$\mathbf{w}_{i+1} = argmin_{\mathbf{w}} \frac{1}{2}||\mathbf{w} - \mathbf{w}_i||^2 + C\xi \quad (3)$$

$$\text{subject to } l(\mathbf{w}; (\mathbf{x}_i, y_i)) \leq \xi \text{ and } \xi \geq 0, \quad (4)$$

where ξ is a slack term and C is a positive parameter which controls the influence of the slack term on the objective function. A large value of C will result in a more aggressive update step. This has a closed form solution as

$$\mathbf{w}_{i+1} = \mathbf{w}_i + \tau_i y_i \mathbf{x}_i \quad (5)$$

where $\tau_i = \min\{C, \frac{l_i}{||\mathbf{x}_i||^2}\}$. As in SVMs, a final weight vector can be represented as a kernel-dependent combination of the stored training examples.

$$\mathbf{w} \cdot \mathbf{x} = \sum_i \tau_i y_i \langle \mathbf{x}_i \cdot \mathbf{x} \rangle \quad (6)$$

Using this formulation the inner product can be replaced with a general Mercer kernel $K(\mathbf{x}_i, \mathbf{x})$ such as a polynomial kernel or a Gaussian kernel.

The combination of features, which can capture correlation information, is important in DLMs. If the kernel-trick (Taylor and Cristianini, 2004) is applied to online margin-based learning, a subset of the observed examples, called the active set, needs to be stored. However in contrast to the support set in SVMs, an example is added to the active set every time the online algorithm makes a prediction mistake or when its confidence in a prediction is inadequately low. Therefore the active set can increase in size significantly and thus the total computational cost becomes proportional to the square of the number of training examples. Since the number of training examples is very large, the computational cost is prohibitive even if we apply the kernel trick.

The calculation of the inner product between two examples can be done by intersection of the activated features in each example. This is similar to a merge sort and can be executed in $O(M)$ time where M is the average number of activated features in an example. When the number of examples in the active set is A, the total computational cost is $O(M \cdot A)$. For fast kernel computation, the Polynomial Kernel Inverted method (PKI)) is proposed (Kudo and Matsumoto, 2003), which is an extension of Inverted Index in Information Retrieval. This algorithm uses a table $h(f_i)$ for each feature item, which stores examples where a feature f_i is fired. Let B be the average of $|h(f_i)|$ over all feature item. Then the kernel computation can be performed in $O(M \cdot B)$ time which is much less than the normal kernel computation time when $B \ll A$. We can easily extend this algorithm into the online setting by updating $h(f_i)$ when an observed example is added to an active set.

5 Latent features by semi-Markov class model

Another problem for DLMs is that the number of features becomes very large, because all possible N-grams are used as features. In particular, the memory requirement becomes a serious problem because quite a few active sets with many features have to be stored, not only at training time, but also at classification time. One way to deal with this is to filter out low-confidence features, but it is difficult to decide which features are important in online learning. For this reason we cluster similar N-grams using a semi-Markov class model.

The class model was originally proposed by (Martin et al., 1998). In the class model, deterministic word-to-class mappings are estimated, keeping the number of classes much smaller than the number of distinct words. A semi-Markov class model (SMCM) is an extended version of the class model, a part of which was proposed by (Deligne and BIMBOT, 1995). In SMCM, a word sequence is partitioned into a variable-length sequence of chunks and then chunks are clustered into classes (Figure 4). How a chunk is clustered depends on which chunks are adjacent to it.

The probability of a sentence $P(w_1, \ldots, w_t)$, in a bi-gram class model is calculated by

$$\prod_i P(w_{i+1}|c_{i+1}) P(c_{i+1}|c_i). \quad (7)$$

On the other hand, the probabilities in a bi-gram semi-Markov class model are calculated by

$$\sum_s \prod_i P(c_i|c_{i-1}) \cdot P(w_{t(i),t(i)+1,\ldots,u(i)}|c_i). \quad (8)$$

where s varies over all possible partitions of S, $t(i)$ and $u(i)$ denote the start and end positions respectively of the i-th chunk in partition s, and $t(i+1) =$

$u(i) + 1$ for all i. Note that each word or variable-length chunk belongs to only one class, in contrast to a hidden Markov model where each word can belong to several classes.

Using a training corpus, the mapping is estimated by maximum likelihood estimation. The log likelihood of the training corpus $(w_1, \ldots, w_n)$ in a bigram class model can be calculated as

$$\log \prod_i P(w_{i+1}|w_i) \quad (9)$$

$$= \sum_i \log P(w_{i+1}|c_{i+1})P(c_{i+1}|c_i) \quad (10)$$

$$= \sum_{c_1,c_2} F(c_1,c_2) \log \frac{F(c_1,c_2)}{F(c_1)F(c_2)} + \sum_w F(w) \log F(w). \quad (11)$$

where $F(w)$, $F(c)$ and $F(c_1, c_2)$ are frequencies of a word w, a class c and a class bi-gram c_1, c_2 in the training corpus. In (11) only the first term is used, since the second term does not depend on the class allocation. The class allocation problem is solved by an exchange algorithm as follows. First, all words are assigned to a randomly determined class. Next, for each word w, we move it to the class c for which the log-likelihood is maximized. This procedure is continued until the log-likelihood converges to a local maximum. A naive implementation of the clustering algorithm scales quadratically to the number of classes, since each time a word is moved between classes, all class bi-gram counts are potentially affected. However, by considering only those counts that actually change, the algorithm can be made to scale somewhere between linearly and quadratically to the number of classes (Martin et al., 1998).

In SMCM, partitions of each sentence are also determined. We used a Viterbi decoding (Deligne and BIMBOT, 1995) for the partition. We applied the exchange algorithm and the Viterbi decoding alternately until the log-likelihood converged to the local maximum.

Since the number of chunks is very large, for example, in our experiments we used about 3 million chunks, the computational cost is still large. We therefore employed the following two techniques. The first was to approximate the computation in the exchange algorithm; the second was to make use of bottom-up clustering to strengthen the convergence.

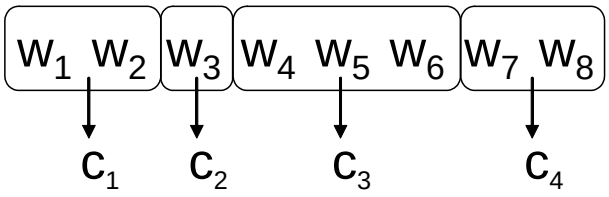

Figure 4: Example of assignment in semi-Markov class model. A sentence is partitioned into variable-length chunks and each chunk is assigned a unique class number.

In each step in the exchange algorithm, the approximate value of the change of the log-likelihood was examined, and the exchange algorithm applied only if the approximate value was larger than a predefined threshold.

The second technique was to reduce memory requirements. Since the matrices used in the exchange algorithm could become very large, we clustered chunks into 2 classes and then again we clustered these two into 2 each, thus obtaining 4 classes. This procedure was applied recursively until the number of classes reached a pre-defined number.

6 Experiments

6.1 Experimental Setup

We partitioned a BNC-corpus into *model-train*, *DLM-train-positive*, and *DLM-test-positive* sets. The numbers of sentences in *model-train*, *DLM-train-positive* and *DLM-test-positive* were 4500k, 250k, and 10k respectively. An NLM was built using *model-train* and Pseudo-Negative examples (250k sentences) were sampled from it. We mixed sentences from *DLM-train-positive* and the Pseudo-Negative examples and then shuffled the order of these sentences to make *DLM-train*. We also constructed *DLM-test* by mixing *DLM-test-positive* and 10k new (not already used) sentences from the Pseudo-Negative examples. We call the sentences from *DLM-train-positive* "positive" examples and the sentences from the Pseudo-Negative examples "negative" examples in the following. From these sentences the ones with less than 5 words were excluded beforehand because it was difficult to decide whether these sentences were correct or not (e.g.

	Accuracy (%)	Training time (s)
Linear classifier		
word tri-gram	51.28	137.1
POS tri-gram	52.64	85.0
SMCM bi-gram ($G = 100$)	51.79	304.9
SMCM bi-gram ($G = 500$)	54.45	422.1
3rd order Polynomial Kernel		
word tri-gram	73.65	20143.7
POS tri-gram	66.58	29622.9
SMCM bi-gram ($G = 100$)	67.11	37181.6
SMCM bi-gram ($G = 500$)	74.11	34474.7

Table 1: Performance on the evaluation data.

compound words).

Let G be the number of classes in SMCMs. Two SMCMs, one with $G = 100$ and the other with $G = 500$, were constructed from *model-train*. Each SMCM contained 2.8 million extracted chunks.

6.2 Experiments on Pseudo-Examples

We examined the property of a sentence being Pseudo-Negative, in order to justify our framework. A native English speaker and two non-native English speaker were asked to assign *correct*/*incorrect* labels to 100 sentences in *DLM-train*[1]. The result for an native English speaker was that all positive sentences were labeled as *correct* and all negative sentences except for one were labeled as *incorrect*. On the other hand, the results for non-native English speakers are 67% and 70%. From this result, we can say that the sampling method was able to generate incorrect sentences and if a classifier can discriminate them, the classifier can also discriminate between correct and incorrect sentences. Note that it takes an average of 25 seconds for the native English speaker to assign the label, which suggests that it is difficult even for a human to determine the correctness of a sentence.

We then examined whether it was possible to discriminate between correct and incorrect sentences using parsing methods, since if so, we could have used parsing as a classification tool. We examined 100 sentences using a phrase structure parser (Charniak and Johnson, 2005) and an HPSG parser (Miyao and Tsujii, 2005). All sentences were parsed correctly except for one positive example. This result indicates that correct sentences and pseudo-negative examples cannot be differentiated syntactically.

6.3 Experiments on DLM-PN

We investigated the performance of classifiers and the effect of different sets of features.

For N-grams and Part of Speech (POS), we used tri-gram features. For SMCM, we used bi-gram features. We used *DLM-train* as a training set. In all experiments, we set $C = 50.0$ where C is a parameter in the classification (Section 4). In all kernel experiments, a 3rd order polynomial kernel was used and values were computed using PKI (the inverted indexing method). Table 1 shows the accuracy results with different features, or in the case of the SMCMs, different numbers of classes. This result shows that the kernel method is important in achieving high performance. Note that the classifier with SMCM features performs as well as the one with *word*.

Table 2 shows the number of features in each method. Note that a new feature is added only if the classifier needs to update its parameters. These numbers are therefore smaller than the possible number of all candidate features. This result and the previous result indicate that SMCM achieves high performance with very few features.

We then examined the effect of PKI. Table 3 shows the results of the classifier with 3rd order polynomial kernel both with and without PKI. In this experiment, only $200K$ sentences in *DLM-train*

[1]Since the PLM also made use of the BNC-corpus for positive examples, we were not able to classify sentences based on word occurrences

	# of distinct features
word tri-gram	15773230
POS tri-gram	35376
SMCM ($G = 100$)	9335
SMCM ($G = 500$)	199745

Table 2: The number of features.

	training time (s)	prediction time (ms)
Baseline	37665.5	370.6
+ Index	4664.9	47.8

Table 3: Comparison between classification performance with/without index

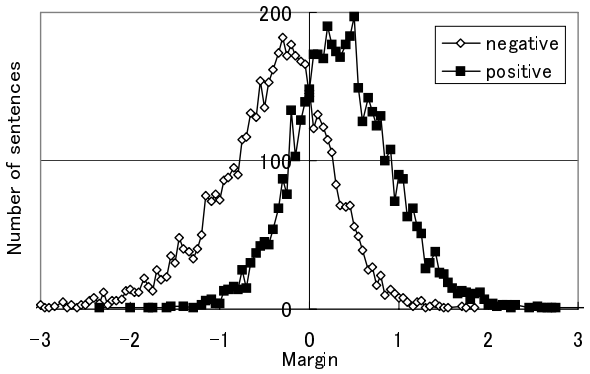

Figure 5: Margin distribution using SMCM bi-gram features.

were used for both experiments because training using all the training data would have required a much longer time than was possible with our experimental setup.

Figure 5 shows the margin distribution for positive and negative examples using SMCM bi-gram features. Although many examples are close to the border line (margin $= 0$), positive and negative examples are distributed on either side of 0. Therefore higher *recall* or *precision* could be achieved by using a pre-defined margin threshold other than 0.

Finally, we generated learning curves to examine the effect of the size of training data on performance. Figure 6 shows the result of the classification task using *SMCM*-bi-gram features. The result suggests that the performance could be further improved by enlarging the training data set.

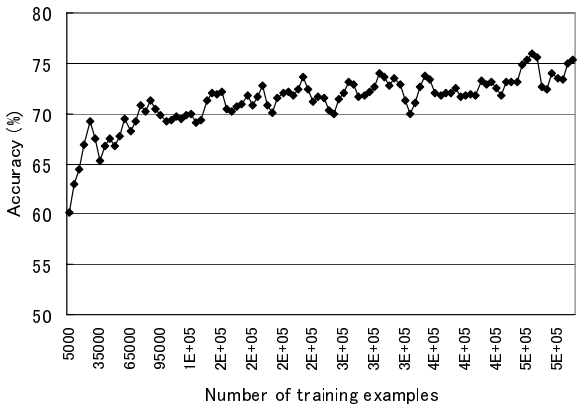

Figure 6: A learning curve for SMCM ($G = 500$). The accuracy is the percentage of sentences in the evaluation set classified correctly.

7 Discussion

Experimental results on pseudo-negative examples indicate that combination of features is effective in a sentence discrimination method. This could be because negative examples include many unsuitable combinations of words such as a sentence containing many nouns. Although in previous PLMs, combination of features has not been discussed except for the topic-based language model (David M. Blei, 2003; Wang et al., 2005), our result may encourage the study of the combination of features for language modeling.

A contrastive estimation method (Smith and Eisner, 2005) is similar to ours with regard to constructing pseudo-negative examples. They build a neighborhood of input examples to allow unsupervised estimation when, for example, a word is changed or deleted. A lattice is constructed, and then parameters are estimated efficiently. On the other hand, we construct independent pseudo-negative examples to enable training. Although the motivations of these studies are different, we could combine these two methods to discriminate sentences finely.

In our experiments, we did not examine the result of using other sampling methods, For example, it would be possible to sample sentences from a whole sentence maximum entropy model (Rosenfeld et al., 2001) and this is a topic for future research.

8 Conclusion

In this paper we have presented a novel discriminative language model using pseudo-negative examples. We also showed that an online margin-based learning method enabled us to use half a million sentences as training data and achieve 74% accuracy in the task of discrimination between correct and incorrect sentences. Experimental results indicate that while pseudo-negative examples can be seen as incorrect sentences, they are also close to correct sentences in that parsers cannot discriminate between them.

Our experimental results also showed that combination of features is important for discrimination between correct and incorrect sentences. This concept has not been discussed in previous probabilistic language models.

Our next step is to employ our model in machine translation and speech recognition. One main difficulty concerns how to encode global scores for the classifier in the local search space, and another is how to scale up the problem size in terms of the number of examples and features. We would like to see more refined online learning methods with kernels (Cheng et al., 2006; Dekel et al., 2005) that we could apply in these areas.

We are also interested in applications such as constructing an extended version of a spelling correction tool by identifying incorrect sentences.

Another interesting idea is to work with probabilistic language models directly without sampling and find ways to construct a more accurate discriminative model.

Abstract

This paper studies the problem of identifying erroneous/correct sentences. The problem has important applications, e.g., providing feedback for writers of English as a Second Language, controlling the quality of parallel bilingual sentences mined from the Web, and evaluating machine translation results. In this paper, we propose a new approach to detecting erroneous sentences by integrating pattern discovery with supervised learning models. Experimental results show that our techniques are promising.

1 Introduction

Detecting erroneous/correct sentences has the following applications. First, it can provide feedback for writers of English as a Second Language (ESL) as to whether a sentence contains errors. Second, it can be applied to control the quality of parallel bilingual sentences mined from the Web, which are critical sources for a wide range of applications, such as statistical machine translation (Brown et al., 1993) and cross-lingual information retrieval (Nie et al., 1999). Third, it can be used to evaluate machine translation results. As demonstrated in (Corston-Oliver et al., 2001; Gamon et al., 2005), the better human reference translations can be distinguished from machine translations by a classification model, the worse the machine translation system is.

The previous work on identifying erroneous sentences mainly aims to find errors from the writing of ESL learners. The common mistakes (Yukio et al., 2001; Gui and Yang, 2003) made by ESL learners include spelling, lexical collocation, sentence structure, tense, agreement, verb formation, wrong Part-Of-Speech (POS), article usage, etc. The previous work focuses on grammar errors, including tense, agreement, verb formation, article usage, etc. However, little work has been done to detect sentence structure and lexical collocation errors.

Some methods of detecting erroneous sentences are based on manual rules. These methods (Heidorn, 2000; Michaud et al., 2000; Bender et al., 2004) have been shown to be effective in detecting certain kinds of grammatical errors in the writing of English learners. However, it could be expensive to write rules manually. Linguistic experts are needed to write rules of high quality; Also, it is difficult to produce and maintain a large number of non-conflicting rules to cover a wide range of grammatical errors. Moreover, ESL writers of different first-language backgrounds and skill levels may make different errors, and thus different sets of rules may be required. Worse still, it is hard to write rules for some grammatical errors, for example, detecting errors concerning the articles and singular plural usage (Nagata et al., 2006).

Instead of asking experts to write hand-crafted rules, statistical approaches (Chodorow and Leacock, 2000; Izumi et al., 2003; Brockett et al., 2006; Nagata et al., 2006) build statistical models to identify sentences containing errors. However, existing

*Work done while the author was a visiting student at MSRA

†Work done while the author was a visiting student at MSRA

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 81–88,
Prague, Czech Republic, June 2007.

statistical approaches focus on some pre-defined errors and the reported results are not attractive. Moreover, these approaches, e.g., (Izumi et al., 2003; Brockett et al., 2006) usually need errors to be specified and tagged in the training sentences, which requires expert help to be recruited and is time consuming and labor intensive.

Considering the limitations of the previous work, in this paper we propose a novel approach that is based on pattern discovery and supervised learning to successfully identify erroneous/correct sentences. The basic idea of our approach is to build a machine learning model to automatically classify each sentence into one of the two classes, "erroneous" and "correct." To build the learning model, we automatically extract *labeled sequential patterns* (LSPs) from both erroneous sentences and correct sentences, and use them as input features for classification models. Our main contributions are:

- We mine *labeled sequential patterns*(LSPs) from the preprocessed training data to build leaning models. Note that LSPs are also very different from N-gram language models that only consider continuous sequences.
- We also enrich the LSP features with other automatically computed linguistic features, including lexical collocation, language model, syntactic score, and function word density. In contrast with previous work focusing on (a specific type of) grammatical errors, our model can handle a wide range of errors, including grammar, sentence structure, and lexical choice.
- We empirically evaluate our methods on two datasets consisting of sentences written by Japanese and Chinese, respectively. Experimental results show that *labeled sequential patterns* are highly useful for the classification results, and greatly outperform other features. Our method outperforms Microsoft Word03 and ALEK (Chodorow and Leacock, 2000) from Educational Testing Service (ETS) in some cases. We also apply our learning model to machine translation (MT) data as a complementary measure to evaluate MT results.

The rest of this paper is organized as follows. The next section discusses related work. Section 3 presents the proposed technique. We evaluate our proposed technique in Section 4. Section 5 concludes this paper and discusses future work.

2 Related Work

Research on detecting erroneous sentences can be classified into two categories. The first category makes use of hand-crafted rules, e.g., template rules (Heidorn, 2000) and mal-rules in context-free grammars (Michaud et al., 2000; Bender et al., 2004). As discussed in Section 1, manual rule based methods have some shortcomings.

The second category uses statistical techniques to detect erroneous sentences. An unsupervised method (Chodorow and Leacock, 2000) is employed to detect grammatical errors by inferring negative evidence from TOEFL administrated by ETS. The method (Izumi et al., 2003) aims to detect omission-type and replacement-type errors and transformation-based leaning is employed in (Shi and Zhou, 2005) to learn rules to detect errors for speech recognition outputs. They also require specifying error tags that can tell the specific errors and their corrections in the training corpus. The phrasal Statistical Machine Translation (SMT) technique is employed to identify and correct writing errors (Brockett et al., 2006). This method must collect a large number of parallel corpora (pairs of erroneous sentences and their corrections) and performance depends on SMT techniques that are not yet mature. The work in (Nagata et al., 2006) focuses on a type of error, namely mass vs. count nouns. In contrast to existing statistical methods, our technique needs neither errors tagged nor parallel corpora, and is not limited to a specific type of grammatical error.

There are also studies on automatic essay scoring at document-level. For example, E-rater (Burstein et al., 1998), developed by the ETS, and Intelligent Essay Assessor (Foltz et al., 1999). The evaluation criteria for documents are different from those for sentences. A document is evaluated mainly by its organization, topic, diversity of vocabulary, and grammar while a sentence is done by grammar, sentence structure, and lexical choice.

Another related work is Machine Translation (MT) evaluation. Classification models are employed in (Corston-Oliver et al., 2001; Gamon et al., 2005)

to evaluate the well-formedness of machine translation outputs. The writers of ESL and MT normally make different mistakes: in general, ESL writers can write overall grammatically correct sentences with some local mistakes while MT outputs normally produce locally well-formed phrases with overall grammatically wrong sentences. Hence, the manual features designed for MT evaluation are not applicable to detect erroneous sentences from ESL learners.

LSPs differ from the traditional sequential patterns, e.g., (Agrawal and Srikant, 1995; Pei et al., 2001) in that LSPs are attached with class labels and we prefer those with discriminating ability to build classification model. In our other work (Sun et al., 2007), labeled sequential patterns, together with labeled tree patterns, are used to build pattern-based classifier to detect erroneous sentences. The classification method in (Sun et al., 2007) is different from those used in this paper. Moreover, instead of labeled sequential patterns, in (Sun et al., 2007) the most significant k labeled sequential patterns with constraints for each training sentence are mined to build classifiers. Another related work is (Jindal and Liu, 2006), where sequential patterns with labels are used to identify comparative sentences.

3 Proposed Technique

This section first gives our problem statement and then presents our proposed technique to build learning models.

3.1 Problem Statement

In this paper we study the problem of identifying erroneous/correct sentences. A set of training data containing correct and erroneous sentences is given. Unlike some previous work, our technique requires neither that the erroneous sentences are tagged with detailed errors, nor that the training data consist of parallel pairs of sentences (an error sentence and its correction). The erroneous sentence contains a wide range of errors on grammar, sentence structure, and lexical choice. We do not consider spelling errors in this paper.

We address the problem by building classification models. The main challenge is to automatically extract representative features for both correct and erroneous sentences to build effective classification models. We illustrate the challenge with an example. Consider an erroneous sentence, "*If* Maggie *will* go to supermarket, she *will* buy a bag for you." It is difficult for previous methods using statistical techniques to capture such an error. For example, N-gram language model is considered to be effective in writing evaluation (Burstein et al., 1998; Corston-Oliver et al., 2001). However, it becomes very expensive if $\mathrm{N} > 3$ and N-grams only consider continuous sequence of words, which is unable to detect the above error *"if...will...will"*.

We propose *labeled sequential patterns* to effectively characterize the features of correct and erroneous sentences (Section 3.2), and design some complementary features (Section 3.3).

3.2 Mining *Labeled Sequential Patterns* (LSP)

Labeled Sequential Patterns (LSP). A labeled sequential pattern, p, is in the form of $\texttt{LHS} \rightarrow \texttt{c}$, where LHS is a sequence and c is a class label. Let I be a set of items and L be a set of class labels. Let D be a sequence database in which each tuple is composed of a list of items in I and a class label in L. We say that a sequence $s_1 =< a_1, ..., a_m >$ is *contained* in a sequence $s_2 =< b_1, ..., b_n >$ if there exist integers $i_1, ...i_m$ such that $1 \leq i_1 < i_2 < ... < i_m \leq n$ and $a_j = b_{i_j}$ for all $j \in 1, ..., m$. Similarly, we say that a LSP p_1 is contained by p_2 if the sequence p_1.*LHS* is contained by p_2.*LHS* and $p_1.c = p_2.c$. Note that it is not required that s_1 appears continuously in s_2. We will further refine the definition of "contain" by imposing some constraints (to be explained soon). A LSP p is attached with two measures, *support* and *confidence*. The support of p, denoted by $\texttt{sup}(p)$, is the percentage of tuples in database D that contain the LSP p. The probability of the LSP p being true is referred to as "the confidence of p ", denoted by $\texttt{conf}(p)$, and is computed as $\frac{\texttt{sup}(p)}{\texttt{sup}(p.LHS)}$. The support is to measure the generality of the pattern p and minimum confidence is a statement of predictive ability of p.

Example 1: Consider a sequence database containing three tuples $t_1 = (< a, d, e, f >, E)$, $t_2 = (< a, f, e, f >, E)$ and $t_3 = (< d, a, f >, C)$. One example LSP $p_1 = < a, e, f > \rightarrow E$, which is contained in tuples t_1 and t_2. Its support is 66.7% and its confidence is 100%. As another example, LSP p_2

$= < a, f > \rightarrow E$ with support 66.7% and confidence 66.7%. p_1 is a better indication of class E than p_2. □

Generating Sequence Database. We generate the database by applying Part-Of-Speech (POS) tagger to tag each training sentence while keeping function words[1] and time words[2]. After the processing, each sentence together with its label becomes a database tuple. The function words and POS tags play important roles in both grammars and sentence structures. In addition, the time words are key clues in detecting errors of tense usage. The combination of them allows us to capture representative features for correct/erroneous sentences by mining LSPs. Some example LSPs include "$<$*a, NNS*$> \rightarrow Error$"(singular determiner preceding plural noun), and "$<$*yesterday, is*$> \rightarrow Error$". Note that the confidences of these LSPs are not necessary 100%.

First, we use MXPOST-Maximum Entropy Part of Speech Tagger Toolkit[3] for POS tags. The MXPOST tagger can provide fine-grained tag information. For example, noun can be tagged with "NN"(singular noun) and "NNS"(plural noun); verb can be tagged with "VB", "VBG", "VBN", "VBP", "VBD" and "VBZ". Second, the function words and time words that we use form a key word list. If a word in a training sentence is not contained in the key word list, then the word will be replaced by its POS. The processed sentence consists of POS and the words of key word list. For example, after the processing, the sentence "*In the past, John was kind to his sister*" is converted into "*In the past, NNP was JJ to his NN*", where the words "*in*", "*the*", "*was*", "*to*" and "*his*" are function words, the word "*past*" is time word, and "*NNP*", "*JJ*", and "*NN*" are POS tags.

Mining LSPs. The length of the discovered LSPs is flexible and they can be composed of contiguous or distant words/tags. Existing frequent sequential pattern mining algorithms (e.g. (Pei et al., 2001)) use *minimum support* threshold to mine frequent sequential patterns whose support is larger than the threshold. These algorithms are not sufficient for our problem of mining LSPs. In order to ensure that all our discovered LSPs are discriminating and are capable of predicting correct or erroneous sentences, we impose another constraint *minimum confidence*. Recall that the higher the confidence of a pattern is, the better it can distinguish between correct sentences and erroneous sentences. In our experiments, we empirically set *minimum support* at 0.1% and minimum confidence at 75%.

Mining LSPs is nontrivial since its search space is exponential, althought there have been a host of algorithms for mining frequent sequential patterns. We adapt the frequent sequence mining algorithm in (Pei et al., 2001) for mining LSPs with constraints.

Converting LSPs to Features. Each discovered LSP forms a binary feature as the input for classification model. If a sentence includes a LSP, the corresponding feature is set at 1.

The LSPs can characterize the correct/erroneous sentence structure and grammar. We give some examples of the discovered LSPs. (1) LSPs for erroneous sentences. For example, "$<$*this, NNS*$>$"(e.g. contained in "*this books* is stolen."), "$<$*past, is*$>$"(e.g. contained in "in the *past*, John *is* kind to his sister."), "$<$*one, of, NN*$>$"(e.g. contained in "it is *one of* important working *language*", "$<$*although, but*$>$"(e.g. contained in "*although* he likes it, *but* he can't buy it."), and "$<$*only, if, I, am*$>$"(e.g. contained in "*only if* my teacher has given permission, *I am* allowed to enter this room"). (2) LSPs for correct sentences. For instance, "$<$*would, VB*$>$"(e.g. contained in "he *would buy* it."), and "$<$*VBD, yeserday*$>$"(e.g. contained in "I *bought* this book *yesterday*.").

3.3 Other Linguistic Features

We use some linguistic features that can be computed automatically as complementary features.

Lexical Collocation (LC) Lexical collocation error (Yukio et al., 2001; Gui and Yang, 2003) is common in the writing of ESL learners, such as "*strong tea*" but not "*powerful tea.*" Our LSP features cannot capture all LCs since we replace some words with POS tags in mining LSPs. We collect five types of collocations: verb-object, adjective-noun, verb-adverb, subject-verb, and preposition-object from a general English corpus[4]. Correct LCs are collected

[1] http://www.marlodge.supanet.com/museum/funcword.html
[2] http://www.wjh.harvard.edu/%7Einquirer/Time%40.html
[3] http://www.cogsci.ed.ac.uk/∼jamesc/taggers/MXPOST.html
[4] The general English corpus consists of about 4.4 million native sentences.

by extracting collocations of high frequency from the general English corpus. Erroneous LC candidates are generated by replacing the word in correct collocations with its confusion words, obtained from WordNet, including synonyms and words with similar spelling or pronunciation. Experts are consulted to see if a candidate is a true erroneous collocation.

We compute three statistical features for each sentence below. (1) The first feature is computed by $\sum_{i=1}^{m} p(co_i)/n$, where m is the number of CLs, n is the number of collocations in each sentence, and probability $p(co_i)$ of each CL co_i is calculated using the method (Lü and Zhou, 2004). (2) The second feature is computed by the ratio of the number of unknown collocations (neither correct LCs nor erroneous LCs) to the number of collocations in each sentence. (3) The last feature is computed by the ratio of the number of erroneous LCs to the number of collocations in each sentence.

Perplexity from Language Model (PLM) Perplexity measures are extracted from a trigram language model trained on a general English corpus using the SRILM-SRI Language Modeling Toolkit (Stolcke, 2002). We calculate two values for each sentence: lexicalized trigram perplexity and part of speech (POS) trigram perplexity. The erroneous sentences would have higher perplexity.

Syntactic Score (SC) Some erroneous sentences often contain words and concepts that are locally correct but cannot form coherent sentences (Liu and Gildea, 2005). To measure the coherence of sentences, we use a statistical parser Toolkit (Collins, 1997) to assign each sentence a parser's score that is the related log probability of parsing. We assume that erroneous sentences with undesirable sentence structures are more likely to receive lower scores.

Function Word Density (FWD) We consider the density of function words (Corston-Oliver et al., 2001), i.e. the ratio of function words to content words. This is inspired by the work (Corston-Oliver et al., 2001) showing that function word density can be effective in distinguishing between human references and machine outputs. In this paper, we calculate the densities of seven kinds of function words [5] respectively as 7 features.

Dataset	Type	Source	Number

	(-)	CLEC (Chinese Learner Error Corpus)	3,199

Table 1: Corpora ((+): correct; (-): erroneous)

4 Experimental Evaluation

We evaluated the performance of our techniques with support vector machine (SVM) and Naive Bayesian (NB) classification models. We also compared the effectiveness of various features. In addition, we compared our technique with two other methods of checking errors, Microsoft Word03 and ALEK method (Chodorow and Leacock, 2000). Finally, we also applied our technique to evaluate the Machine Translation outputs.

4.1 Experimental Setup

Classification Models. We used two classification models, SVM[6] and NB classification model.

Data. We collected two datasets from different domains, Japanese Corpus (JC) and Chinese Corpus (CC). Table 1 gives the details of our corpora. In the learner's corpora, all of the sentences are erroneous. Note that our data does not consist of parallel pairs of sentences (one error sentence and its correction). The erroneous sentences includes grammar, sentence structure and lexical choice errors, but not spelling errors.

For each sentence, we generated five kinds of features as presented in Section 3. For a non-binary feature X, its value x is normalized by z-score, $norm(x) = \frac{x - mean(X)}{\sqrt{var(X)}}$, where `mean`(x) is the empirical mean of X and `var`(X) is the variance of X. Thus each sentence is represented by a vector.

Metrics We calculated the `precision`, `recall`, and `F-score` for correct and erroneous sentences, respectively, and also report the overall accuracy.

[5] including determiners/quantifiers, all pronouns, different pronoun types: Wh, 1^{st}, 2^{nd}, and 3^{rd} person pronouns, prepositions and adverbs, auxiliary verbs, and conjunctions.

All the experimental results are obtained thorough 10-fold cross-validation.

4.2 Experimental Results

The Effectiveness of Various Features. The experiment is to evaluate the contribution of each feature to the classification. The results of SVM are given in Table 2. We can see that the performance of *labeled sequential patterns* (LSP) feature consistently outperforms those of all the other individual features. It also performs better even if we use all the other features together. This is because other features only provide some relatively abstract and simple linguistic information, whereas the discovered LSPs characterize significant linguistic features as discussed before. We also found that the results of NB are a little worse than those of SVM. However, all the features perform consistently on the two classification models and we can observe the same trend. Due to space limitation, we do not give results of NB.

In addition, the discovered LSPs themselves are intuitive and meaningful since they are intuitive features that can distinguish correct sentences from erroneous sentences. We discovered 6309 LSPs in JC data and 3742 LSPs in CC data. Some example LSPs discovered from erroneous sentences are *<a, NNS>* (*support*:0.39%, *confidence*:85.71%), *<to, VBD>* (*support*:0.11%, *confidence*:84.21%), and *<the, more, the, JJ>* (*support*:0.19%, *confidence*:0.93%) [7]; Similarly, we also give some example LSPs mined from correct sentences: *<NN, VBZ>* (*support*:2.29%, *confidence*:75.23%), and *<have, VBN, since>* (*support*:0.11%, *confidence*:85.71%) [8]. However, other features are abstract and it is hard to derive some intuitive knowledge from the opaque statistical values of these features.

As shown in Table 2, our technique achieves the highest accuracy, e.g. 81.75% on the Japanese dataset, when we use all the features. However, we also notice that the improvement is not very significant compared with using LSP feature individually (e.g. 79.63% on the Japanese dataset). The similar results are observed when we combined the features *PLM, SC, FWD,* and LC. This could be explained by two reasons: (1) A sentence may contain several kinds of errors. A sentence detected to be erroneous by one feature may also be detected by another feature; and (2) Various features give conflicting results. The two aspects suggest the directions of our future efforts to improve the performance of our models.

Comparing with Other Methods. It is difficult to find benchmark methods to compare with our technique because, as discussed in Section 2, existing methods often require error tagged corpora or parallel corpora, or focus on a specific type of errors. In this paper, we compare our technique with the grammar checker of Microsoft Word03 and the ALEK (Chodorow and Leacock, 2000) method used by ETS. ALEK is used to detect inappropriate usage of specific vocabulary words. Note that we do not consider spelling errors. Due to space limitation, we only report the `precision`, `recall`, `F-score` for erroneous sentences, and the overall accuracy.

As can be seen from Table 3, our method outperforms the other two methods in terms of overall accuracy, F-score, and recall, while the three methods achieve comparable precision. We realize that the grammar checker of Word is a general tool and the performance of ALEK (Chodorow and Leacock, 2000) can be improved if larger training data is used. We found that Word and ALEK usually cannot find sentence structure and lexical collocation errors, e.g., "*The more you listen to English, the easy it becomes*." contains the discovered LSP *<the, more, the, JJ>* $\rightarrow$ *Error*.

Cross-domain Results. To study the performance of our method on cross-domain data from writers of the same first-language background, we collected two datasets from Japanese writers, one is composed of 694 parallel sentences (+:347, -:347), and the other 1,671 non-parallel sentences (+:795, -:876). The two datasets are used as test data while we use JC dataset for training. Note that the test sentences come from different domains from the JC data. The results are given in the first two rows of Table 4. This experiment shows that our leaning model trained for one domain can be effectively applied to independent data in the other domains from the writes of the same first-language background, no matter whether the test data is parallel or not. We also noticed that

Table 4: The Cross-domain Results of our Method

LSPs play dominating role in achieving the results. Due to space limitation, no details are reported.

To further see the performance of our method on data written by writers with different first-language backgrounds, we conducted two experiments. (1) We merge the JC dataset and CC dataset. The 10-fold cross-validation results on the merged dataset are given in the third row of Table 4. The results demonstrate that our models work well when the training data and test data contain sentences from different first-language backgrounds. (2) We use the JC dataset (resp. CC dataset) for training while the CC dataset (resp. JC dataset) is used as test data. As shown in the fourth (resp. fifth) row of Table 4, the results are worse than their corresponding results of Word given in Table 3. The reason is that the mistakes made by Japanese and Chinese are different, thus the learning model trained on one data does not work well on the other data. Note that our method is not designed to work in this scenario.

Application to Machine Translation Evaluation. Our learning models could be used to evaluate the MT results as an complementary measure. This is based on the assumption that if the MT results can be accurately distinguished from human references by our technique, the MT results are not natural and may contain errors as well.

The experiment was conducted using 10-fold cross validation on two LDC data, low-ranked and high-ranked data[9]. The results using SVM as classification model are given in Table 5. As expected, the classification accuracy on low-ranked data is higher than that on high-ranked data since low-ranked MT results are more different from human references than high-ranked MT results. We also found that LSPs are the most effective features. In addition, our discovered LSPs could indicate the common errors made by the MT systems and provide some suggestions for improving machine translation results.

As a summary, the mined LSPs are indeed effective for the classification models and our proposed technique is effective.

5 Conclusions and Future Work

This paper proposed a new approach to identifying erroneous/correct sentences. Empirical evaluating using diverse data demonstrated the effectiveness of

[9]One LDC data contains 14,604 low ranked (score 1-3) machine translations and the corresponding human references; the other LDC data contains 808 high ranked (score 3-5) machine translations and the corresponding human references

Data	Feature	A	(-)F	(-)R	(-)P	(+)F	(+)R	(+)P
Low-ranked data (1-3 score)	LSP	84.20	83.95	82.19	85.82	84.44	86.25	82.73
	LSP+LC+PLM+SC+FWD	86.60	86.84	88.96	84.83	86.35	84.27	88.56
High-ranked data (3-5 score)	LSP	71.74	73.01	79.56	67.59	70.23	64.47	77.40
	LSP+LC+PLM+SC+FWD	72.87	73.68	68.95	69.20	71.92	67.22	77.60

Table 5: The Results on Machine Translation Data

our techniques. Moreover, we proposed to mine LSPs as the input of classification models from a set of data containing correct and erroneous sentences. The LSPs were shown to be much more effective than the other linguistic features although the other features were also beneficial.

We will investigate the following problems in the future: (1) to make use of the discovered LSPs to provide detailed feedback for ESL learners, e.g. the errors in a sentence and suggested corrections; (2) to integrate the features effectively to achieve better results; (3) to further investigate the application of our techniques for MT evaluation.

{puurula, mikkok}@cis.hut.fi

Abstract

Speech recognition in many morphologically rich languages suffers from a very high out-of-vocabulary (OOV) ratio. Earlier work has shown that vocabulary decomposition methods can practically solve this problem for a subset of these languages. This paper compares various vocabulary decomposition approaches to open vocabulary speech recognition, using Estonian speech recognition as a benchmark. Comparisons are performed utilizing large models of 60000 lexical items and smaller vocabularies of 5000 items. A large vocabulary model based on a manually constructed morphological tagger is shown to give the lowest word error rate, while the unsupervised morphology discovery method Morfessor Baseline gives marginally weaker results. Only the Morfessor-based approach is shown to adequately scale to smaller vocabulary sizes.

1 Introduction

1.1 OOV problem

Open vocabulary speech recognition refers to automatic speech recognition (ASR) of continuous speech, or "speech-to-text" of spoken language, where the recognizer is expected to recognize any word spoken in that language. This capability is a recent development in ASR, and is required or beneficial in many of the current applications of ASR technology. Moreover, large vocabulary speech recognition is not possible in most languages of the world without first developing the tools needed for open vocabulary speech recognition. This is due to a fundamental obstacle in current ASR called the out-of-vocabulary (OOV) problem.

The OOV problem refers to the existence of words encountered that a speech recognizer is unable to recognize, as they are not covered in the vocabulary. The OOV problem is caused by three intertwined issues. Firstly, the language model training data and the test data always come from different samplings of the language, and the mismatch between test and training data introduces some OOV words, the amount depending on the difference between the data sets. Secondly, ASR systems always use finite and preferably small sized vocabularies, since the speed of decoding rapidly slows down as the vocabulary size is increased. Vocabulary sizes depend on the application domain, sizes larger than 60000 being very rare. As some of the words encountered in the training data are left out of the vocabulary, there will be OOV words during recognition. The third and final issue is the fundamental one; languages form novel sentences not only by combining words, but also by combining sub-word items called morphs to make up the words themselves. These morphs in turn correspond to abstract grammatical items called morphemes, and morphs of the same morpheme are called allomorphs of that morpheme. The study of these facets of language is aptly called morphology, and has been largely neglected in modern ASR technology. This is due to

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 89–95,
Prague, Czech Republic, June 2007.

ASR having been developed primarily for English, where the OOV problem is not as severe as in other languages of the world.

1.2 Relevance of morphology for ASR

Morphologies in natural languages are characterized typologically using two parameters, called indexes of synthesis and fusion. Index of synthesis has been loosely defined as the ratio of morphs per word forms in the language(Comrie, 1989), while index of fusion refers to the ratio of morphs per morpheme. High frequency of verb paradigms such as "hear, hear + d, hear + d" would result in a high synthesis, low fusion language, whereas high frequency of paradigms such as "sing, sang, sung" would result in almost the opposite. Counting distinct item types and not instances of the types, the first example would have 2 word forms, 2 morphs and 2 morphemes, the second 3 word forms, 3 morphs and 1 morpheme. Although in the first example, there are 3 word instances of the 2 word forms, the latter word form being an ambiguous one referring to two distinct grammatical constructions. It should also be noted that the first morph of the first example has 2 pronunciations. Pronunciational boundaries do not always follow morphological ones, and a morph may and will have several pronunciations that depend on context, if the language in question has significant orthographic irregularity.

As can be seen, both types of morphological complexity increase the amount of distinct word forms, resulting in an increase in the OOV rate of any finite sized vocabulary for that language. In practice, the OOV increase caused by synthesis is much larger, as languages can have thousands of different word forms per word that are caused by addition of processes of word formation followed by inflections. Thus the OOV problem in ASR has been most pronounced in languages with much synthesis, regardless of the amount of fusion. The morpheme-based modeling approaches evaluated in this work are primarily intended for fixing the problem caused by synthesis, and should work less well or even adversely when attempted with low synthesis, high fusion languages. It should be noted that models based on finite state transducers have been shown to be adequate for describing fusion as well(Koskenniemi, 1983), and further work should evaluate these types of models in ASR of languages with higher indexes of fusion.

1.3 Approaches for solving the OOV problem

The traditional method for reducing OOV would be to simply increase the vocabulary size so that the rate of OOV words becomes sufficiently low. Naturally this method fails when the words are derived, compounded or inflected forms of rarer words. While this approach might still be practical in languages with a low index of synthesis such as English, it fails with most languages in the world. For example, in English with language models (LM) of 60k words trained from the Gigaword Corpus V.2(Graff et al., 2005), and testing on a very similar Voice of America -portion of TDT4 speech corpora(Kong and Graff, 2005), this gives a OOV rate of 1.5%. It should be noted that every OOV causes roughly two errors in recognition, and vocabulary decomposition approaches such as the ones evaluated here give some benefits to word error rate (WER) even in recognizing languages such as English(Bisani and Ney, 2005).

Four different approaches to lexical unit selection are evaluated in this work, all of which have been presented previously. These are hence called "word", "hybrid", "morph" and "grammar". The word approach is the default approach to lexical item selection, and is provided here as a baseline for the alternative approaches. The alternatives tested here are all based on decomposing the in-vocabulary words, OOV words, or both, in LM training data into sequences of sub-word fragments. During recognition the decoder can then construct the OOV words encountered as combinations of these fragments. Word boundaries are marked in LMs with tokens so that the words can be reconstructed from the sub-word fragments after decoding simply by removing spaces between fragments, and changing the word boundaries tokens to spaces. As splitting to sub-word items makes the span of LM histories shorter, higher order n-grams must be used to correct this. Varigrams(Siivola and Pellom, 2005) are used in this work, and to make LMs trained with each approach comparable, the varigrams have been grown to roughly sizes of 5 million counts. It should be noted that the names for the approaches here are somewhat arbitrary, as from a theoretical perspec-

tive both morph- and grammar-based approaches try to model the grammatical morph set of a language, difference being that "morph" does this with an unsupervised data-driven machine learning algorithm, whereas "grammar" does this using segmentations from a manually constructed rule-based morphological tagger.

2 Modeling approaches

2.1 Word approach

The first approach evaluated in this work is the traditional word based LM, where items are simply the most frequent words in the language model training data. OOV words are simply treated as unknown words in language model training. This has been the default approach to selection of lexical items in speech recognition for several decades, and as it has been sufficient in English ASR, there has been limited interest in any alternatives.

2.2 Hybrid approach

The second approach is a recent refinement of the traditional word-based approach. This is similar to what was introduced as "flat hybrid model"(Bisani and Ney, 2005), and it tries to model OOV-words as sequences of words and fragments. "Hybrid" refers to the LM histories being composed of hybrids of words and fragments, while "flat" refers to the model being composed of one n-gram model instead of several models for the different item types. The models tested in this work differ in that since Estonian has a very regular phonemic orthography, grapheme sequences can be directly used instead of more complex pronunciation modeling. Subsequently the fragments used are just one grapheme in length.

2.3 Morph approach

The morph-based approach has shown superior results to word-based models in languages of high synthesis and low fusion, including Estonian. This approach, called "Morfessor Baseline" is described in detail in (Creutz et al., 2007). An unsupervised machine learning algorithm is used to discover the morph set of the language in question, using minimum description length (MDL) as an optimization criterion. The algorithm is given a word list of the language, usually pruned to about 100 000 words, that it proceeds to recursively split to smaller items, using gains in MDL to optimize the item set. The resulting set of morphs models the morph set well in languages of high synthesis, but as it does not take fusion into account any manner, it should not work in languages of high fusion. It neither preserves information about pronunciations, and as these do not follow morph boundaries, the approach is unsuitable in its basic form to languages of high orthographic irregularity.

2.4 Grammar approach

The final approach applies a manually constructed rule-based morphological tagger(Alumäe, 2006). This approach is expected to give the best results, as the tagger should give the ideal segmentation along the grammatical morphs that the unsupervised and language-independent morph approach tries to find. To make this approach more comparable to the morph models, OOV morphs are modeled as sequences of graphemes similar to the hybrid approach. Small changes to the original approach were also made to make the model comparable to the other models presented here, such as using the tagger segmentations as such and not using pseudo-morphemes, as well as not tagging the items in any manner. This approach suffers from the same handicaps as the morph approach, as well as from some additional ones: morphological analyzers are not readily available for most languages, they must be tailored by linguists for new datasets, and it is an open problem as to how pronunciation dictionaries should be written for grammatical morphs in languages with significant orthographic irregularity.

2.5 Text segmentation and language modeling

For training the LMs, a subset of 43 million words from the Estonian Segakorpus was used(Segakorpus, 2005), preprocessed with a morphological analyzer(Alumäe, 2006). After selecting the item types, segmenting the training corpora and generation of a pronunciation dictionary, LMs were trained for each lexical item type. Table 1 shows the text format for LM training data after segmentation with each model. As can be seen, the word-based approach doesn't use word boundary tokens. To keep the LMs comparable between each model-

model	text segmentation
word 5k	voodis reeglina loeme
word 60k	voodis reeglina loeme
hybrid 5k	v o o d i s <w> reeglina <w> l o e m e
hybrid 60k	voodis <w> reeglina <w> loeme
morph 5k	voodi s <w> re e g lina <w> loe me
morph 60k	voodi s <w> reegli na <w> loe me
grammar 5k	voodi s <w> reegli na <w> loe me
grammar 60k	voodi s <w> reegli na <w> loe me

Table 1. Sample segmented texts for each model.

ing approach, growing varigram models(Siivola and Pellom, 2005) were used with no limits as to the order of n-grams, but limiting the number of counts to 4.8 and 5 million counts. In some models this growing method resulted in the inclusion of very frequent long item sequences to the varigram, up to a 28-gram. Models of both 5000 and 60000 lexical items were trained in order to test if and how the modeling approaches would scale to smaller and therefore much faster vocabularies. Distribution of counts in n-gram orders can be seen in figure 1.

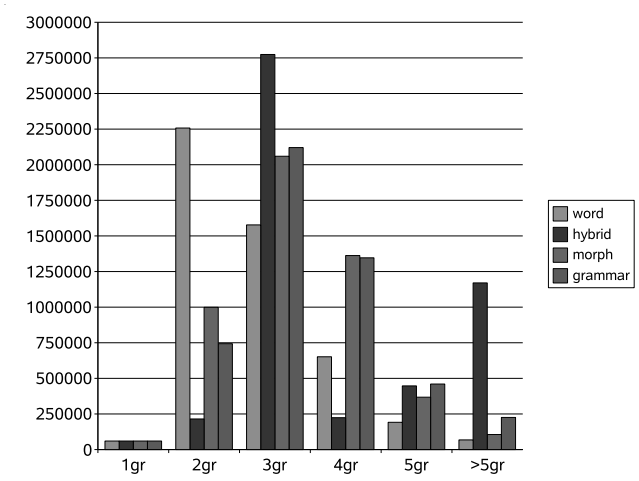

Figure 1. Number of counts included for each n-gram order in the 60k varigram models.

The performance of the statistical language models is often evaluated by perplexity or cross-entropy. However, we decided to only report the real ASR performance, because perplexity does not suit well to the comparison of models that use different lexica, have different OOV rates and have lexical units of different lengths.

3 Experimental setup

3.1 Evaluation set

Acoustic models for Estonian ASR were trained on the Estonian Speechdat-like corpus(Meister et al., 2002). This consists of spoken newspaper sentences and shorter utterances, read over a telephone by 1332 different speakers. The data therefore was quite clearly articulated, but suffered from 8kHz sample rate, different microphones, channel noises and occasional background noises. On top of this the speakers were selected to give a very broad coverage of different dialectal varieties of Estonian and were of different age groups. For these reasons, in spite of consisting of relatively common word forms from newspaper sentences, the database can be considered challenging for ASR.

Held-out sentences were from the same corpus used as development and evaluation set. 8 different sentences from 50 speakers each were used for evaluation, while sentences from 15 speakers were used for development. LM scaling factor was optimized for each model separately on the development set. On total over 200 hours of data from the database was used for acoustic model training, of which less than half was speech.

3.2 Decoding

The acoustic models were Hidden Markov Models (HMM) with Gaussian Mixture Models (GMM) for state modeling based on 39-dimensional MFCC+P+D+DD features, with windowed cepstral mean subtraction (CMS) of 1.25 second window. Maximum likelihood linear transformation (MLLT) was used during training. State-tied cross-word triphones and 3 left-to-right states were used, state durations were modeled using gamma distributions. On total 3103 tied states and 16 Gaussians per state were used.

Decoding was done with the decoder developed at TKK(Pylkkönen, 2005), which is based on a one-pass Viterbi beam search with token passing on a lexical prefix tree. The lexical prefix tree included a cross-word network for modeling triphone contexts, and the nodes in the prefix tree were tied at the triphone state level. Bigram look-ahead models were

used in speeding up decoding, in addition to pruning with global beam, history, histogram and word end pruning. Due to the properties of the decoder and varigram models, very high order n-grams could be used without significant degradation in decoding speed.

As the decoder was run with only one pass, adaptation was not used in this work. In preliminary experiments simple adaptation with just constrained maximum likelihood linear regression (CMLLR) was shown to give as much as 20 % relative word error rate reductions (RWERR) with this dataset. Adaptation was not used, since it interacts with the model types, as well as with the WER from the first round of decoding, providing larger RWERR for the better models. With high WER models, adaptation matrices are less accurate, and it is also probable that the decomposition methods yield more accurate matrices, as they produce results where fewer HMM-states are misrecognized. These issues should be investigated in future research.

After decoding, the results were post-processed by removing words that seemed to be sequences of junk fragments: consonant-only sequences and 1-phoneme words. This treatment should give very significant improvements with noisy data, but in preliminary experiments it was noted that the use of sentence boundaries resulted in almost 10% RWERR weaker results for the approaches using fragments, as that almost negates the gains achieved from this post-processing. Since sentence boundary forcing is done prior to junk removal, it seems to work erroneously when it is forced to operate on noisy data. Sentence boundaries were nevertheless used, as in the same experiments the word-based models gained significantly from their use, most likely because they cannot use the fragment items for detection of acoustic junk, as the models with fragments can.

4 Results

Results of the experiments were consistent with earlier findings(Hirsimäki et al., 2006; Kurimo et al., 2006). Traditional word based LMs showed the worst performance, with all of the recently proposed alternatives giving better results. Hybrid LMs consistently outperformed traditional word-based LMs in both large and small vocabulary conditions. The two morphology-driven approaches gave similar and clearly superior results. Only the morph approach seems to scale down well to smaller vocabulary sizes, as the WER for the grammar approach increased rapidly as size of the vocabulary was decreased.

size	word	hybrid	morph	grammar
60000	53.1	47.1	39.4	38.7
5000	82.0	63.0	43.5	47.6

Table 2. Word error rates for the models (WER %).

Table 2 shows the WER for the large (60000) and small (5000) vocabulary sizes and different modeling approaches. Table 3 shows the corresponding letter error rates (LER). LERs are more comparable across some languages than WERs, as WER depends more on factors such as length, morphological complexity, and OOV of the words. However, for within-language and between-model comparisons, the RWERR should still be a valid metric, and is also usable in languages that do not use a phonemic writing system. The RWERRs of different novel methods seems to be comparable between different languages as well. Both WER and LER are high considering the task. However, standard methods such as adaptation were not used, as the intention was only to study the RWERR of the different approaches.

size	word	hybrid	morph	grammar
60000	17.8	15.8	12.4	12.3
5000	35.5	20.8	14.4	15.4

Table 3. Letter error rates for the models (LER %).

5 Discussion

Four different approaches to lexical item selection for large and open vocabulary ASR in Estonian were evaluated. It was shown that the three approaches utilizing vocabulary decomposition give substantial improvements over the traditional word based approach, and make large vocabulary ASR technology possible for languages similar to Estonian, where the traditional approach fails due to very

high OOV rates. These include memetic relatives Finnish and Turkish, among other languages that have morphologies of high fusion, low synthesis and low orthographic irregularity.

5.1 Performance of the approaches

The morpheme-based approaches outperformed the word- and hybrid-based approaches clearly. The results for "hybrid" are in in the range suggested by earlier work(Bisani and Ney, 2005). One possible explanation for the discrepancy between the hybrid and morpheme-based approaches would be that the morpheme-based approaches capture items that make sense in n-gram modeling, as morphs are items that the system of language naturally operates on. These items would then be of more use when trying to predict unseen data(Creutz et al., 2007). As modeling pronunciations is much more straightforward in Estonian, the morpheme-based approaches do not suffer from erroneous pronunciations, resulting in clearly superior performance.

As for the superiority of the "grammar" over the unsupervised "morph", the difference is marginal in terms of RWERR. The grammatical tagger was tailored by hand for that particular language, whereas Morfessor method is meant to be unsupervised and language independent. There are further arguments that would suggest that the unsupervised approach is one that should be followed; only "morph" scaled well to smaller vocabulary sizes, the usual practice of pruning the word list to produce smaller morph sets gives better results than here and most importantly, it is questionable if "grammar" can be taken to languages with high indexes of fusion and orthographic irregularity, as the models have to take these into account as well.

5.2 Comparison to previous results

There are few previous results published on Estonian open vocabulary ASR. In (Alumäe, 2006) a WER of 44.5% was obtained with word-based trigrams and a WER of 37.2% with items similar to ones from "grammar" using the same speech corpus as in this work. Compared to the present work, the WER for the morpheme-based models was measured with compound words split in both hypothesis and reference texts, making the task slightly easier than here. In (Kurimo et al., 2006) a WER of 57.6% was achieved with word-based varigrams and a WER of 49.0% with morphs-based ones. This used the same evaluation set as this work, but had slightly different LMs and different acoustic modelling which is the main reason for the higher WER levels. In summary, morpheme-based approaches seem to consistently outperform the traditional word based one in Estonian ASR, regardless of the specifics of the recognition system, test set and models.

In (Hirsimäki et al., 2006) a corresponding comparison of unsupervised and grammar-based morphs was presented in Finnish, and the grammar-based model gave a significantly higher WER in one of the tasks. This result is interesting, and may stem from a number of factors, among them the different decoder and acoustic models, 4-grams versus varigrams, as well as differences in post-processing. Most likely the difference is due to lack of coverage for domain-specific words in the Finnish tagger, as it has a 4.2% OOV rate on the training data. On top of this the OOV words are modeled simply as grapheme sequences, instead of modeling only OOV morphs in that manner, as is done in this work.

5.3 Open problems in vocabulary decomposition

As stated in the introduction, modeling languages with high indexes of fusion such as Arabic will require more complex vocabulary decomposition approaches. This is verified by recent empirical results, where gains obtained from simple morphological decomposition seem to be marginal(Kirchhoff et al., 2006; Creutz et al., 2007). These languages would possibly need novel LM inference algorithms and decoder architectures. Current research seems to be heading in this direction, with weighted finite state transducers becoming standard representations for the vocabulary instead of the lexical prefix tree.

Another issue in vocabulary decomposition is orthographic irregularity, as the items resulting from decomposition do not necessarily have unambiguous pronunciations. As most modern recognizers use the Viterbi approximation with vocabularies of one pronunciation per item, this is problematic. One solution to this is expanding the different items with tags according to pronunciation, shifting the problem to language modeling(Creutz et al., 2007). For example, English plural "s" would expand to "s#1"

with pronunciation "/s/", and "s#2" with pronunciation "/z/", and so on. In this case the vocabulary size increases by the amount of different pronunciations added. The new items will have pronunciations that depend on their language model context, enabling the prediction of pronunciations with language model probabilities. The only downside to this is complicating the search for optimal vocabulary decomposition, as the items should make sense in both pronunciational and morphological terms.

One can consider the originally presented hybrid approach as an approach to vocabulary decomposition that tries to keep the pronunciations of the items as good as possible, whereas the morph approach tries to find items that make sense in terms of morphology. This is obviously due to the methods having been developed on very different types of languages. The morph approach was developed for the needs of Finnish speech recognition, which is a high synthesis, moderate fusion and very low orthographic irregularity language, whereas the hybrid approach in (Bisani and Ney, 2005) was developed for English, which has low synthesis, moderate fusion, and very high orthographic irregularity. A universal approach to vocabulary decomposition would have to take all of these factors into account.

Acknowledgements

Abstract

Grapheme-to-phoneme conversion (g2p) is a core component of any text-to-speech system. We show that adding simple syllabification and stress assignment constraints, namely 'one nucleus per syllable' and 'one main stress per word', to a joint n-gram model for g2p conversion leads to a dramatic improvement in conversion accuracy.

Secondly, we assessed morphological preprocessing for g2p conversion. While morphological information has been incorporated in some past systems, its contribution has never been quantitatively assessed for German. We compare the relevance of morphological preprocessing with respect to the morphological segmentation method, training set size, the g2p conversion algorithm, and two languages, English and German.

1 Introduction

Grapheme-to-Phoneme conversion (g2p) is the task of converting a word from its spelling (e.g. "Sternanisöl", Engl: star-anise oil) to its pronunciation (/ˈʃtɛrnʔaniːsʔøːl/). Speech synthesis modules with a g2p component are used in text-to-speech (TTS) systems and can be be applied in spoken dialogue systems or speech-to-speech translation systems.

1.1 Syllabification and Stress in g2p conversion

In order to correctly synthesize a word, it is not only necessary to convert the letters into phonemes, but also to syllabify the word and to assign word stress.

The problems of word phonemization, syllabification and word stress assignment are inter-dependent. Information about the position of a syllable boundary helps grapheme-to-phoneme conversion. (Marchand and Damper, 2005) report a word error rate (WER) reduction of approx. 5 percentage points for English when the letter string is augmented with syllabification information. The same holds vice-versa: we found that WER was reduced by 50% when running our syllabifier on phonemes instead of letters (see Table 4). Finally, word stress is usually defined on syllables; in languages where word stress is assumed[1] to partly depend on syllable weight (such as German or Dutch), it is important to know where exactly the syllable boundaries are in order to correctly calculate syllable weight. For German, (Müller, 2001) show that information about stress assignment and the position of a syllable within a word improve g2p conversion.

1.2 Morphological Preprocessing

It has been argued that using morphological information is important for languages where morphology has an important influence on pronunciation, syllabification and word stress such as German, Dutch, Swedish or, to a smaller extent, also English (Sproat, 1996; Möbius, 2001; Pounder and Kommenda, 1986; Black et al., 1998; Taylor, 2005). Unfortunately, these papers do not quantify the contribution of morphological preprocessing in the task.

Important questions when considering the integration of a morphological component into a speech

[1] This issue is controversial among linguists; for an overview see (Jessen, 1998).

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 96–103,
Prague, Czech Republic, June 2007.

synthesis system are 1) How large are the improvements to be gained from morphological preprocessing? 2) Must the morphological system be perfect or can performance improvements also be reached with relatively simple morphological components? and 3) How much does the benefit to be expected from explicit morphological information depend on the g2p algorithm? To determine these factors, we compared morphological segmentations based on manual morphological annotation from CELEX to two rule-based systems and several unsupervised data-based approaches. We also analysed the role of explicit morphological preprocessing on data sets of different sizes and compared its relevance with respect to a decision tree and a joint n-gram model for g2p conversion.

The paper is structured as follows: We introduce the g2p conversion model we used in section 2 and explain how we implemented the phonological constraints in section 3. Section 4 is concerned with the relation between morphology, word pronunciation, syllabification and word stress in German, and presents different sources for morphological segmentation. In section 5, we evaluate the contribution of each of the components and compare our methods to state-of-the-art systems. Section 6 summarizes our results.

2 Methods

We used a joint n-gram model for the grapheme-to-phoneme conversion task. Models of this type have previously been shown to yield very good g2p conversion results (Bisani and Ney, 2002; Galescu and Allen, 2001; Chen, 2003). Models that do not use *joint* letter-phoneme states, and therefore are not conditional on the preceding letters, but only on the actual letter and the preceding phonemes, achieved inferior results. Examples of such approaches using Hidden Markov Models are (Rentzepopoulos and Kokkinakis, 1991) (who applied the HMM to the related task of phoneme-to-grapheme conversion), (Taylor, 2005) and (Minker, 1996).

The g2p task is formulated as searching for the most probable sequence of phonemes given the orthographic form of a word. One can think of it as a tagging problem where each letter is tagged with a (possibly empty) phoneme-sequence p. In our particular implementation, the model is defined as a higher-order Hidden Markov Model, where the hidden states are a letter–phoneme-sequence pair $\langle l; p\rangle$, and the observed symbols are the letters l. The output probability of a hidden state is then equal to one, since all hidden states that do not contain the observed letter are pruned directly.

The model for grapheme-to-phoneme conversion uses the Viterbi algorithm to efficiently compute the most probable sequence $\hat{p}_1^n$ of phonemes $\hat{p}_1, \hat{p}_2, ..., \hat{p}_n$ for a given letter sequence l_1^n. The probability of a letter–phon-seq pair depends on the *k* preceding letter–phon-seq pairs. Dummy states '#' are appended at both ends of each word to indicate the word boundary and to ensure that all conditional probabilities are well-defined.

$$\hat{p}_1^n = \arg\max_{p_1^n} \prod_{i=1}^{n+1} P(\langle l; p\rangle_i \,|\, \langle l; p\rangle_{i-k}^{i-1})$$

In an integrated model where g2p conversion, syllabification and word stress assignment are all performed at the same time, a state additionally contains a syllable boundary flag b and a stress flag a, yielding $\langle l; p; b; a\rangle_i$.

As an alternative architecture, we also designed a modular system that comprises one component for syllabification and one for word stress assignment. The model for syllabification computes the most probable sequence $\hat{b}_1^n$ of syllable boundary-tags $\hat{b}_1$, $\hat{b}_2, ..., \hat{b}_n$ for a given letter sequence l_1^n.

$$\hat{b}_1^n = \arg\max_{b_1^n} \prod_{i=1}^{n+1} P(\langle l; b\rangle_i \,|\, \langle l; b\rangle_{i-k}^{i-1})$$

The stress assignment model works on syllables. It computes the most probable sequence $\hat{a}_1^n$ of word accent-tags $\hat{a}_1, \hat{a}_2, ..., \hat{a}_n$ for a given syllable sequence syl_1^n.

$$\hat{a}_1^n = \arg\max_{a_1^n} \prod_{i=1}^{n+1} P(\langle syl; a\rangle_i \,|\, \langle syl; a\rangle_{i-k}^{i-1})$$

2.1 Smoothing

Because of major data sparseness problems, smoothing is an important issue, in particular for the stress model which is based on syllable–stress-tag pairs. Performance varied by up to 20% in function of the smoothing algorithm chosen. Best results were obtained when using a variant of Modified Kneser-Ney Smoothing[2] (Chen and Goodman, 1996).

[2]For a formal definition, see(Demberg, 2006).

2.2 Pruning

In the g2p-model, each letter can on average map onto one of 12 alternative phoneme-sequences. When working with 5-grams[3], there are about 12^5 = 250,000 state sequences. To improve time and space efficiency, we implemented a simple pruning strategy that only considers the t best states at any moment in time. With a threshold of $t = 15$, about 120 words are processed per minute on a 1.5GHz machine. Conversion quality is only marginally worse than when the whole search space is calculated.

Running time for English is faster, because the average number of candidate phonemes for each letter is lower. We measured running time (including training and the actual g2p conversion in 10-fold cross validation) for a Perl implementation of our algorithm on the English NetTalk corpus (20,008 words) on an Intel Pentium 4, 3.0 GHz machine. Running time was less than 1h for each of the following three test conditions: c1) g2p conversion only, c2) syllabification first, then g2p conversion, c3) simultaneous g2p conversion and syllabification, given perfect syllable boundary input, c4) simultaneous g2p conversion and syllabification when correct syllabification is not available beforehand. This is much faster than the times for Pronunciation by Analogy (PbA) (Marchand and Damper, 2005) on the same corpus. Marchand and Damper reported a processing time of several hours for c4), two days for c2) and several days for c3).

2.3 Alignment

Our current implementation of the joint n-gram model is not integrated with an automatic alignment procedure. We therefore first aligned letters and phonemes in a separate, semi-automatic step. Each letter was aligned with zero to two phonemes and, in the integrated model, zero or one syllable boundaries and stress markers.

3 Integration of Phonological Constraints

When analysing the results from the model that does g2p conversion, syllabification and stress assignment in a single step, we found that a large proportion of the errors was due to the violation of basic phonological constraints.

Some syllables had no syllable nucleus, while others contained several vowels. The reason for the errors is that German syllables can be very long and therefore sparse, often causing the model to back-off to smaller contexts. If the context is too small to cover the syllable, the model cannot decide whether the current syllable contains a nucleus.

In stress assignment, this problem is even worse: the context window rarely covers the whole word. The algorithm does not know whether it already assigned a word stress outside the context window. This leads to a high error rate with 15-20% of incorrectly stressed words. Thereof, 37% have more than one main stress, about 27% are not assigned any stress and 36% are stressed in the wrong position. This means that we can hope to reduce the errors by almost 2/3 by using phonological constraints.

Word stress assignment is a difficult problem in German because the underlying processes involve some deeper morphological knowledge which is not available to the simple model. In complex words, stress mainly depends on morphological structure (i.e. on the compositionality of compounds and on the stressing status of affixes). Word stress in simplex words is assumed to depend on the syllable position within the word stem and on syllable weight. The current language-independent approach does not model these processes, but only captures some of its statistics.

Simple constraints can help to overcome the problem of lacking context by explicitly requiring that every syllable must have exactly one syllable nucleus and that every word must have exactly one syllable receiving primary stress.

3.1 Implementation

Our goal is to find the most probable syllabified and stressed phonemization of a word that does not violate the constraints. We tried two different approaches to enforce the constraints.

In the first variant (v1), we modified the probability model to enforce the constraints. Each state now corresponds to a sequence of 4-tuples consisting of a letter l, a phoneme sequence p, a syllable boundary tag b, an accent tag a (as before) plus two

[3]There is a trade-off between long context windows which capture the context accurately and data sparseness issues. The optimal value k for the context window size depends on the source language (existence of multiletter graphemes, complexity of syllables etc.).

new flags A and N which indicate whether an accent/nucleus precedes or not. The A and N flags of the new state are a function of its accent and syllable boundary tag and the A and N flag of the preceding state. They split each state into four new states. The new transition probabilities are defined as:

$$P(\langle l; p; b; a\rangle_i \mid \langle l; p; b; a\rangle_{i-k}^{i-1}, A, N)$$

The probability is 0 if the transition violates a constraint, e.g., when the A flag is set and a_i indicates another accent.

A positive side effect of the syllable flag is that it stores separate phonemization probabilities for consonants in the syllable onset vs. consonants in the coda. The flag in the onset is 0 since the nucleus has not yet been encountered, whereas it is set to 1 in the coda. In German, this can e.g. help in for syllable-final devoicing of voiced stops and fricatives.

The increase in the number of states aggravates sparse-data problems. Therefore, we implemented another variant (v2) which uses the same set of states (with A and N flags), but with the transition probabilities of the original model, which did not enforce the constraints. Instead, we modified the Viterbi algorithm to eliminate the invalid transitions: For example, a transition from a state with the A flag set to a state where a_i introduces a second stress, is always ignored. On small data sets, better results were achieved with v2 (see Table 5).

4 Morphological Preprocessing

In German, information about morphological boundaries is needed to correctly insert glottal stops [ʔ] in complex words, to determine irregular pronunciation of affixes (*v* is pronounced [v] in *vertikal* but [f] in *ver+ticker+n*, and the suffix syllable *heit* is not stressed although superheavy and word final) and to disambiguate letters (e.g. *e* is always pronounced /ə/ when occurring in inflectional suffixes). Vowel length and quality has been argued to also depend on morphological structure (Pounder and Kommenda, 1986). Furthermore, morphological boundaries overrun default syllabification rules, such as the maximum onset principle.

Applying default syllabification to the word "Sternanisöl" would result in a syllabification into `Ster-na-ni-söl` (and subsequent phonemization to something like /ʃtɛʁˈnaːnizøːl/) instead of `Stern-a-nis-öl` (/ˈʃtɛʁnʔaniːsʔøːl/). Syllabification in turn affects phonemization since voiced fricatives and stops are devoiced in syllable-final position. Morphological information also helps for graphemic parsing of words such as "Röschen" (Engl: little rose) where the morphological boundary between *Rös* and *chen* causes the string *sch* to be transcribed to /sç/ instead of /ʃ/. Similar ambiguities can arise for all other sounds that are represented by several letters in orthography (e.g. doubled consonants, diphtongs, *ie*, *ph*, *th*), and is also valid for English. Finally, morphological information is also crucial to determine word stress in morphologically complex words.

4.1 Methods for Morphological Segmentation

Good segmentation performance on arbitrary words is hard to achieve. We compared several approaches with different amounts of built-in knowledge. The morphological information is encoded in the letter string, where different digits represent different kinds of morphological boundaries (prefixes, stems, derivational and inflectional suffixes).

Manual Annotation from CELEX

To determine the upper bound of what can be achieved when exploiting perfect morphological information, we extracted morphological boundaries and boundary types from the CELEX database.

The manual annotation is not perfect as it contains some errors and many cases where words are not decomposed entirely. The words tagged [F] for "lexicalized inflection", e.g. *gedrängt* (past participle of *drängen*, Engl: push) were decomposed semi-automatically for the purpose of this evaluation. As expected, annotating words with CELEX morphological segmentation yielded the best g2p conversion results. Manual annotation is only available for a small number of words. Therefore, only automatically annotated morphological information can scale up to real applications.

Rule-based Systems

The traditional approach is to use large morpheme lexica and a set of rules that segment words into affixes and stems. Drawbacks of using such a system are the high development costs, limited coverage

and problems with ambiguity resolution between alternative analyses of a word.

The two rule-based systems we evaluated, the ETI[4] morphological system and SMOR[5] (Schmid et al., 2004), are both high-quality systems with large lexica that have been developed over several years. Their performance results can help to estimate what can realistically be expected from an automatic segmentation system. Both of the rule-based systems achieved an F-score of approx. 80% morphological boundaries correct with respect to CELEX manual annotation.

Unsupervised Morphological Systems

Most attractive among automatic systems are methods that use unsupervised learning, because these require neither an expert linguist to build large rule-sets and lexica nor large manually annotated word lists, but only large amounts of tokenized text, which can be acquired e.g. from the internet. Unsupervised methods are in principle[6] language-independent, and can therefore easily be applied to other languages.

We compared four different state-of-the-art unsupervised systems for morphological decomposition (cf. (Demberg, 2006; Demberg, 2007)). The algorithms were trained on a German newspaper corpus (taz), containing about 240 million words. The same algorithms have previously been shown to help a speech recognition task (Kurimo et al., 2006).

5 Experimental Evaluations

5.1 Training Set and Test Set Design

The German corpus used in these experiments is CELEX (German Linguistic User Guide, 1995). CELEX contains a phonemic representation of each word, syllable boundaries and word stress information. Furthermore, it contains manually verified morphological boundaries.

Our training set contains approx. 240,000 words and the test set consists of 12,326 words. The test set is designed such that word stems in training and test sets are disjoint, i.e. the inflections of a certain stem are either all in the training set or all in the test set. Stem overlap between training and test set only occurs in compounds and derivations. If a simple random splitting (90% for training set, 10% for test set) is used on inflected corpora, results are much better: Word error rates (WER) are about 60% lower when the set of stems in training and test set are not disjoint. The same effect can also be observed for the syllabification task (see Table 4).

5.2 Results for the Joint n-gram Model

The joint n-gram model is language-independent. An aligned corpus with words and their pronunciations is needed, but no further adaptation is required.

Table 1 shows the performance of our model in comparison to alternative approaches on the German and English versions of the CELEX corpus, the English NetTalk corpus, the English Teacher's Word Book (TWB) corpus, the English beep corpus and the French Brulex corpus. The joint n-gram model performs significantly better than the decision tree (essentially based on (Lucassen and Mercer, 1984)), and achieves scores comparable to the Pronunciation by Analogy (PbA) algorithm (Marchand and Damper, 2005). For the Nettalk data, we also compared the influence of syllable boundary annotation from a) automatically learnt and b) manually annotated syllabification information on phoneme accuracy. Automatic syllabification for our model integrated phonological constraints (as described in section 3.1), and therefore led to an improvement in phoneme accuracy, while the word error rate increased for the PbA approach, which does not incorporate such constraints.

(Chen, 2003) also used a joint n-gram model. The two approaches differ in that Chen uses small chunks ($\langle\langle l : |0..1| \rangle : \langle p : |0..1| \rangle\rangle$ pairs only) and iteratively optimizes letter-phoneme alignment during training. Chen smoothes higher-order Markov Models with Gaussian Priors and implements additional language modelling such as consonant doubling.

[4] Eloquent Technology, Inc. (ETI) TTS system. http://www.mindspring.com/~ssshp/ssshp_cd/ss_eloq.htm

[5] The lexicon used by SMOR, IMSLEX, contains morphologically complex entries, which leads to high precision and low recall. The results reported here refer to a version of SMOR, where the lexicon entries were decomposed using a rather naïve high-recall segmentation method. SMOR itself does not disambiguate morphological analyses of a word. Our version used transition weights learnt from CELEX morphological annotation. For more details refer to (Demberg, 2006).

[6] Most systems make some assumptions about the underlying morphological system, for instance that morphology is a concatenative process, that stems have a certain minimal length or that prefixing and suffixing are the most relevant phenomena.

corpus	size	jnt n-gr	PbA	Chen	dec.tree
G - CELEX	230k	7.5%			15.0%
E - Nettalk	20k	35.4%	34.65%	34.6%	
a) auto.syll		35.3%	35.2%		
b) man.syll		29.4%	28.3%		
E - TWB	18k	28.5%	28.2%		
E - beep	200k	14.3%	13.3%		
E - CELEX	100k	23.7%			31.7%
F - Brulex	27k	10.9%			

Table 1: Word error rates for different g2p conversion algorithms. Constraints were only used in the E-Nettalk auto. syll condition.

5.3 Benefit of Integrating Constraints

The accuracy improvements achieved by integrating the constraints (see Table 2) are highly statistically significant. The numbers for conditions "G-syllab.+stress+g2p" and "E-syllab.+g2p" in Table 2 differ from the numbers for "G-CELEX" and "E-Nettalk" in Table 1 because phoneme conversion errors, syllabification errors and stress assignment errors are all counted towards word error rates reported in Table 2.

Word error rate in the combined g2p-syllable-stress model was reduced from 21.5% to 13.7%. For the separate tasks, we observed similar effects: The word error rate for inserting syllable boundaries was reduced from 3.48% to 3.1% on letters and from 1.84% to 1.53% on phonemes. Most significantly, word error rate was decreased from 30.9% to 9.9% for word stress assignment on graphemes.

We also found similarly important improvements when applying the syllabification constraint to English grapheme-to-phoneme conversion and syllabification. This suggests that our findings are not specific to German but that this kind of general constraints can be beneficial for a range of languages.

	no constr.	constraint(s)
G - syllab.+stress+g2p	21.5%	13.7%
G - syllab. on letters	3.5%	3.1%
G - syllab. on phonemes	1.84%	1.53%
G - stress assignm. on letters	30.9%	9.9%
E - syllab.+g2p	40.5%	37.5%
E - syllab. on phonemes	12.7%	8.8%

Table 2: Improving performance on g2p conversion, syllabification and stress assignment through the introduction of constraints. The table shows word error rates for German CELEX (G) and English NetTalk (E).

5.4 Modularity

Modularity is an advantage if the individual components are more specialized to their task (e.g. by applying a particular level of description of the problem, or by incorporating some additional source of knowledge).In a modular system, one component can easily be substituted by another – for example, if a better way of doing stress assignment in German was found. On the other hand, keeping everything in one module for strongly inter-dependent tasks (such as determining word stress and phonemization) allows us to simultaneously optimize for the best combination of phonemes and stress.

Best results were obtained from the joint n-gram model that does syllabification, stress assignment and g2p conversion all in a single step and integrates phonological constraints for syllabification and word stress (WER = 14.4% using method v1, WER = 13.7% using method v2). If the modular architecture is chosen, best results are obtained when g2p conversion is done before syllabification and stress assignment (15.2% WER), whereas doing syllabification and stress assignment first and then g2p conversion leads to a WER of 16.6%. We can conclude from this finding that an integrated approach is superior to a pipeline architecture for strongly inter-dependent tasks such as these.

5.5 The Contribution of Morphological Preprocessing

A statistically significant (according to a two-tailed t-test) improvement in g2p conversion accuracy (from 13.7% WER to 13.2% WER) was obtained with the manually annotated morphological boundaries from CELEX. The segmentation from both of the rule-based systems (ETI and SMOR) also resulted in an accuracy increase with respect to the baseline (13.6% WER), which is not annotated with morphological boundaries.

Among the unsupervised systems, best results[7] on the g2p task with morphological annotation were obtained with the RePortS system (Keshava and Pitler, 2006). But none of the segmentations led to an error reduction when compared to a baseline that used no morphological information (see Table 3). Word error rate even increased when the quality of the

[7]For all results refer to (Demberg, 2006).

	Precis.	Recall	F-Meas.	WER
RePortS (unsuperv.)	71.1%	50.7%	59.2%	15.1%
no morphology				13.7%
SMOR (rule-based)	87.1%	80.4%	83.6%	
ETI (rule-based)	75.4%	84.1%	79.5%	13.6%
CELEX (manual)	100%	100%	100%	13.2%

Table 3: Systems evaluation on German CELEX manual annotation and on the g2p task using a joint n-gram model. WERs refer to implementation v2.

morphological segmentation was too low (the unsupervised algorithms achieved 52%-62% F-measure with respect to CELEX manual annotation).

Table 4 shows that high-quality morphological information can also significantly improve performance on a syllabification task for German. We used the syllabifier described in (Schmid et al., 2005), which works similar to the joint n-gram model used for g2p conversion. Just as for g2p conversion, we found a significant accuracy improvement when using the manually annotated data, a smaller improvement for using data from the rule-based morphological system, and no improvement when using segmentations from an unsupervised algorithm. Syllabification works best when performed on phonemes, because syllables are phonological units and therefore can be determined most easily in terms of phonological entities such as phonemes.

Whether morphological segmentation is worth the effort depends on many factors such as training set size, the g2p algorithm and the language considered.

	disj. stems	random
RePortS (unsupervised morph.)	4.95%	
no morphology	3.10%	0.72%
ETI (rule-based morph.)	2.63%	
CELEX (manual annot.)	1.91%	0.53%
on phonemes	1.53%	0.18%

Table 4: Word error rates (WER) for syllabification with a joint n-gram model for two different training and test set designs (see Section 5.1).

Morphology for Data Sparseness Reduction

Probably the most important aspect of morphological segmentation information is that it can help to resolve data sparseness issues. Because of the additional knowledge given to the system through the morphological information, similarly-behaving letter sequences can be grouped more effectively.

Therefore, we hypothesized that morphological information is most beneficial in situations where the training corpus is rather small. Our findings confirm this expectation, as the relative error reduction through morphological annotation for a training corpus of 9,600 words is 6.67%, while it is only 3.65% for a 240,000-word training corpus.

In our implementation, the stress flags and syllable flags we use to enforce the phonological constraints increase data sparseness. We found v2 (the implementation that uses the states without stress and syllable flags and enforces the constraints by eliminating invalid transitions, cf. section 3.1) to outperform the integrated version, v1, and more significantly in the case of more severe data sparseness. The only condition when we found v1 to perform better than v2 was with a large data set and additional data sparseness reduction through morphological annotation, as in section 4 (see Table 5).

WER: designs	v1		v2	
data set size	240k	9.6k	240k	9.6k
no morph.	14.4%	32.3%	**13.7%**	25.5%
CELEX	**12.5%**	29%	13.2%	23.8%

Table 5: The interactions of constraints in training and different levels of data sparseness.

g2p Conversion Algorithms

The benefit of using morphological preprocessing is also affected by the algorithm that is used for g2p conversion. Therefore, we also evaluated the relative improvement of morphological annotation when using a decision tree for g2p conversion.

Decision trees were one of the first data-based approaches to g2p and are still widely used (Kienappel and Kneser, 2001; Black et al., 1998). The tree's efficiency and ability for generalization largely depends on pruning and the choice of possible questions. In our implementation, the decision tree can ask about letters within a context window of five back and five ahead, about five phonemes back and groups of letters (e.g. consonants vs. vowels).

Both the decision tree and the joint n-gram model convert graphemes to phonemes, insert syllable boundaries and assign word stress in a single step (marked as "WER-ss" in Table 6. The implementation of the joint n-gram model incorporates the phonological constraints described in section 3 ("WER-ss+"). Our main finding is that the joint n-gram model profits less from morphological annotation. Without the constraints, the performance

difference is smaller: the joint n-gram model then achieves a word error rate of 21.5% on the no-morphology-condition.

In very recent work, (Demberg, 2007) developed an unsupervised algorithm (f-meas: 68%; an extension of RePortS) whose segmentations improve g2p when using a the decision tree (PER: 3.45%).

	decision tree		joint n-gram	
	PER	WER-ss	PER	WER-ss$^+$
RePortS	3.83%	28.3%		15.1%
no morph.	3.63%	26.59%	2.52%	13.7%
ETI	2.8%	21.13%	2.53%	13.6%
CELEX	2.64%	21.64%	2.36%	13.2%

Table 6: The effect of morphological preprocessing on phoneme error rates (PER) and word error rates (WER) in grapheme-to-phoneme conversion.

Morphology for other Languages

We also investigated the effect of morphological information on g2p conversion and syllabification in English, using manually annotated morphological boundaries from CELEX and the automatic unsupervised RePortS system which achieves an F-score of about 77% for English. The cases where morphological information affects word pronunciation are relatively few in comparison to German, therefore the overall effect is rather weak and we did not even find improvements with perfect boundaries.

6 Conclusions

Our results confirm that the integration of phonological constraints 'one nucleus per syllable' and 'one main stress per word' can significantly boost accuracy for g2p conversion in German and English. We implemented the constraints using a joint n-gram model for g2p conversion, which is language-independent and well-suited to the g2p task.

We systematically evaluated the benefit to be gained from morphological preprocessing on g2p conversion and syllabification. We found that morphological segmentations from rule-based systems led to some improvement. But the magnitude of the accuracy improvement strongly depends on the g2p algorithm and on training set size. State-of-the-art unsupervised morphological systems do not yet yield sufficiently good segmentations to help the task, if a good conversion algorithm is used: Low quality segmentation even led to higher error rates.

Redundancy Ratio: An Invariant Property of the Consonant Inventories of the World's Languages

Department of Computer Science and Engineering,
Indian Institute of Technology, Kharagpur
{animeshm,monojit,anupam,niloy}@cse.iitkgp.ernet.in

Abstract

In this paper, we put forward an information theoretic definition of the *redundancy* that is observed across the sound inventories of the world's languages. Through rigorous statistical analysis, we find that this redundancy is an invariant property of the consonant inventories. The statistical analysis further unfolds that the vowel inventories do not exhibit any such property, which in turn points to the fact that the organizing principles of the vowel and the consonant inventories are quite different in nature.

1 Introduction

Redundancy is a strikingly common phenomenon that is observed across many natural systems. This redundancy is present mainly to reduce the risk of the complete loss of information that might occur due to accidental errors (Krakauer and Plotkin, 2002). Moreover, redundancy is found in every level of granularity of a system. For instance, in biological systems we find redundancy in the codons (Lesk, 2002), in the genes (Woollard, 2005) and as well in the proteins (Gatlin, 1974). A linguistic system is also not an exception. There is for example, a number of words with the same meaning (synonyms) in almost every language of the world. Similarly, the basic unit of language, the human speech sounds or the phonemes, is also expected to exhibit some sort of a redundancy in the information that it encodes.

In this work, we attempt to mathematically capture the redundancy observed across the sound (more specifically the consonant) inventories of the world's languages. For this purpose, we present an information theoretic definition of redundancy, which is calculated based on the set of *features*[1] (Trubetzkoy, 1931) that are used to express the consonants. An interesting observation is that this quantitative feature-based measure of redundancy is *almost* an invariance over the consonant inventories of the world's languages. The observation is important since it can shed enough light on the organization of the consonant inventories, which unlike the vowel inventories, lack a complete and holistic explanation. The invariance of our measure implies that every inventory tries to be similar in terms of the measure, which leads us to argue that redundancy plays a very important role in shaping the structure of the consonant inventories. In order to validate this argument we determine the possibility of observing such an invariance if the consonant inventories had evolved by random chance. We find that the redundancy observed across the randomly generated inventories is substantially different from their real counterparts, which leads us to conclude that the invariance is not just "by-chance" and the measure that we define, indeed, largely governs the organizing principles of the consonant inventories.

[1] In phonology, features are the elements, which distinguish one phoneme from another. The features that distinguish the consonants can be broadly categorized into three different classes namely the *manner of articulation*, the *place of articulation* and *phonation*. Manner of articulation specifies how the flow of air takes place in the vocal tract during articulation of a consonant, whereas place of articulation specifies the active speech organ and also the place where it acts. Phonation describes the activity regarding the vibration of the vocal cords during the articulation of a consonant.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 104–111,
Prague, Czech Republic, June 2007.

Interestingly, this redundancy, when measured for the vowel inventories, does not exhibit any similar invariance. This immediately reveals that the principles that govern the formation of these two types of inventories are quite different in nature. Such an observation is significant since whether or not these principles are similar/different for the two inventories had been a question giving rise to perennial debate among the past researchers (Trubetzkoy, 1969/1939; Lindblom and Maddieson, 1988; Boersma, 1998; Clements, 2004). A possible reason for the observed dichotomy in the behavior of the vowel and consonant inventories with respect to redundancy can be as follows: while the organization of the vowel inventories is known to be governed by a single force - the *maximal perceptual contrast* (Jakobson, 1941; Liljencrants and Lindblom, 1972; de Boer, 2000)), consonant inventories are shaped by a complex interplay of several forces (Mukherjee et al., 2006). The invariance of redundancy, perhaps, reflects some sort of an equilibrium that arises from the interaction of these divergent forces.

The rest of the paper is structured as follows. In section 2 we briefly discuss the earlier works in connection to the sound inventories and then systematically build up the quantitative definition of redundancy from the linguistic theories that are already available in the literature. Section 3 details out the data source necessary for the experiments, describes the baseline for the experiments, reports the experiments performed, and presents the results obtained each time comparing the same with the baseline results. Finally we conclude in section 4 by summarizing our contributions, pointing out some of the implications of the current work and indicating the possible future directions.

2 Formulation of Redundancy

Linguistic research has documented a wide range of regularities across the sound systems of the world's languages. It has been postulated earlier by functional phonologists that such regularities are the consequences of certain general principles like *maximal perceptual contrast* (Liljencrants and Lindblom, 1972), which is desirable between the phonemes of a language for proper perception of each individual phoneme in a noisy environment, *ease of articulation* (Lindblom and Maddieson, 1988; de Boer, 2000), which requires that the sound systems of all languages are formed of certain universal (and highly frequent) sounds, and *ease of learnability* (de Boer, 2000), which is necessary for a speaker to learn the sounds of a language with minimum effort. In fact, the organization of the vowel inventories (especially those with a smaller size) across languages has been satisfactorily explained in terms of the single principle of maximal perceptual contrast (Jakobson, 1941; Liljencrants and Lindblom, 1972; de Boer, 2000).

On the other hand, in spite of several attempts (Lindblom and Maddieson, 1988; Boersma, 1998; Clements, 2004) the organization of the consonant inventories lacks a satisfactory explanation. However, one of the earliest observations about the consonant inventories has been that consonants tend to occur in pairs that exhibit strong correlation in terms of their features (Trubetzkoy, 1931). In order to explain these trends, *feature economy* was proposed as the organizing principle of the consonant inventories (Martinet, 1955). According to this principle, languages tend to maximize the combinatorial possibilities of a few distinctive features to generate a large number of consonants. Stated differently, a given consonant will have a higher than expected chance of occurrence in inventories in which all of its features have distinctively occurred in other consonants. The idea is illustrated, with an example, through Table 1. Various attempts have been made in the past to explain the aforementioned trends through linguistic insights (Boersma, 1998; Clements, 2004) mainly establishing their statistical significance. On the contrary, there has been very little work pertaining to the quantification of feature economy except in (Clements, 2004), where the author defines *economy index*, which is the ratio of the size of an inventory to the number of features that characterizes the inventory. However, this definition does not take into account the complexity that is involved in communicating the information about the inventory in terms of its constituent features.

Inspired by the aforementioned studies and the concepts of information theory (Shannon and Weaver, 1949) we try to quantitatively capture the amount of redundancy found across the consonant

plosive	voiced	voiceless
dental	/d/	/t/
bilabial	/b/	/p/

Table 1: The table shows four plosives. If a language has in its consonant inventory any three of the four phonemes listed in this table, then there is a higher than average chance that it will also have the fourth phoneme of the table in its inventory.

inventories in terms of their constituent features. Let us assume that we want to communicate the information about an inventory of size N over a transmission channel. Ideally, one should require $\log N$ bits to do the same (where the logarithm is with respect to base 2). However, since every natural system is to some extent redundant and languages are no exceptions, the number of bits actually used to encode the information is more than $\log N$. If we assume that the features are boolean in nature, then we can compute the number of bits used by a language to encode the information about its inventory by measuring the *entropy* as follows. For an inventory of size N let there be p_f consonants for which a particular feature f (where f is assumed to be boolean in nature) is present and q_f other consonants for which the same is absent. Thus the probability that a particular consonant chosen uniformly at random from this inventory has the feature f is $\frac{p_f}{N}$ and the probability that the consonant lacks the feature f is $\frac{q_f}{N}$ (=1–$\frac{p_f}{N}$). If F is the set of all features present in the consonants forming the inventory, then *feature entropy* F_E can be expressed as

$$F_E = \sum_{f \in F} (-\frac{p_f}{N} \log \frac{p_f}{N} - \frac{q_f}{N} \log \frac{q_f}{N}) \qquad (1)$$

F_E is therefore the measure of the minimum number of bits that is required to communicate the information about the entire inventory through the transmission channel. The lower the value of F_E the better it is in terms of the information transmission overhead. In order to capture the redundancy involved in the encoding we define the term *redundancy ratio* as follows,

$$RR = \frac{F_E}{\log N} \qquad (2)$$

which expresses the excess number of bits that is used by the constituent consonants of the inventory in terms of a ratio. The process of computing the value of RR for a hypothetical consonant inventory is illustrated in Figure 1.

I = {/b/, /d/, /g/} N = 3

F = {voiced, dental, bilabial, velar, plosive}

F	voiced	dental	bilabial	velar	plosive
/b/	1	0	1	0	1
/d/	1	1	0	0	1
/g/	1	0	0	1	1
p_f/N	1	0.33	0.33	0.33	1
q_f/N	0	0.67	0.67	0.67	0

F_E = 2.75

RR = F_E / log(N) = 1.74

Figure 1: The process of computing RR for a hypothetical inventory.

In the following section, we present the experimental setup and also report the experiments which we perform based on the above definition of redundancy. We subsequently show that redundancy ratio is invariant across the consonant inventories whereas the same is not true in the case of the vowel inventories.

3 Experiments and Results

In this section we discuss the data source necessary for the experiments, describe the baseline for the experiments, report the experiments performed, and present the results obtained each time comparing the same with the baseline results.

3.1 Data Source

Many typological studies (Ladefoged and Maddieson, 1996; Lindblom and Maddieson, 1988) of segmental inventories have been carried out in past on the UCLA Phonological Segment Inventory Database (UPSID) (Maddieson, 1984). UPSID gathers phonological systems of languages from all over the world, sampling more or less uniformly all the linguistic families. In this work we have used UPSID comprising of 317 languages and 541 consonants found across them, for our experiments.

3.2 Redundancy Ratio across the Consonant Inventories

In this section we measure the redundancy ratio (described earlier) of the consonant inventories of the languages recorded in UPSID. Figure 2 shows the scatter-plot of the redundancy ratio RR of each of the consonant inventories (y-axis) versus the inventory size (x-axis). The plot immediately reveals that the measure (i.e., RR) is almost invariant across the consonant inventories with respect to the inventory size. In fact, we can fit the scatter-plot with a straight line (by means of least square regression), which as depicted in Figure 2, has a negligible slope (m = – 0.018) and this in turn further confirms the above fact that RR is an invariant property of the consonant inventories with regard to their size. It is important to mention here that in this experiment we report the redundancy ratio of all the inventories of size less than or equal to 40. We neglect the inventories of the size greater than 40 since they are extremely rare (less than 0.5% of the languages of UPSID), and therefore, cannot provide us with statistically meaningful estimates. The same convention has been followed in all the subsequent experiments. Nevertheless, we have also computed the values of RR for larger inventories, whereby we have found that for an inventory size ≤ 60 the results are similar to those reported here. It is interesting to note that the largest of the consonant inventories Ga (size = 173) has an $RR = 1.9$, which is lower than all the other inventories.

The aforementioned claim that RR is an invariant across consonant inventories can be validated by performing a standard test of hypothesis. For this purpose, we randomly construct language inventories, as discussed later, and formulate a null hypothesis based on them.

Null Hypothesis: The invariance in the distribution of RRs observed across the real consonant inventories is also prevalent across the randomly generated inventories.

Having formulated the null hypothesis we now systematically attempt to reject the same with a very high probability. For this purpose we first construct random inventories and then perform a two sample t-test (Cohen, 1995) comparing the RRs of the real and the random inventories. The results show that

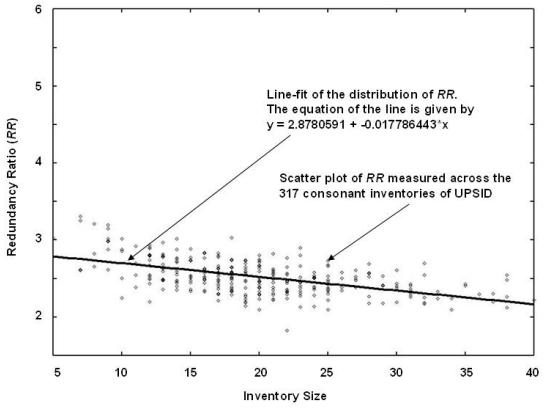

Figure 2: The scatter-plot of the redundancy ratio RR of each of the consonant inventories (y-axis) versus the inventory size (x-axis). The straight line-fit is also depicted by the bold line in the figure.

indeed the null hypothesis can be rejected with a very high probability. We proceed as follows.

3.2.1 Construction of Random Inventories

We employ two different models to generate the random inventories. In the first model the inventories are filled uniformly at random from the pool of 541 consonants. In the second model we assume that the distribution of the occurrence of the consonants over languages is known *a priori*. Note that in both of these cases, the size of the random inventories is same as its real counterpart. The results show that the distribution of RRs obtained from the second model has a closer match with the real inventories than that of the first model. This indicates that the occurrence frequency to some extent governs the law of organization of the consonant inventories. The detail of each of the models follow.

Model I – Purely Random Model: In this model we assume that the distribution of the consonant inventory size is known *a priori*. For each language inventory L let the size recorded in UPSID be denoted by s_L. Let there be 317 bins corresponding to each consonant inventory L. A bin corresponding to an inventory L is packed with s_L consonants chosen uniformly at random (without repetition) from the pool of 541 available consonants. Thus the consonant inventories of the 317 languages corresponding to the bins are generated. The method is summarized

in Algorithm 1.

for *I = 1 to 317* **do**
  for *size = 1 to* s_L **do**
    Choose a consonant c uniformly at random (without repetition) from the pool of 541 available consonants;
    Pack the consonant c in the bin corresponding to the inventory L;
  end
end

Algorithm 1: Algorithm to construct random inventories using Model I

Model II – Occurrence Frequency based Random Model: For each consonant c let the frequency of occurrence in UPSID be denoted by f_c. Let there be 317 bins each corresponding to a language in UPSID. f_c bins are then chosen uniformly at random and the consonant c is packed into these bins. Thus the consonant inventories of the 317 languages corresponding to the bins are generated. The entire idea is summarized in Algorithm 2.

for *each consonant c* **do**
  for *i = 1 to* f_c **do**
    Choose one of the 317 bins, corresponding to the languages in UPSID, uniformly at random;
    Pack the consonant c into the bin so chosen if it has not been already packed into this bin earlier;
  end
end

3.2.2 Results Obtained from the Random Models

In this section we enumerate the results obtained by computing the RRs of the randomly generated inventories using Model I and Model II respectively. We compare the results with those of the real inventories and in each case show that the null hypothesis can be rejected with a significantly high probability.

Parameters	Real Inv.	Random Inv.
Mean	2.51177	3.59331
SDV	0.209531	0.475072

Parameters	Values
t	12.15
DF	66
p	$\leq$ 9.289e-17

Table 2: The results of the t-test comparing the distribution of RRs for the real and the random inventories (obtained through Model I). SDV: standard deviation, t: t-value of the test, DF: degrees of freedom, p: residual uncertainty.

Results from Model I: Figure 3 illustrates, for all the inventories obtained from 100 different simulation runs of Algorithm 1, the average redundancy ratio exhibited by the inventories of a particular size (y-axis), versus the inventory size (x-axis). The term "redundancy ratio exhibited by the inventories of a particular size" actually means the following. Let there be n consonant inventories of a particular inventory-size k. The average redundancy ratio of the inventories of size k is therefore given by $\frac{1}{n}\sum_{i=1}^{n} RR_i$ where RR_i signifies the redundancy ratio of the i^{th} inventory of size k. In Figure 3 we also present the same curve for the real consonant inventories appearing in UPSID. In these curves we further depict the error bars spanning the entire range of values starting from the minimum RR to the maximum RR for a given inventory size. The curves show that in case of real inventories the error bars span a very small range as compared to that of the randomly constructed ones. Moreover, the slopes of the curves are also significantly different. In order to test whether this difference is significant, we perform a t-test comparing the distribution of the values of RR that gives rise to such curves for the real and the random inventories. The results of the test are noted in Table 2. These statistics clearly shows that the distribution of RRs for the real and the random inventories are significantly different in nature. Stated differently, we can reject the null hypothesis with (100 - 9.29e-15)% confidence.

Results from Model II: Figure 4 illustrates, for all the inventories obtained from 100 different simu-

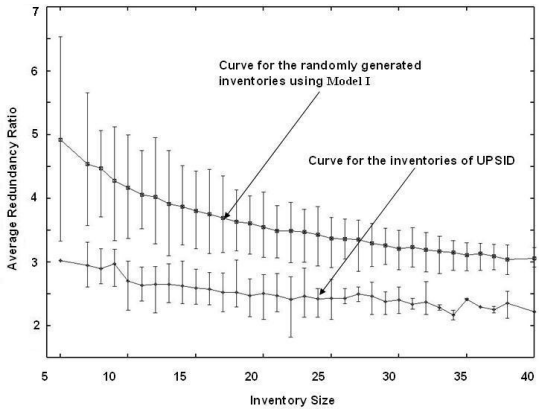

Figure 3: Curves showing the average redundancy ratio exhibited by the real as well as the random inventories (obtained through Model I) of a particular size (y-axis), versus the inventory size (x-axis).

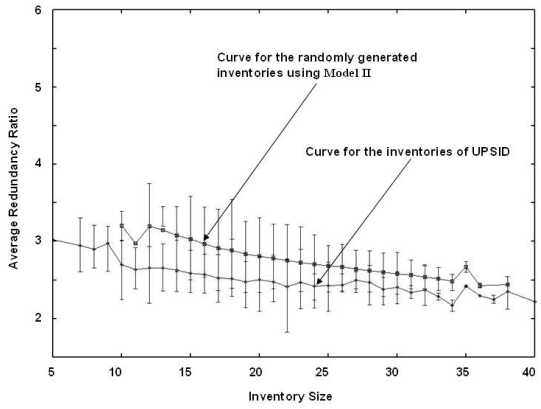

Figure 4: Curves showing the average redundancy ratio exhibited by the real as well as the random inventories (obtained through Model II) of a particular size (y-axis), versus the inventory size (x-axis).

lation runs of Algorithm 2, the average redundancy ratio exhibited by the inventories of a particular size (y-axis), versus the inventory size (x-axis). The figure shows the same curve for the real consonant inventories also. For each of the curve, the error bars span the entire range of values starting from the minimum RR to the maximum RR for a given inventory size. It is quite evident from the figure that the error bars for the curve representing the real inventories are smaller than those of the random ones. The nature of the two curves are also different though the difference is not as pronounced as in case of Model I. This is indicative of the fact that it is not only the occurrence frequency that governs the organization of the consonant inventories and there is a more complex phenomenon that results in such an invariant property. In fact, in this case also, the t-test statistics comparing the distribution of RRs for the real and the random inventories, reported in Table 3, allows us to reject the null hypothesis with (100–2.55e–3)% confidence.

Parameters	Real Inv.	Random Inv.
Mean	2.51177	2.76679
SDV	0.209531	0.228017

Parameters	Values
t	4.583
DF	60
p	$\leq$ 2.552e-05

Table 3: The results of the t-test comparing the distribution of RRs for the real and the random inventories (obtained through Model II).

3.3 Comparison with Vowel Inventories

Until now we have been looking into the organizational aspects of the consonant inventories. In this section we show that this organization is largely different from that of the vowel inventories in the sense that there is no such invariance observed across the vowel inventories unlike that of consonants. For this reason we start by computing the RRs of all the vowel inventories appearing in UPSID. Figure 5 shows the scatter plot of the redundancy ratio of each of the vowel inventories (y-axis) versus the inventory size (x-axis). The plot clearly indicates that the measure (i.e., RR) is not invariant across the vowel inventories and in fact, the straight line that fits the distribution has a slope of –0.14, which is around 10 times higher than that of the consonant inventories.

Figure 6 illustrates the average redundancy ratio exhibited by the vowel and the consonant inventories of a particular size (y-axis), versus the inventory size (x-axis). The error bars indicating the variability of RR among the inventories of a fixed size also span a much larger range for the vowel inventories than for the consonant inventories.

The significance of the difference in the nature of the distribution of RRs for the vowel and the consonant inventories can be again estimated by performing a t-test. The null hypothesis in this case is as follows.

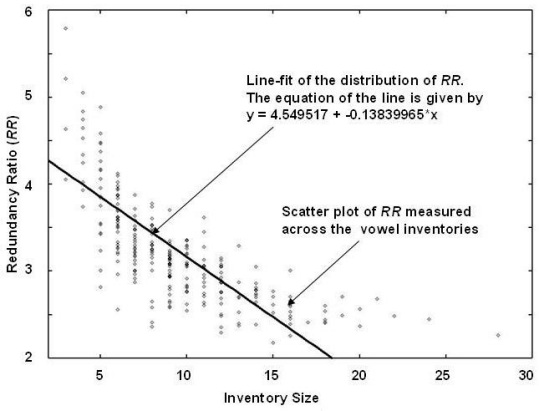

Figure 5: The scatter-plot of the redundancy ratio RR of each of the vowel inventories (y-axis) versus the inventory size (x-axis). The straight line-fit is depicted by the bold line in the figure.

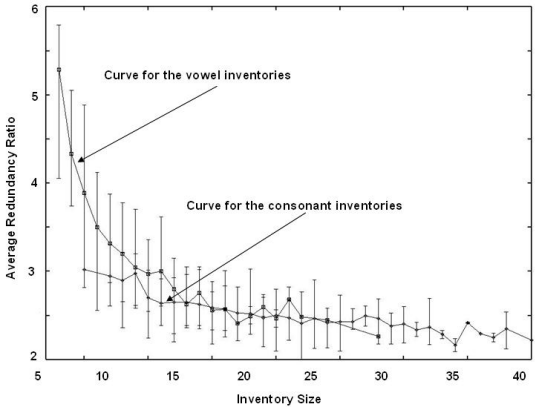

Figure 6: Curves showing the average redundancy ratio exhibited by the vowel as well as the consonant inventories of a particular size (y-axis), versus the inventory size (x-axis).

Null Hypothesis: The nature of the distribution of RRs for the vowel and the consonant inventories is same.

We can now perform the t-test to verify whether we can reject the above hypothesis. Table 4 presents the results of the test. The statistics immediately confirms that the null hypothesis can be rejected with 99.932% confidence.

Parameters	Consonant Inv.	Vowel Inv.
Mean	2.51177	2.98797
SDV	0.209531	0.726547

Parameters	Values
t	3.612
DF	54
p	≤ 0.000683

Table 4: The results of the t-test comparing the distribution of RRs for the consonant and the vowel inventories.

4 Conclusions, Discussion and Future Work

In this paper we have mathematically captured the redundancy observed across the sound inventories of the world's languages. We started by systematically defining the term redundancy ratio and measuring the value of the same for the inventories. Some of our important findings are,

1. Redundancy ratio is an invariant property of the consonant inventories with respect to the inventory size.

2. A more complex phenomenon than merely the occurrence frequency results in such an invariance.

3. Unlike the consonant inventories, the vowel inventories are not indicative of such an invariance.

Until now we have concentrated on establishing the invariance of the redundancy ratio across the consonant inventories rather than reasoning why it could have emerged. One possible way to answer this question is to look for the error correcting capability of the encoding scheme that nature had employed for characterization of the consonants. Ideally, if redundancy has to be invariant, then this capability should be almost constant. As a proof of concept we randomly select a consonant from inventories of different size and compute its hamming distance from the rest of the consonants in the inventory. Figure 7 shows for a randomly chosen consonant c from an inventory of size 10, 15, 20 and 30 respectively, the number of the consonants at a particular hamming distance from c (y-axis) versus the hamming distance (x-axis). The curve clearly indicates that majority of the consonants are at a hamming distance of 4 from c, which in turn implies that the encoding scheme has almost a fixed error correcting capability of 1 bit. This can be the precise reason behind the invariance of the redundancy ra-

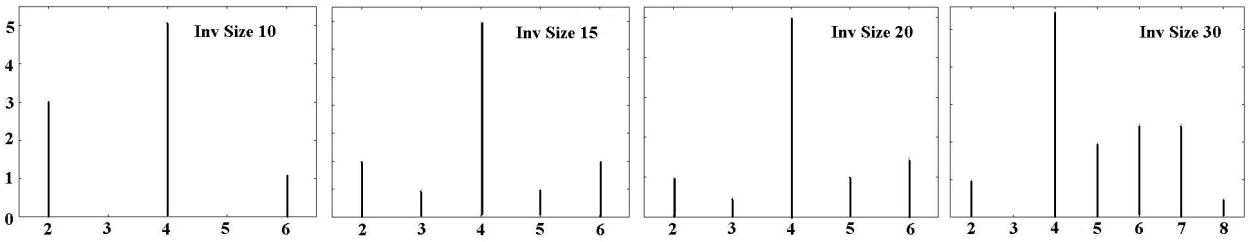

Figure 7: Histograms showing the the number of consonants at a particular hamming distance (y-axis), from a randomly chosen consonant c, versus the hamming distance (x-axis).

tio. Initial studies into the vowel inventories show that for a randomly chosen vowel, its hamming distance from the other vowels in the same inventory varies with the inventory size. In other words, the error correcting capability of a vowel inventory seems to be dependent on the size of the inventory.

We believe that these results are significant as well as insightful. Nevertheless, one should be aware of the fact that the formulation of RR heavily banks on the set of features that are used to represent the phonemes. Unfortunately, there is no consensus on the set of representative features, even though there are numerous suggestions available in the literature. However, the basic concept of RR and the process of analysis presented here is independent of the choice of the feature set. In the current study we have used the binary features provided in UPSID, which could be very well replaced by other representations, including multi-valued feature systems; we look forward to do the same as a part of our future work.

Multilingual Transliteration Using Feature based Phonetic Method

Su-Youn Yoon, Kyoung-Young Kim and Richard Sproat
University of Illinois at Urbana-Champaign

Abstract

In this paper we investigate named entity transliteration based on a phonetic scoring method. The phonetic method is computed using phonetic features and carefully designed pseudo features. The proposed method is tested with four languages – Arabic, Chinese, Hindi and Korean – and one source language – English, using comparable corpora. The proposed method is developed from the phonetic method originally proposed in Tao et al. (2006). In contrast to the phonetic method in Tao et al. (2006) constructed on the basis of pure linguistic knowledge, the method in this study is trained using the Winnow machine learning algorithm. There is salient improvement in Hindi and Arabic compared to the previous study. Moreover, we demonstrate that the method can also achieve comparable results, when it is trained on language data different from the target language. The method can be applied both with minimal data, and without target language data for various languages.

1 Introduction.

In this paper, we develop a multi-lingual transliteration system for named entities. Named entity transliteration is the process of producing, for a name in a source language, a set of one or more transliteration candidates in a target language. The correct transliteration of named entities is crucial, since they are frequent and important key words in information retrieval. In addition, requests in retrieving relevant documents in multiple languages require the development of the multi-lingual system.

The system is constructed using paired comparable texts. The comparable texts are about the same or related topics, but are not, in general, translations of each other. Using this data, the transliteration method aims to find transliteration correspondences in the paired languages. For example, if there were an English and Arabic newspaper on the same day, each of the newspapers would contain articles about the same important international events. From these comparable articles across the paired languages, the same named entities are expected to be found. Thus, from the named entities in an English newspaper, the method would find transliteration correspondences in comparable texts in other languages.

The multi-lingual transliteration system entails solving several problems which are very challenging. First, it should show stable performance for many unrelated languages. The transliteration will be influenced by the difference in the phonological systems of the language pairs, and the process of transliteration differs according to the languages involved. For example, in Arabic texts, short vowels are rarely written while long vowels are written. When transliterating English names, the vowels are disappeared or written as long vowels. For example *London* is transliterated as *lndn* لنـــدن, and both vowels are not represented in the transliteration. However, *Washington* is often transliterated as *wSnjTwn* واشـــــــنطون , and the final vowel is realized with long vowel. Transliterations in Chinese are very different from the original English pronunciation due to the

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 112–119,
Prague, Czech Republic, June 2007.

limited syllable structure and phoneme inventory of Chinese. For example, Chinese does not allow consonant clusters or coda consonants except [n,ŋ], and this results in deletion, substitution of consonants or insertion of vowels. Thus while a syllable initial /d/ may surface as in *Baghdad* 巴格达 *ba-ge-da*, note that the syllable final /d/ is not represented. Multi-lingual transliteration system should solve these language dependent characteristics.

One of the most important concerns in a multilingual transliteration system is its applicability given a small amount of training data, or even no training data: for arbitrary language pairs, one cannot in general assume resources such as name dictionaries. Indeed, for some rarely spoken languages, it is practically impossible to find enough training data. Therefore, the proposed method aims to obtain comparable performance with little training data.

2 Previous Work

Previous work — e.g. (Knight and Graehl, 1998; Meng et al., 2001; Al-Onaizan and Knight, 2002; Gao et al., 2004) — has mostly assumed that one has a training lexicon of transliteration pairs, from which one can learn a model, often a source-channel or MaxEnt-based model.

Comparable corpora have been studied extensively in the literature, but transliteration in the context of comparable corpora has not been well addressed. In our work, we adopt the method proposed in (Tao et al., 2006) and apply it to the problem of transliteration.

Measuring phonetic similarity between words has been studied for a long time. In many studies, two strings are aligned using a string alignment algorithm, and an edit distance (the sum of the cost for each edit operation), is used as the phonetic distance between them. The resulting distance depends on the costs of the edit operation. There are several approaches that use distinctive features to determine the costs of the edit operation. Gildea and Jurafsky (1996) counted the number of features whose values are different, and used them as a substitution cost. However, this approach has a crucial limitation: the cost does not consider the importance of the features. Nerbonne and Heeringa (1997) assigned a weight for each feature based on entropy and information gain, but the results were even less accurate than the method without weight.

3 Phonetic transliteration method

In this paper, the phonetic transliteration is performed using the following steps:

1) **Generation of the pronunciation for English words and target words**:

a. Pronunciations for English words are obtained using the Festival text-to-speech system (Taylor et al., 1998).

b. Target words are automatically converted into their phonemic level transcriptions by various language-dependent means. In the case of Mandarin Chinese, this is based on the standard Pinyin transliteration system. Arabic words are converted based on orthography, and the resulting transcriptions are reasonably correct except for the fact that short vowels were not represented. Similarly, the pronunciation of Hindi and Korean can be well-approximated based on the standard orthographic representation. All pronunciations are based on the WorldBet transliteration system (Hieronymus, 1995), an ascii-only version of the IPA.

2) **Training a linear classifier using the Winnow algorithm**:

A linear classifier is trained using the training data which is composed of transliteration pairs and non-transliteration pairs. Transliteration pairs are extracted from the transliteration dictionary, while non-transliteration pairs are composed of an English named entity and a random word from the target language newspaper.

a. For all the training data, the pairs of pronunciations are aligned using standard string alignment algorithm based on Kruskal (1999). The substitution/insertion/deletion cost for the string alignment algorithm is based on the baseline cost from (Tao et al, 2006).

b. All phonemes in the pronunciations are decomposed into their features. The features used in this study will be explained in detail in part 3.1.

c. For every phoneme pair (p_1, p_2) in the aligned pronunciations, a feature x_i has a '+1' value or a '–1' value:

$$x_i = \begin{cases} +1 & \text{when } p_1 \text{ and } p_2 \text{ have the same values for feature } x_i \\ -1 & \text{otherwise} \end{cases}$$

d. A linear classifier is trained using the Winnow algorithm from the SNoW toolkit (Carlson et al., 1999).

3) **Scoring English-target word pair:**

a. For a given English word, the score between it and a target word is computed using the linear classifier.

b. The score ranges from 0 to any positive number, and the candidate with the highest score is selected as the transliteration of the given English name.

3.1 Feature set

Halle and Clements (1983)'s distinctive features are used in order to model the substitution/ insertion/deletion costs for the string-alignment algorithm and linear classifier. A distinctive feature is a feature that describes the phonetic characteristics of phonetic segments.

However, distinctive features alone are not enough to model the frequent sound change patterns that occur when words are adapted across languages. For example, stop and fricative consonants such as /p, t, k, b, d, g, s, z/ are frequently deleted when they appear in the coda position. This tendency is extremely salient when the target languages do not allow coda consonants or consonant clusters. For example, since Chinese only allows /n, ŋ/ in coda position, stop consonants in the coda position are frequently lost; *Stanford* is transliterated as *sitanfu*, with the final /d/ lost. Since traditional distinctive features do not consider the position in the syllable, this pattern cannot be captured by distinctive features alone. To capture these sound change patterns, additional features such as "deletion of stop/fricative consonant in the coda position" must be considered.

Based on the pronunciation error data of learners of English as a second language as reported in (Swan and Smith, 2002), we propose the use of what we will term *pseudofeatures.* The pseudo features in this study are same as in Tao et al. (2006). Swan & Smith (2002)'s study covers 25 languages including Asian languages such as Thai, Korean, Chinese and Japanese, European languages such as German, Italian, French and Polish, and Middle East languages such as Arabic and Farsi. The substitution/insertion/deletion errors of phonemes were collected from this data. The following types of errors frequently occur in second language learners' speech production.

(1) **Substitution**: If the learner's first language does not have a particular phoneme found in English, it is substituted by the most similar phoneme in their first language.

(2) **Insertion**: If the learner's first language does not have a particular consonant cluster in English, a vowel is inserted.

(3) **Deletion**: If the learner's first language does not have a particular consonant cluster in English, one consonant in the consonant cluster is deleted.

The same substitution/deletion/insertion patterns in a second language learner's errors also appear in the transliteration of foreign names. The deletion of the stop consonant which appears in English-Chinese transliterations occurs frequently in the English pronunciation spoken by Chinese speakers. Therefore, the error patterns in second language learners' can be used in transliteration.

Based on (1) ~ (3), 21 pseudo features were designed. All features have binary values. Using these 21 pseudo features and 20 distinctive features, a linear classifier is trained. Some examples of pseudo features are presented in Table 1.

Pseudo-Feature	Description	Example
Consonant-coda	Substitution of consonant feature in coda position	
Sonorant-coda	Substitution of sonorant feature in coda position	Substitution between [ŋ] and [g] in coda position in Arabic
Labial-coda	Substitution of labial feature in coda position	Substitution between [m] and [n] in coda position in Chinese
j-exception	Substitution of [j] and [dʒ]	Spanish/Catalan and Festival error
w-exception	Substitution of [v] and [w]	Chinese/Farsi and Festival error

Table 1. Examples of pseudo features

3.2 Scoring the English-target word pair

A linear classifier is trained using the Winnow algorithm from the SNoW toolkit.

The Winnow algorithm is one of the update rules for linear classifier. A linear classifier is an algorithm to find a linear function that best separates the data. For the set of features X and set of weights W, the linear classifier is defined as [1] (Mitchell, T., 1997)

$$X = \{x_1, x_2, \ldots x_n\}$$
$$W = \{w_1, w_2, \ldots w_n\} \qquad [1]$$
$$f(x) = \begin{cases} 1 \text{ if } w_0 + w_1x_1 + w_2x_2 + \ldots + w_nx_n > 0 \\ -1 \text{ otherwise} \end{cases}$$

The linear function assigns label +1 when the paired target language word is the transliteration of given English word, while it assigns label –1 when it is not a transliteration of given English word.

The score of an English word and target word pair is computed using equation [2] which is part of the definition of *f(x)* in equation [1].

$$w_0 + \sum_{i=1}^{n} w_i x_i \qquad [2]$$

The output of equation [2] is termed *the target node activation*. If this value is high, class 1 is more activated, and the pair is more likely to be a transliteration pair. To illustrate, let us assume there are two candidates in target language (t_1 and t_2) for an English word e. If the score of (e, t_1) is higher than the score of (e, t_2), the pair (e, t_1) has stronger activation than (e, t_2). It means that t_1 scores higher as the transliteration of e than t_2. Therefore, the candidate with the highest score (in this case t_1) is selected as the transliteration of the given English name.

4 Experiment and Results

The linear function was trained for each language, separately. 500 transliteration pairs were randomly selected from each transliteration dictionary, and used as positive examples in the training procedure. This is quite small compared to previous approaches such as Knight and Graehl (1998) or Gao et al. (2004). In addition, 1500 words were randomly selected from the newspaper in the target languages, and paired with English words in the positive examples. A total of 750,000 pairs (500 English words × 1500 target words) were generated, and used as negative examples in the training procedure.

Table 2 presents the source of training data for each language.

	Transliteration pair	Target word
Arabic	New Mexico State University	Xinhua Arabic newswire
Chinese	Behavior Design Corporation	Xinhua Chinese newswire
Hindi	Naidunia Hindi newswire	Naidunia Hindi newswire
Korean	the National Institute of the Korean language	Chosun Korean newspaper

Table 2. Sources of the training data

The phonetic transliteration method was evaluated using comparable corpora, consisting of newspaper articles in English and the target languages—Arabic, Chinese, Hindi, and Korean– from the same day, or almost the same day. Using comparable corpora, the named-entities for persons and locations were extracted from the English text; in this paper, the English named-entities were extracted using the named-entity recognizer described in Li et al. (2004), based on the SNoW machine learning toolkit (Carlson et al., 1999).

The transliteration task was performed using the following steps:

1) English text was tagged using the named-entity recognizer. The 200 most frequent named entities were extracted from seven days' worth of the English newswire text. Among pronunciations of words generated by the Festival text-to speech system, 3% contained errors representing monophthongs instead of diphthongs or vice versa. 1.5% of all cases misrepresented single consonant, and 6% showed errors in the vowels. Overall, 10.5% of the tokens contained pronunciation errors which could trigger errors in transliteration.

2) To generate the Arabic and Hindi candidates, all words from the same seven days were extracted. In the case of Korean corpus, the collection of newspapers was from every five days, unlike the other three language corpora which were collected every day; therefore, candidates of Korean were

generated from one month of newspapers, since seven days of newspaper articles did not show a sufficient number of transliteration candidates. This caused the total number of candidates to be much bigger than for the other languages.

The words were stemmed all possible ways using simple hand-developed affix lists: for example, given a Hindi word c1c2c3, if both c3 and c2c3 are in the suffix and ending list, then this single word generated three possible candidates: c1, c1c2, and c1c2c3.

3) Segmenting Chinese sentences requires a dictionary or supervised segmenter. Since the goal is to use minimal knowledge or data from the target language, using supervised methods is inappropriate for our approach. Therefore, Chinese sentences were not segmented. Using the 495 characters that are frequently used for transliterating foreign names (Sproat et al., 1996), a sequence of three of more characters from the list was taken as a possible candidate for Chinese.

4) For the given 200 English named entities and target language candidate lists, all the possible pairings of English and target-language name were considered as possible transliteration pairs.

The number of candidates for each target language is presented in Table 3.

Language	The number of candidates
Arabic	12,466
Chinese	6,291
Hindi	10,169
Korean	42,757

Table 3. Number of candidates for each target language.

5) Node activation scores were calculated for each pair in the test data, and the candidates were ranked by their score. The candidate with the highest node activation score was selected as the transliteration of the given English name.

Some examples of English words and the top three ranking candidates among all of the potential target-language candidates were given in Tables 4, 5. Starred entries are correct.

English Word	Rank	Candidate	
		Script	Romanization
Arafat	*1 2 3	阿拉法特 拉法地奥 拉维奇	a-la-fa-te la-fa-di-ao la-wei-qi

Table 4. Examples of the top-3 candidates in the transliteration of English – Chinese

English Word	Rank	Candidate	
		Script	Romanization
Vietnam	*1	베트남	be-thu-nam
	2	베트남측	be-thu-nam-chug
	3	표준어와	pyo-jun-e-wa
Australia	*1	오스트레일리아	o-su-thu-ley-il-li-a
	2	웃돌아	us-tol-la
	3	오스트레일리아에서	o-su-thu-ley-il-li-a-ey-se

Table 5. Examples of the top-3 candidates in the transliteration of English-Korean

To evaluate the proposed transliteration methods quantitatively, the Mean Reciprocal Rank (MRR), a measure commonly used in information retrieval when there is precisely one correct answer (Kandor and Vorhees, 2000) was measured, following Tao and Zhai (2005).

Since the evaluation data obtained from the comparable corpus was small, the systems were evaluated using both held-out data from the transliteration dictionary and comparable corpus.

First, the results of the held-out data will be presented. For a given English name and target language candidates, all possible combinations were generated. Table 6 presents the size of held-out data, and Table 7 presents MRR of the held-out data.

	Number of English named entities	Number of Candidates in target language	Number of total pairs used in the evaluation
Arabic	500	1,500	750,000
Chinese	500	1,500	750,000
Hindi	100	1,500	150,000
Korean	100	1,500	150,000

Table 6. Size of the test data

	Baseline	Winnow	
		Total feature	distinctive feature only
Arabic	0.66	0.74	0.70
Chinese	0.74	0.74	0.72
Hindi	0.87	0.91	0.91
Korean	0.82	0.85	0.82

Table 7. MRRs of the phonetic transliteration

The baseline was computed using the phonetic transliteration method proposed in Tao et al. (2006). In contrast to the method in this study, the baseline system is purely based on linguistic knowledge. In the baseline system, the edit distance, which was the result of the string alignment algorithm, was used as the score of an English-target word pair. The performance of the edit distance was dependent on insertion/deletion/ substitution costs. These costs were determined based on the distinctive features and pseudo features, based on the pure linguistic knowledge without training data. As illustrated in Table 7, the phonetic transliteration method using features worked adequately for multilingual data, as phonetic features are universal, unlike the phonemes which are composed of them. Adopting phonetic features as the units for transliteration yielded the baseline performance.

In order to evaluate the effectiveness of pseudo features, the method was trained using two different feature sets: a total feature set and a distinctive feature-only set. For Arabic, Chinese and Korean, the MRR of the total feature set was higher than the MRR of the distinctive feature-only set. The improvement of the total set was 4% for Arabic, 2.6% for Chinese, 2.4% for Korean. There was no improvement of the total set in Hindi. In general, the pseudo features improved the accuracy of the transliteration.

For all languages, the MRR of the Winnow algorithm with the total feature set was higher than the baseline. There was 7% improvement for Arabic, 0.7% improvement for Chinese, 4% improvement for Hindi and 3% improvement for Korean.

We turn now to the results on comparable corpora. We attempted to create a complete set of answers for the 200 English names in our test set, but part of the English names did not seem to have any standard transliteration in the target language according to the native speaker's judgment. Accordingly, we removed these names from the evaluation set. Thus, the resulting list was less than 200 English names, as shown in the second column of Table 8; (Table 8 *All*). Furthermore, some correct transliterations were not found in our candidate list for the target languages, since the answer never occurred in the target news articles; (Table 8 *Missing*). Thus this results in a smaller number of candidates to evaluate. This smaller number is given in the fourth column of Table 8; (Table 8 *Core*).

Language	# All	# Missing	#Core
Arabic	192	121	71
Chinese	186	92	94
Hindi	144	83	61
Korean	195	114	81

Table 8. Number of evaluated English Name

MRRs were computed on the two sets represented by the count in column 2, and the smaller set represented by the count in column 4. We termed the former MRR "AllMRR" and the latter "CoreMRR". In Table 9, "CoreMRR" and "AllMRR" of the method were presented.

	Baseline		Winnow	
	All-MRR	Core MRR	All-MRR	Core MRR
Arabic	0.20	0.53	0.22	0.61
Chinese	0.25	0.49	0.25	0.50
Hindi	0.30	0.69	0.36	0.86
Korean	0.30	0.71	0.29	0.69

Table 9. MRRs of the phonetic transliteration

		test data			
		Arabic	Chinese	Hindi	Korean
training data	Arabic	**0.61**	0.50	0.86	0.63
	Chinese	0.59	**0.50**	0.80	0.66
	Hindi	0.59	0.54	**0.86**	0.67
	Korean	0.56	0.51	0.76	**0.69**

Table 10. MRRs for the phonetic transliteration 2

In both methods, CoreMRRs were higher than 0.49 for all languages. That is, if the answer is in the target language texts, then the method finds the correct answer within the top 2 words.

As with the previously discussed results, there were salient improvements in Arabic and Hindi when using the Winnow algorithm. The MRRs of the Winnow algorithm except Korean were higher than the baseline. There was 7% improvement for Arabic and 17% improvement for Hindi in CoreMRR. In contrast to the 3% improvement in held-out data, there was a 2% decrease in Korean: the MRRs of Korean from the Winnow algorithm were lower than baseline, possibly because of the limited size of the evaluation data. Similar to the results of held-out data, the improvement in Chinese was small (1%).

The MRRs of Hindi and the MRRs of Korean were higher than the MRRs of Arabic and Chinese. The lower MRRs of Arabic and Chinese may result from the phonological structures of the languages. In general, transliteration of English word into Arabic and Chinese is much more irregular than the transliteration into Hindi and Korean in terms of phonetics.

To test the applicability to languages for which training data is not available, we also investigated the use of models trained on language pairs *different from* the target language pair. Thus, for each test language pair, we evaluated the performance of models trained on each of the other language pairs. For example, three models were trained using Chinese, Hindi, and Korean, and they were tested with Arabic data. The CoreMRRs of this experiment were presented in Table 10. Note that the diagonal in this Table represents the within-language-pair training and testing scenario that we reported on above.

For Arabic, Hindi, and Korean, MRRs were indeed the highest when the methods were trained using data from the same language, as indicated by the boldface MRR scores on the diagonal. In general, however, the MRRs were not saliently lower across the board when using different language data than using same-language data in training and testing. For all languages, MRRs for the cross-language case were best when the methods were trained using Hindi. The differences between MRRs of the method trained from Hindi and MRRs of the method by homogeneous language data were 2% for Arabic and Korean. In the case of Chinese, MRRs of the method trained by Hindi was actually *better* than MRRs obtained by Chinese training data. Hindi has a large phoneme inventory compared to Korean, Arabic, and Chinese, so the relationship between English phonemes and Hindi phonemes is relatively regular, and only small number of language specific transliteration rules exist. That is, the language specific influences from Hindi are smaller than those from other languages. This characteristic of Hindi may result in the high MRRs for other languages. What these results imply is that named entity transliteration could be performed without training data for the target language with phonetic feature as a unit. This approach is especially valuable for languages for which training data is minimal or lacking.

5 Conclusion

In this paper, a phonetic method for multilingual transliteration was proposed. The method was based on string alignment, and linear classifiers trained using the Winnow algorithm. In order to learn both language-universal and language-specific transliteration characteristics, distinctive

features and pseudo features were used in training. The method can be trained using a small amount of training data, and the performance decreases only by a small degree when it is trained with a language different from the test data. Therefore, this method is extremely useful for underrepresented languages for which training data is difficult to find.

Abstract

Words of foreign origin are referred to as borrowed words or loanwords. A loanword is usually imported to Chinese by phonetic transliteration if a translation is not easily available. Semantic transliteration is seen as a good tradition in introducing foreign words to Chinese. Not only does it preserve how a word sounds in the source language, it also carries forward the word's original semantic attributes. This paper attempts to automate the semantic transliteration process for the first time. We conduct an inquiry into the feasibility of semantic transliteration and propose a probabilistic model for transliterating personal names in Latin script into Chinese. The results show that semantic transliteration substantially and consistently improves accuracy over phonetic transliteration in all the experiments.

1 Introduction

The study of Chinese transliteration dates back to the seventh century when Buddhist scriptures were translated into Chinese. The earliest bit of Chinese translation theory related to transliteration may be the principle of "Names should follow their bearers, while things should follow Chinese." In other words, names should be transliterated, while things should be translated according to their meanings. The same theory still holds today.

Transliteration has been practiced in several ways, including phonetic transliteration and phonetic-semantic transliteration. By phonetic transliteration, we mean rewriting a foreign word in native grapheme such that its original pronunciation is preserved. For example, *London* becomes 伦敦 /Lun-Dun/[1] which does not carry any clear connotations. Phonetic transliteration represents the common practice in transliteration. Phonetic-semantic transliteration, hereafter referred to as semantic transliteration for short, is an advanced translation technique that is considered as a recommended translation practice for centuries. It translates a foreign word by preserving both its original pronunciation and meaning. For example, Xu Guangqi[2] translated *geo-* in *geometry* into Chinese as 几何 /Ji-He/, which carries the pronunciation of *geo-* and expresses the meaning of "a science concerned with measuring the earth".

Many of the loanwords exist in today's Chinese through semantic transliteration, which has been well received (Hu and Xu, 2003; Hu, 2004) by the people because of many advantages. Here we just name a few. (1) It brings in not only the sound, but also the meaning that fills in the semantic blank left by phonetic transliteration. This also reminds people that it is a loanword and avoids misleading; (2) It provides etymological clues that make it easy to trace back to the root of the words. For example, a transliterated Japanese name will maintain its Japanese identity in its Chinese appearance; (3) It evokes desirable associations, for example, an English girl's name is transliterated with Chinese characters that have clear feminine association, thus maintaining the gender identity.

[1] Hereafter, Chinese characters are also denoted in *Pinyin* romanization system, for ease of reference.

[2] Xu Quangqi (1562–1633) translated The Original Manuscript of Geometry to Chinese jointly with Matteo Ricci.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 120–127,
Prague, Czech Republic, June 2007.

Unfortunately, most of the reported work in the area of machine transliteration has not ventured into semantic transliteration yet. The Latin-scripted personal names are always assumed to homogeneously follow the English phonic rules in automatic transliteration (Li et al., 2004). Therefore, the same transliteration model is applied to all the names indiscriminatively. This assumption degrades the performance of transliteration because each language has its own phonic rule and the Chinese characters to be adopted depend on the following semantic attributes of a foreign name.

(1) Language of origin: An English word is not necessarily of pure English origin. In English news reports about Asian happenings, an English personal name may have been originated from Chinese, Japanese or Korean. The language origin affects the phonic rules and the characters to be used in transliteration[3]. For example, a Japanese name *Matsumoto* should be transliterated as 松本 /Song-Ben/, instead of 马茨莫托 /Ma-Ci-Mo-Tuo/ as if it were an English name.

(2) Gender association: A given name typically implies a clear gender association in both the source and target languages. For example, the Chinese transliterations of *Alice* and *Alexandra* are 爱丽丝 /Ai-Li-Si/ and 亚历山大 /Ya-Li-Shan-Da/ respectively, showing clear feminine and masculine characteristics. Transliterating *Alice* as 埃里斯 /Ai-Li-Si/ is phonetically correct, but semantically inadequate due to an improper gender association.

(3) Surname and given name: The Chinese name system is the original pattern of names in Eastern Asia such as China, Korea and Vietnam, in which a limited number of characters[4] are used for surnames while those for given names are less restrictive. Even for English names, the character set for given name transliterations are different from that for surnames.

Here are two examples of semantic transliteration for personal names. *George Bush* and *Yamamoto Akiko* are transliterated into 乔治␣布什 and 山本 亚喜子 that arouse to the following associations: 乔治 /Qiao-Zhi/ - male given name, English origin; 布什 /Bu-Shi/ - surname, English origin; 山本 /Shan-Ben/ - surname, Japanese origin; 亚喜子 /Ya-Xi-Zi/ - female given name, Japanese origin.

In Section 2, we summarize the related work. In Section 3, we discuss the linguistic feasibility of semantic transliteration for personal names. Section 4 formulates a probabilistic model for semantic transliteration. Section 5 reports the experiments. Finally, we conclude in Section 6.

2 Related Work

In general, computational studies of transliteration fall into two categories: transliteration modeling and extraction of transliteration pairs. In transliteration modeling, transliteration rules are trained from a large, bilingual transliteration lexicon (Lin and Chen, 2002; Oh and Choi, 2005), with the objective of translating unknown words on the fly in an open, general domain. In the extraction of transliterations, data-driven methods are adopted to extract actual transliteration pairs from a corpus, in an effort to construct a large, up-to-date transliteration lexicon (Kuo et al., 2006; Sproat et al., 2006).

Phonetic transliteration can be considered as an extension to the traditional grapheme-to-phoneme (G2P) conversion (Galescu and Allen, 2001), which has been a much-researched topic in the field of speech processing. If we view the grapheme and phoneme as two symbolic representations of the same word in two different *languages*, then G2P is a transliteration task by itself. Although G2P and phonetic transliteration are common in many ways, transliteration has its unique challenges, especially as far as E-C transliteration is concerned. E-C transliteration is the conversion between English graphemes, phonetically associated English letters, and Chinese graphemes, characters which represent ideas or meanings. As a Chinese transliteration can arouse to certain connotations, the choice of Chinese characters becomes a topic of interest (Xu et al., 2006).

Semantic transliteration can be seen as a subtask of statistical machine translation (SMT) with

[3] In the literature (Knight and Graehl,1998; Qu et al., 2003), translating romanized Japanese or Chinese names to Chinese characters is also known as *back-transliteration*. For simplicity, we consider all conversions from Latin-scripted words to Chinese as transliteration in this paper.

[4] The 19 most common surnames cover 55.6% percent of the Chinese population (Ning and Ning 1995).

monotonic word ordering. By treating a letter/character as a word and a group of letters/characters as a phrase or token unit in SMT, one can easily apply the traditional SMT models, such as the IBM generative model (Brown et al., 1993) or the phrase-based translation model (Crego et al., 2005) to transliteration. In transliteration, we face similar issues as in SMT, such as lexical mapping and alignment. However, transliteration is also different from general SMT in many ways. Unlike SMT where we aim at optimizing the semantic transfer, semantic transliteration needs to maintain the phonetic equivalence as well.

In computational linguistic literature, much effort has been devoted to phonetic transliteration, such as English-Arabic, English-Chinese (Li et al., 2004), English-Japanese (Knight and Graehl, 1998) and English-Korean. In G2P studies, Font Llitjos and Black (2001) showed how knowledge of language of origin may improve conversion accuracy. Unfortunately semantic transliteration, which is considered as a good tradition in translation practice (Hu and Xu, 2003; Hu, 2004), has not been adequately addressed computationally in the literature. Some recent work (Li et al., 2006; Xu et al., 2006) has attempted to introduce preference into a probabilistic framework for selection of Chinese characters in phonetic transliteration. However, there is neither analytical result nor semantic-motivated transliteration solution being reported.

3 Feasibility of Semantic Transliteration

A Latin-scripted personal name is written in letters, which represent the pronunciations closely, whereas each Chinese character represents not only the syllables, but also the semantic associations. Thus, character rendering is a vital issue in transliteration. Good transliteration adequately projects semantic association while an inappropriate one may lead to undesirable interpretation.

Is semantic transliteration possible? Let's first conduct an inquiry into the feasibility of semantic transliteration on 3 bilingual name corpora, which are summarizied in Table 1 and will be used in experiments. E-C corpus is an augmented version of *Xinhua* English to Chinese dictionary –for English names (Xinhua, 1992). J-C corpus is a romanized Japanese to Chinese dictionary for Japanese names. The C-C corpus is a Chinese *Pinyin* to character dictionary for Chinese names. The entries are classified into surname, male and female given name categories. The E-C corpus also contains some entries without gender/surname labels, referred to as *unclassified*.

	E-C	J-C[5]	C-C[6]
Surname (S)	12,490	36,352	569,403
Given name (M)	3,201	35,767	345,044
Given name (F)	4,275	11,817	122,772
Unclassified	22,562	-	-
All	42,528	83,936	1,972,851

Table 1: Number of entries in 3 corpora

Phonetic transliteration has not been a problem as Chinese has over 400 unique syllables that are enough to approximately transcribe all syllables in other languages. Different Chinese characters may render into the same syllable and form a range of homonyms. Among the homonyms, those arousing positive meanings can be used for personal names. As discussed elsewhere (Sproat et al., 1996), out of several thousand common Chinese characters, a subset of a few hundred characters tends to be used overwhelmingly for transliterating English names to Chinese, e.g. only 731 Chinese characters are adopted in the E-C corpus. Although the character sets are shared across languages and genders, the statistics in Table 2 show that each semantic attribute is associated with some unique characters. In the C-C corpus, out of the total of 4,507 characters, only 776 of them are for surnames. It is interesting to find that female given names are represented by a smaller set of characters than that for male across 3 corpora.

	E-C	J-C	C-C	All
S	327	2,129	776	2,612 (19.2%)
M	504	1,399	4,340	4,995 (20.0%)
F	479	1,178	1,318	2,192 (26.3%)
All	731 (44.2%)	2,533 (46.2%)	4,507 (30.0%)	5,779 (53.6%)

Table 2: Chinese character usage in 3 corpora. The numbers in brackets indicate the percentage of characters that are shared by at least 2 corpora.

Note that the overlap of Chinese characters usage across genders is higher than that across languages. For instance, there is a 44.2% overlap

[5] http://www.cjk.org

[6] http://technology.chtsai.org/namelist

across gender for the transcribed English names; but only 19.2% overlap across languages for the surnames.

In summary, the semantic attributes of personal names are characterized by the choice of characters, and therefore their *n*-gram statistics as well. If the attributes are known in advance, then the semantic transliteration is absolutely feasible. We may obtain the semantic attributes from the context through trigger words. For instance, from "Mr *Tony Blair*", we realize "*Tony*" is a male given name while "*Blair*" is a surname; from "Japanese Prime Minister *Koizumi*", we resolve that "*Koizumi*" is a Japanese surname. In the case where contextual trigger words are not available, we study detecting the semantic attributes from the personal names themselves in the next section.

4 Formulation of Transliteration Model

Let *S* and *T* denote the name written in the source and target writing systems respectively. Within a probabilistic framework, a transliteration system produces the optimum target name, T^*, which yields the highest posterior probability given the source name, *S*, *i.e.*

$$T^* = \arg\max_{T \in \mathcal{T}_S} P(T \mid S) \tag{1}$$

where $\mathcal{T}_S$ is the set of all possible transliterations for the source name, *S*. The alignment between *S* and *T* is assumed implicit in the above formulation. In a standard phonetic transliteration system, $P(T \mid S)$, the posterior probability of the hypothesized transliteration, *T*, given the source name, *S*, is directly modeled without considering any form of semantic information. On the other hand, semantic transliteration described in this paper incorporates language of origin and gender information to capture the semantic structure. To do so, $P(T \mid S)$ is rewritten as

$$P(T \mid S) = \sum_{L \in \mathcal{L}, G \in \mathcal{G}} P(T, L, G \mid S) \tag{2}$$

$$= \sum_{L \in \mathcal{L}, G \in \mathcal{G}} P(T \mid S, L, G) P(L, G \mid S) \tag{3}$$

where $P(T \mid S, L, G)$ is the transliteration probability from source *S* to target *T*, given the language of origin (*L*) and gender (*G*) labels. $\mathcal{L}$ and $\mathcal{G}$ denote the sets of languages and genders respectively. $P(L, G \mid S)$ is the probability of the language and the gender given the source, *S*.

Given the alignment between *S* and *T*, the transliteration probability given *L* and *G* may be written as

$$P(T \mid S, L, G) = \prod_{i=1}^{I} P(t_i \mid T_1^{i-1}, S_1^i) \tag{4}$$

$$\approx \prod_{i=1}^{I} P(t_i \mid t_{i-1}, s_{i-1}, s_i) \tag{5}$$

where s_i and t_i are the i^{th} token of *S* and *T* respectively and *I* is the total number of tokens in both *S* and *T*. S_j^k and T_j^k represent the sequence of tokens $(s_j, s_{j+1}, \ldots, s_k)$ and $(t_j, t_{j+1}, \ldots, t_k)$ respectively. Eq. (4) is in fact the *n*-gram likelihood of the token pair $\langle t_i, s_i \rangle$ sequence and Eq. (5) approximates this probability using a bigram language model. This model is conceptually similar to the joint source-channel model (Li et al., 2004) where the target token t_i depends on not only its source token s_i but also the history t_{i-1} and s_{i-1}. Each character in the target name forms a token. To obtain the source tokens, the source and target names in the training data are aligned using the EM algorithm. This yields a set of possible source tokens and a mapping between the source and target tokens. During testing, each source name is first segmented into all possible token sequences given the token set. These source token sequences are mapped to the target sequences to yield an *N*-best list of transliteration candidates. Each candidate is scored using an *n*-gram language model given by Eqs. (4) or (5).

As in Eq. (3), the transliteration also greatly depends on the prior knowledge, $P(L, G \mid S)$. When no prior knowledge is available, a uniform probability distribution is assumed. By expressing $P(L, G \mid S)$ in the following form,

$$P(L, G \mid S) = P(G \mid L, S) P(L \mid S) \tag{6}$$

prior knowledge about language and gender may be incorporated. For example, if the language of *S* is known as L_S, we have

$$P(L \mid S) = \begin{cases} 1 & L = L_S \\ 0 & L \neq L_S \end{cases} \tag{7}$$

Similarly, if the gender information for *S* is known as G_S, then,

$$P(G \mid L,S) = \begin{cases} 1 & G = G_S \\ 0 & G \neq G_S \end{cases} \quad (8)$$

Note that personal names have clear semantic associations. In the case where the semantic attribute information is not available, we propose learning semantic information from the names themselves. Using Bayes' theorem, we have

$$P(L,G \mid S) = \frac{P(S \mid L,G)P(L,G)}{P(S)} \quad (9)$$

$P(S \mid L,G)$ can be modeled using an *n*-gram language model for the letter sequence of all the Latin-scripted names in the training set. The prior probability, $P(L,G)$, is typically uniform. $P(S)$ does not depend on *L* and *G*, thus can be omitted.

Incorporating $P(L,G \mid S)$ into Eq. (3) can be viewed as performing a soft decision of the language and gender semantic attributes. By contrast, hard decision may also be performed based on maximum likelihood approach:

$$\overline{L}_S = \arg\max_{L \in \mathcal{L}} P(S \mid L) \quad (10)$$

$$\overline{G}_S = \arg\max_{G \in \mathcal{G}} P(S \mid L,G) \quad (11)$$

where $\overline{L}_S$ and $\overline{G}_S$ are the detected language and gender of *S* respectively. Therefore, for hard decision, $P(L,G \mid S)$ is obtained by replacing L_S and G_S in Eq. (7) and (8) with $\overline{L}_S$ and $\overline{G}_S$ respectively. Although hard decision eliminates the need to compute the likelihood scores for all possible pairs of *L* and *G*, the decision errors made in the early stage will propagate to the transliteration stage. This is potentially bad if a poor detector is used (see Table 9 in Section 5.3).

If we are unable to model the prior knowledge of semantic attributes $P(L,G \mid S)$, then a more general model will be used for $P(T \mid S,L,G)$ by dropping the dependency on the information that is not available. For example, Eq. (3) is reduced to $\sum_{L \in \mathcal{L}} P(T \mid S,L)P(L \mid S)$ if the gender information is missing. Note that when both language and gender are unknown, the system simplifies to the baseline phonetic transliteration system.

5 Experiments

This section presents experiments on database of 3 language origins (Japanese, Chinese and English) and gender information (surname[7], male and female). In the experiments of determining the language origin, we used the full data set for the 3 languages as in shown in Table 1. The training and test data for semantic transliteration are the subset of Table 1 comprising those with surnames, male and female given names labels. In this paper, J, C and E stand for Japanese, Chinese and English; S, M and F represent Surname, Male and Female given names, respectively.

L	Data set	# unique entries			
		S	M	F	All
J	Train	21.7k	5.6k	1.7k	27.1k
	Test	2.6k	518	276	2.9k
C	Train	283	29.6k	9.2k	31.5k
	Test	283	2.9k	1.2k	3.1k
E	Train	12.5k	2.8k	3.8k	18.5k
	Test	1.4k	367	429	2.1k

Table 3: Number of unique entries in training and test sets, categorized by semantic attributes

Table 3 summarizes the number of *unique*[8] name entries used in training and testing. The test sets were randomly chosen such that the amount of test data is approximately 10-20% of the whole corpus. There were no overlapping entries between the training and test data. Note that the Chinese surnames are typically single characters in a small set; we assume there is no unseen surname in the test set. All the Chinese surname entries are used for both training and testing.

5.1 Language of Origin

For each language of origin, a 4-gram language model was trained for the letter sequence of the source names, with a 1-letter shift.

Japanese	Chinese	English	All
96.46	96.44	89.90	94.81

Table 4: Language detection accuracies (%) using a 4-gram language model for the letter sequence of the source name in Latin script.

[7] In this paper, surnames are treated as a special class of gender. Unlike given names, they do not have any gender association. Therefore, they fall into a third category which is neither male nor female.

[8] By contrast, Table 1 shows the total number of name examples available. For each unique entry, there may be multiple examples.

Table 4 shows the language detection accuracies for all the 3 languages using Eq. (10). The overall detection accuracy is 94.81%. The corresponding Equal Error Rate (EER)[9] is 4.52%. The detection results may be used directly to infer the semantic information for transliteration. Alternatively, the language model likelihood scores may be incorporated into the Bayesian framework to improve the transliteration performance, as described in Section 4.

5.2 Gender Association

Similarly, gender detection[10] was performed by training a 4-gram language model for the letter sequence of the source names for each language and gender pair.

Language	Male	Female	All
Japanese	90.54	80.43	87.03
Chinese	64.34	71.66	66.52
English	75.20	72.26	73.62

Table 5: Gender detection accuracies (%) using a 4-gram language model for the letter sequence of the source name in Latin script.

Table 5 summarizes the gender detection accuracies using Eq. (11) assuming language of origin is known, $\overline{G}_s = \arg\max_{G \in \mathcal{G}} P(S \mid L = L_s, G)$. The overall detection accuracies are 87.03%, 66.52% and 73.62% for Japanese, Chinese and English respectively. The corresponding EER are 13.1%, 21.8% and 19.3% respectively. Note that gender detection is generally harder than language detection. This is because the tokens (syllables) are shared very much across gender categories, while they are quite different from one language to another.

5.3 Semantic Transliteration

The performance was measured using the Mean Reciprocal Rank (MRR) metric (Kantor and Voorhees, 2000), a measure that is commonly used in information retrieval, assuming there is precisely one correct answer. Each transliteration system generated at most 50-best hypotheses for each word when computing MRR. The word and character accuracies of the top best hypotheses are also reported.

We used the phonetic transliteration system as the baseline to study the effects of semantic transliteration. The phonetic transliteration system was trained by pooling all the available training data from all the languages and genders to estimate a language model for the source-target token pairs. Table 6 compares the MRR performance of the baseline system using unigram and bigram language models for the source-target token pairs.

	J	C	E	All
Unigram	0.5109	0.4869	0.2598	0.4443
Bigram	0.5412	0.5261	0.3395	0.4895

Table 6: MRR performance of phonetic transliteration for 3 corpora using unigram and bigram language models.

The MRR performance for Japanese and Chinese is in the range of 0.48-0.55. However, due to the small amount of training and test data, the MRR performance of the English name transliteration is slightly poor (approximately 0.26-0.34). In general, a bigram language model gave an overall relative improvement of 10.2% over a unigram model.

L	G	Set	J	C	E

		All	0.5412	0.5261	0.3395
✓	×	S	0.6500	0.7971	0.7178
		M	0.6733	0.5245	0.4978
		F	0.5956	0.5191	0.4115
		All	0.6491	0.5404	0.6228
	✓	S	0.6822	0.9969	0.7382
		M	0.7267	0.6466	0.4319
		F	0.5856	0.7844	0.4340
		All	**0.6811**	**0.7075**	**0.6294**
○	○	S	0.6541	0.6733	0.7129
		M	0.6974	0.5362	0.4821
		F	0.5743	0.6574	0.4138
		All	0.6477	0.5764	0.6168

Table 7: The effect of language and gender information on the overall MRR performance of transliteration (L=Language, G=Gender, ×=unknown, ✓=known, ○=soft decision).

Next, the scenarios with perfect language and/or gender information were considered. This com-

[9] EER is defined as the error of false acceptance and false rejection when they are equal.

[10] In most writing systems, the ordering of surname and given name is known. Therefore, gender detection is only performed for male and female classes.

parison is summarized in Table 7. All the MRR results are based on transliteration systems using bigram language models. The table clearly shows that having perfect knowledge, denoted by "✓", of language and gender helps improve the MRR performance; detecting semantic attributes using soft decision, denoted by "○", has a clear win over the baseline, denoted by "×", where semantic information is not used. The results strongly recommend the use of semantic transliteration for personal names in practice.

Next let's look into the effects of automatic language and gender detection on the performance.

	J	C	E	All
×	0.5412	0.5261	0.3395	0.4895
◇	0.6292	0.5290	0.5780	0.5734
○	**0.6162**	**0.5301**	**0.6088**	**0.5765**
✓	0.6491	0.5404	0.6228	0.5952

Table 8: The effect of language detection schemes on MRR using bigram language models and unknown gender information (hereafter, ×=unknown, ✓=known, ◇=hard decision, ○=soft decision).

Table 8 compares the MRR performance of the semantic transliteration systems with different prior information, using bigram language models. Soft decision refers to the incorporation of the language model scores into the transliteration process to improve the prior knowledge in Bayesian inference. Overall, both hard and soft decision methods gave similar MRR performance of approximately 0.5750, which was about 17.5% relatively improvement compared to the phonetic transliteration system with 0.4895 MRR. The hard decision scheme owes its surprisingly good performance to the high detection accuracies (see Table 4).

	S	M	F	All
×	0.6825	0.5422	0.5062	0.5952
◇	0.7216	0.4674	0.5162	0.5855
○	**0.7216**	**0.5473**	**0.5878**	**0.6267**
✓	0.7216	0.6368	0.6786	0.6812

Table 9: The effect of gender detection schemes on MRR using bigram language models with perfect language information.

Similarly, the effect of various gender detection methods used to obtain the prior information is shown in Table 9. The language information was assumed known *a-priori*. Due to the poorer detection accuracy for the Chinese male given names (see Table 5), hard decision of gender had led to deterioration in MRR performance of the male names compared to the case where no prior information was assumed. Soft decision of gender yielded further gains of 17.1% and 13.9% relative improvements for male and female given names respectively, over the hard decision method.

L	G	MRR	Overall Accuracy (%)	
			Word	Character
×	×	0.4895	36.87	58.39
✓	×	0.5952	46.92	65.18
	✓	0.6812	58.16	70.76
◇	◇	0.5824	47.09	66.84
○	○	**0.6122**	**49.38**	**69.21**

Table 10: Overall transliteration performance using bigram language model with various language and gender information.

Finally, Table 10 compares the performance of various semantic transliteration systems using bigram language models. The baseline phonetic transliteration system yielded 36.87% and 58.39% accuracies at word and character levels respectively; and 0.4895 MRR. It can be conjectured from the results that semantic transliteration is substantially superior to phonetic transliteration. In particular, knowing the language information improved the overall MRR performance to 0.5952; and with additional gender information, the best performance of 0.6812 was obtained. Furthermore, both hard and soft decision of semantic information improved the performance, with the latter being substantially better. Both the word and character accuracies improvements were consistent and have similar trend to that observed for MRR.

The performance of the semantic transliteration using soft decisions (last row of Table 10) achieved 25.1%, 33.9%, 18.5% relative improvement in MRR, word and character accuracies respectively over that of the phonetic transliteration (first row of Table 10). In addition, soft decision also presented 5.1%, 4.9% and 3.5% relative improvement over hard decision in MRR, word and character accuracies respectively.

5.4 Discussions

It was found that the performance of the baseline phonetic transliteration may be greatly improved by incorporating semantic information such as the language of origin and gender. Furthermore, it was found that the soft decision of language and gender

outperforms the hard decision approach. The soft decision method incorporates the semantic scores $P(L,G \mid S)$ with transliteration scores $P(T \mid S,L,G)$, involving all possible semantic specific models in the decoding process.

In this paper, there are 9 such models (3 languages $\times$ 3 genders). The hard decision relies on Eqs. (10) and (11) to decide language and gender, which only involves one semantic specific model in the decoding. Neither soft nor hard decision requires any prior information about the names. It provides substantial performance improvement over phonetic transliteration at a reasonable computational cost. If the prior semantic information is known, e.g. via trigger words, then semantic transliteration attains its best performance.

6 Conclusion

Transliteration is a difficult, artistic human endeavor, as rich as any other creative pursuit. Research on automatic transliteration has reported promising results for regular transliteration, where transliterations follow certain rules. The generative model works well as it is designed to capture regularities in terms of rules or patterns. This paper extends the research by showing that semantic transliteration of personal names is feasible and provides substantial performance gains over phonetic transliteration. This paper has presented a successful attempt towards semantic transliteration using personal name transliteration as a case study. It formulates a mathematical framework that incorporates explicit semantic information (prior knowledge), or implicit one (through soft or hard decision) into the transliteration model. Extending the framework to machine transliteration of named entities in general is a topic for further research.

Abstract

We present a novel method for predicting inflected word forms for generating morphologically rich languages in machine translation. We utilize a rich set of syntactic and morphological knowledge sources from both source and target sentences in a probabilistic model, and evaluate their contribution in generating Russian and Arabic sentences. Our results show that the proposed model substantially outperforms the commonly used baseline of a trigram target language model; in particular, the use of morphological and syntactic features leads to large gains in prediction accuracy. We also show that the proposed method is effective with a relatively small amount of data.

1 Introduction

Machine Translation (MT) quality has improved substantially in recent years due to applying data intensive statistical techniques. However, state-of-the-art approaches are essentially lexical, considering every surface word or phrase in both the source sentence and the corresponding translation as an independent entity. A shortcoming of this word-based approach is that it is sensitive to data sparsity. This is an issue of importance as aligned corpora are an expensive resource, which is not abundantly available for many language pairs. This is particularly problematic for morphologically rich languages, where word stems are realized in many different surface forms, which exacerbates the sparsity problem.

In this paper, we explore an approach in which words are represented as a collection of morphological entities, and use this information to aid in MT for morphologically rich languages. Our goal is two-fold: first, to allow generalization over morphology to alleviate the data sparsity problem in morphology generation. Second, to model syntactic coherence in the form of morphological agreement in the target language to improve the generation of morphologically rich languages. So far, this problem has been addressed in a very limited manner in MT, most typically by using a target language model.

In the framework suggested in this paper, we train a model that predicts the inflected forms of a sequence of word stems in a target sentence, given the corresponding source sentence. We use word and word alignment information, as well as lexical resources that provide morphological information about the words on both the source and target sides. Given a sentence pair, we also obtain syntactic analysis information for both the source and translated sentences. We generate the inflected forms of words in the target sentence using all of the available information, using a log-linear model that learns the relevant mapping functions.

As a case study, we focus on the English-Russian and English-Arabic language pairs. Unlike English, Russian and Arabic have very rich systems of morphology, each with distinct characteristics. Translating from a morphology-poor to a morphology-rich language is especially challenging since detailed morphological information needs to be decoded from a language that does not encode this information or does so only implicitly (Koehn, 2005). We believe that these language pairs are represen-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 128–135,
Prague, Czech Republic, June 2007.

tative in this respect and therefore demonstrate the generality of our approach.

There are several contributions of this work. First, we propose a general approach that shows promise in addressing the challenges of MT into morphologically rich languages. We show that the use of both syntactic and morphological information improves translation quality. We also show the utility of source language information in predicting the word forms of the target language. Finally, we achieve these results with limited morphological resources and training data, suggesting that the approach is generally useful for resource-scarce language pairs.

2 Russian and Arabic Morphology

Table 1 describes the morphological features relevant to Russian and Arabic, along with their possible values. The rightmost column in the table refers to the morphological features that are shared by Russian and Arabic, including person, number, gender and tense. While these features are fairly generic (they are also present in English), note that Russian includes an additional gender (neuter) and Arabic has a distinct number notion for two (dual). A central dimension of Russian morphology is case marking, realized as suffixation on nouns and nominal modifiers[1]. The Russian case feature includes six possible values, representing the notions of subject, direct object, location, etc. In Arabic, like other Semitic languages, word surface forms may include proclitics and enclitics (or prefixes and suffixes as we refer to them in this paper), concatenated to inflected stems. For nouns, prefixes include conjunctions (*wa*: "and", *fa*: "and, so"), prepositions (*bi*: "by, with", *ka*: "like, such as", *li*: "for, to") and a determiner, and suffixes include possessive pronouns. Verbal prefixes include conjunction and negation, and suffixes include object pronouns. Both object and possessive pronouns are captured by an indicator function for its presence or absence, as well as by the features that indicate their person, number and gender. As can be observed from the table, a large number of surface inflected forms can be generated by the combination of these features, making the morphological generation of these languages a non-trivial task.

Morphologically complex languages also tend to display a rich system of agreements. In Russian, for example, adjectives agree with head nouns in number, gender and case, and verbs agree with the subject noun in person and number (past tense verbs agree in gender and number). Arabic has a similarly rich system of agreement, with unique characteristics. For example, in addition to agreement involving person, number and gender, it also requires a determiner for each word in a definite noun phrase with adjectival modifiers; in a noun compound, a determiner is attached to the last noun in the chain. Also, non-human subject plural nouns require the verb to be inflected in a singular feminine form. Generating these morphologically complex languages is therefore more difficult than generating English in terms of capturing the agreement phenomena.

3 Related Work

The use of morphological features in language modelling has been explored in the past for morphology-rich languages. For example, (Duh and Kirchhoff, 2004) showed that factored language models, which consider morphological features and use an optimized backoff policy, yield lower perplexity.

In the area of MT, there has been a large body of work attempting to modify the *input* to a translation system in order to improve the generated alignments for particular language pairs. For example, it has been shown (Lee, 2004) that determiner segmentation and deletion in Arabic sentences in an Arabic-to-English translation system improves sentence alignment, thus leading to improved overall translation quality. Another work (Koehn and Knight, 2003) showed improvements by splitting compounds in German. (Nießen and Ney, 2004) demonstrated that a similar level of alignment quality can be achieved with smaller corpora applying morpho-syntactic source restructuring, using hierarchical lexicon models, in translating from German into English. (Popović and Ney, 2004) experimented successfully with translating from inflectional languages into English making use of POS tags, word stems and suffixes in the source language. More recently, (Goldwater and McClosky, 2005) achieved improvements in Czech-English MT, optimizing a

[1]Case marking also exists in Arabic. However, in many instances, it is realized by diacritics which are ignored in standard orthography. In our experiments, we include case marking in Arabic only when it is reflected in the orthography.

Features	Russian	Arabic	Both
POS	(11 categories)	(18 categories)	
Person			1,2,3

Table 1: Morphological features used for Russian and Arabic

set of possible source transformations, incorporating morphology. In general, this line of work focused on translating from morphologically rich languages into English; there has been limited research in MT in the opposite direction. Koehn (2005) includes a survey of statistical MT systems in both directions for the Europarl corpus, and points out the challenges of this task. A recent work (El-Kahlout and Oflazer, 2006) experimented with English-to-Turkish translation with limited success, suggesting that inflection generation given morphological features may give positive results.

In the current work, we suggest a probabilistic framework for morphology generation performed as *post-processing*. It can therefore be considered as complementary to the techniques described above. Our approach is general in that it is not specific to a particular language pair, and is novel in that it allows modelling of agreement on the target side. The framework suggested here is most closely related to (Suzuki and Toutanova, 2006), which uses a probabilistic model to generate Japanese case markers for English-to-Japanese MT. This work can be viewed as a generalization of (Suzuki and Toutanova, 2006) in that our model generates inflected forms of words, and is not limited to generating a small, closed set of case markers. In addition, the morphology generation problem is more challenging in that it requires handling of complex agreement phenomena along multiple morphological dimensions.

4 Inflection Prediction Framework

In this section, we define the task of of morphological generation as inflection prediction, as well as the lexical operations relevant for the task.

4.1 Morphology Analysis and Generation

Morphological analysis can be performed by applying language specific rules. These may include a full-scale morphological analysis with contextual disambiguation, or, when such resources are not available, simple heuristic rules, such as regarding the last few characters of a word as its morphogical suffix. In this work, we assume that lexicons L_S and L_T are available for the source and translation languages, respectively. Such lexicons can be created manually, or automatically from data. Given a lexicon L and a surface word w, we define the following operations:

- *Stemming* - let $S_w = \{s^1, ..., s^l\}$ be the set of possible morphological stems (lemmas) of w according to L.[2]
- *Inflection* - let $I_w = \{i^1, ..., i^m\}$ be the set of surface form words that have the same stem as w. That is, $i \in I_w$ *iff* $S_i \bigcap S_w \neq \emptyset$.
- *Morphological analysis* - let $A_w = \{a^1, ..., a^v\}$ be the set of possible morphological analyses for w. A morphological analysis a is a vector of categorical values, where the dimensions and possible values for each dimension in the vector representation space are defined by L.

4.2 The Task

We assume that we are given aligned sentence pairs, where a sentence pair includes a source and a tar-

[2]Multiple stems are possible due to ambiguity in morphological analysis.

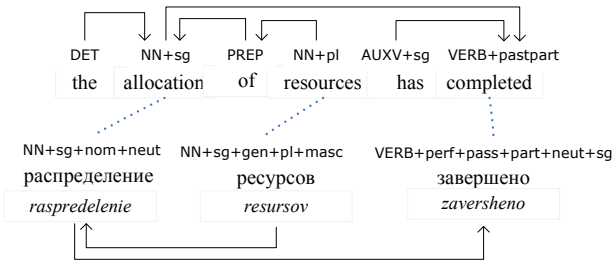

Figure 1: Aligned English-Russian sentence pair with syntactic and morphological annotation

get sentence, and lexicons L_S and L_T that support the operations described in the section above. Let a sentence $w_1, ...w_t, ...w_n$ be the output of a MT system in the target language. This sentence can be converted into the corresponding stem set sequence $S_1, ...S_t, ...S_n$, applying the stemming operation. Then the task is, for every stem set S_t in the output sentence, to predict an inflection y_t from its inflection set I_t. The predicted inflections should both reflect the meaning conveyed by the source sentence, and comply with the agreement rules of the target language. [3]

Figure 1 shows an example of an aligned English-Russian sentence pair: on the source (English) side, POS tags and word dependency structure are indicated by solid arcs. The alignments between English and Russian words are indicated by the dotted lines. The dependency structure on the Russian side, indicated by solid arcs, is given by a treelet MT system in our case (see Section 6.1), projected from the word dependency structure of English and word alignment information. Note that the Russian sentence displays agreement in number and gender between the subject noun (*raspredelenie*) and the predicate (*zaversheno*); note also that *resursov* is in genitive case, as it modifies the noun on its left.

5 Models for Inflection Prediction

5.1 A Probabilistic Model

Our learning framework uses a Maximum Entropy Markov model (McCallum et al., 2000). The model decomposes the overall probability of a predicted inflection sequence into a product of local probabilities for individual word predictions. The local probabilities are conditioned on the previous k predictions. The model implemented here is of second order: at any decision point t we condition the probability distribution over labels on the previous two predictions y_{t-1} and y_{t-2} in addition to the given (static) word context from both the source and target sentences. That is, the probability of a predicted inflection sequence is defined as follows:

$$p(\overline{y} \mid \overline{x}) = \prod_{t=1}^{n} p(y_t \mid y_{t-1}, y_{t-2}, x_t), y_t \in I_t$$

where x_t denotes the given context at position t and I_t is the set of inflections corresponding to S_t, from which the model should choose y_t.

The features we constructed pair up predicates on the *context* ($\bar{x}, y_{t-1}, y_{t-2}$) and the *target label* (y_t). In the suggested framework, it is straightforward to encode the morphological properties of a word, in addition to its surface inflected form. For example, for a particular inflected word form y_t and its context, the derived paired features may include:

$$\phi_k = \begin{cases} 1 & \text{if surface word } y_t \text{ is } y' \text{ and } s' \in S_{t+1} \\ 0 & \text{otherwise} \end{cases}$$

$$\phi_{k+1} = \begin{cases} 1 & \text{if } \textit{Gender}(y_t) = \textit{“Fem”} \text{ and } \textit{Gender}(y_{t-1}) = \textit{“Fem”} \\ 0 & \text{otherwise} \end{cases}$$

In the first example, a given neighboring stem set S_{t+1} is used as a context feature for predicting the target word y_t. The second feature captures the gender agreement with the previous word. This is possible because our model is of second order. Thus, we can derive context features describing the morphological properties of the two previous predictions.[4] Note that our model is not a simple multi-class classifier, because our features are shared across multiple target labels. For example, the gender feature above applies to many different inflected forms. Therefore, it is a structured prediction model, where the structure is defined by the morphological properties of the target predictions, in addition to the word sequence decomposition.

5.2 Feature Categories

The information available for estimating the distribution over y_t can be split into several categories,

[3] That is, assuming that the stem sequence that is output by the MT system is correct.

[4] Note that while we decompose the prediction task left-to-right, an appealing alternative is to define a top-down decomposition, traversing the dependency tree of the sentence. However, this requires syntactic analysis of sufficient quality.

corresponding to feature source. The first major distinction is monolingual versus bilingual features: *monolingual* features refer only to the context (and predicted label) in the target language, while *bilingual* features have access to information in the source sentences, obtained by traversing the word alignment links from target words to a (set of) source words, as shown in Figure 1.

Both monolingual and bilingual features can be further split into three classes: *lexical*, *morphological* and *syntactic*. *Lexical* features refer to surface word forms, as well as their stems. Since our model is of second order, our monolingual lexical features include the features of a standard word trigram language model. Furthermore, since our model is discriminative (predicting word forms given their stems), the monolingual lexical model can use stems in addition to predicted words for the left and current position, as well as stems from the *right* context. *Morphological* features are those that refer to the features given in Table 1. Morphological information is used in describing the target label as well as its context, and is intended to capture morphological generalizations. Finally, *syntactic* features can make use of syntactic analyses of the source and target sentences. Such analyses may be derived for the target language, using the pre-stemmed sentence. Without loss of generality, we will use here a dependency parsing paradigm. Given a syntactic analysis, one can construct syntactic features; for example, the stem of the *parent* word of y_t. Syntactic features are expected to be useful in capturing agreement phenomena.

5.3 Features

Table 2 gives the full set of suggested features for Russian and Arabic, detailed by type. For *monolingual lexical* features, we consider the stems of the predicted word and its immediately adjacent words, in addition to traditional word bigram and trigram features. For *monolingual morphological* features, we consider the morphological attributes of the two previously predicted words and the current prediction; for *monolingual syntactic* features, we use the stem of the parent node.

The bilingual features include the set of words aligned to the focus word at position t, where they are treated as bag-of-words, i.e., each aligned word is assigned a separate feature. *Bilingual lexical* features can refer to words aligned to y_t as all as words aligned to its immediate neighbors y_{t-1} and y_{t+1}. *Bilingual morphological and syntactic* features refer to the features of the source language, which are expected to be useful for predicting morphology in the target language. For example, the bilingual *Det* (determiner) feature is computed according to the source dependency tree: if a child of a word aligned to w_t is a determiner, then the feature value is assigned its surface word form (such as *a* or *the*). The bilingual *Prep* feature is computed similarly, by checking the parent chain of the word aligned to w_t for the existence of a preposition. This feature is hoped to be useful for predicting Arabic inflected forms with a prepositional prefix, as well as for predicting case marking in Russian. The bilingual *ObjPron* and *PossPron* features represent any object pronoun of the word aligned to w_t and a preceding possessive pronoun, respectively. These features are expected to map to the object and possessive pronoun features in Arabic. Finally, the bilingual *Compound* feature checks whether a word appears as part of a noun compound in the English source. f this is the case, the feature is assigned the value of "head" or "dependent". This feature is relevant for predicting a genitive case in Russian and definiteness in Arabic.

Feature categories	**Instantiations**
Monolingual lexical	
Word stem	s_{t-1},s_{t-2},s_t,s_{t+1}
Predicted word	y_t, y_{t-1}, y_{t-2}
Monolingual morphological	
f : POS, Person, Number, Gender, Tense Neg, Det, Prep, Conj, ObjPron, PossPron	$f(y_{t-2})$,$f(y_{t-1})$,$f(y_t)$
Monolingual syntactic	
Parent stem	$s_{HEAD(t)}$
Bilingual lexical	
Aligned word set Al	Al_t, Al_{t-1}, Al_{t+1}
Bilingual morph & syntactic	
f : POS, Person, Number, Gender, Tense Neg, Det, Prep, Conj, ObjPron, PossPron, Comp	$f(Al_t)$, $f(Al_{t-1})$, $f(Al_{t+1})$, $f(Al_{HEAD(t)})$

Table 2: The feature set suggested for English-Russian and English-Arabic pairs

6 Experimental Settings

In order to evaluate the effectiveness of the suggested approach, we performed *reference experiments*, that is, using the aligned sentence pairs of

Data	Eng-Rus		Eng-Ara	
Avg. sentlen	**Eng**	**Rus**	**Eng**	**Ara**
Training	1M		470K	
	14.06	12.90	12.85	11.90
Development	1,000		1,000	
	13.73	12.91	13.48	12.90
Test	1,000		1,000	
	13.61	12.84	8.49	7.50

Table 3: Data set statistics: corpus size and average sentence length (in words)

reference translations rather than the output of an MT system as input.[5] This allows us to evaluate our method with a reduced noise level, as the words and word order are perfect in reference translations. These experiments thus constitute a preliminary step for tackling the real task of inflecting words in MT.

6.1 Data

We used a corpus of approximately 1 million aligned sentence pairs for English-Russian, and 0.5 million pairs for English-Arabic. Both corpora are from a technical (software manual) domain, which we believe is somewhat restricted along some morphological dimensions, such as tense and person. We used 1,000 sentence pairs each for development and testing for both language pairs. The details of the datasets used are given in Table 3.

The sentence pairs were word-aligned using GIZA++ (Och and Ney, 2000) and submitted to a treelet-based MT system (Quirk et al., 2005), which uses the word dependency structure of the source language and projects word dependency structure to the target language, creating the structure shown in Figure 1 above.

6.2 Lexicon

Table 4 gives some relevant statistics of the lexicons we used. For Russian, a general-domain lexicon was available to us, consisting of about 80,000 lemmas (stems) and 9.4 inflected forms per stem.[6] Limiting the lexicon to word types that are seen in the training set reduces its size substantially to about 14,000 stems, and an average of 3.8 inflections per stem. We will use this latter "domain-adapted" lexicon in our experiments.

[5] In this case, y_t should equal w_t, according to the task definition.

[6] The averages reported in Table 4 are by type and do not consider word frequencies in the data.

	Source	Stems	Avg($\mid I \mid$)	Avg($\mid S \mid$)
Rus.	Lexicon	79,309	9.4	
	Lexicon $\cap$ Train	13,929	3.8	1.6
Ara.	Lexicon $\cap$ Train	12,670	7.0	1.7

Table 4: Lexicon statistics

For Arabic, as a full-size Arabic lexicon was not available to us, we used the Buckwalter morphological analyzer (Buckwalter, 2004) to derive a lexicon. To acquire the *stemming* and *inflection* operators, we submit all words in our training data to the Buckwalter analyzer. Note that Arabic displays a high level of ambiguity, each word corresponding to many possible segmentations and morphological analyses; we considered all of the different stems returned by the Buckwalter analyzer in creating a word's stem set. The lexicon created in this manner contains 12,670 distinct stems and 89,360 inflected forms.

For the generation of *word features*, we only consider one dominant analysis for any surface word for simplicity. In case of ambiguity, we considered only the first (arbitrary) analysis for Russian. For Arabic, we apply the following heuristic: use the most frequent analysis estimated from the gold standard labels in the Arabic Treebank (Maamouri et al., 2005); if a word does not appear in the treebank, we choose the first analysis returned by the Buckwalter analyzer. Ideally, the best word analysis should be provided as a result of contextual disambiguation (e.g., (Habash and Rambow, 2005)); we leave this for future work.

6.3 Baseline

As a baseline, we pick a morphological inflection y_t at random from I_t. This random baseline serves as an indicator for the difficulty of the problem. Another more competitive baseline we implemented is a word trigram language model (LM). The LMs were trained using the CMU language modelling toolkit (Clarkson and Rosenfeld, 1997) with default settings on the training data described in Table 3.

6.4 Experiments

In the experiments, our primary goal is to evaluate the effectiveness of the proposed model using all features available to us. Additionally, we are interested in knowing the contribution of each information source, namely of morpho-syntactic and bilingual features. Therefore, we study the performance

of models including the full feature schemata as well as models that are restricted to feature subsets according to the feature types as described in Section 5.2. The models are as follows: *Monolingual-Word*, including LM-like and stem n-gram features only; *Bilingual-Word*, which also includes bilingual lexical features;[7] *Monolingual-All*, which has access to all the information available in the target language, including morphological and syntactic features; and finally, *Bilingual-All*, which includes all feature types from Table 2.

For each model and language, we perform feature selection in the following manner. The features are represented as feature *templates*, such as "POS=X", which generate a set of binary features corresponding to different instantiations of the template, as in "POS=NOUN". In addition to individual features, conjunctions of up to three features are also considered for selection (e.g., "POS=NOUN & Number=plural"). Every conjunction of feature templates considered contains at least one predicate on the prediction y_t, and up to two predicates on the context. The feature selection algorithm performs a greedy forward stepwise feature selection on the feature templates so as to maximize development set accuracy. The algorithm is similar to the one described in (Toutanova, 2006). After this process, we performed some manual inspection of the selected templates, and finally obtained 11 and 36 templates for the *Monolingual-All* and *Bilingual-All* settings for Russian, respectively. These templates generated 7.9 million and 9.3 million binary feature instantiations in the final model, respectively. The corresponding numbers for Arabic were 27 feature templates (0.7 million binary instantiations) and 39 feature templates (2.3 million binary instantiations) for *Monolingual-All* and *Bilingual-All*, respectively.

7 Results and Discussion

Table 5 shows the accuracy of predicting word forms for the baseline and proposed models. We report accuracy only on words that appear in our lexicons. Thus, punctuation, English words occurring in the target sentence, and words with unknown lemmas are excluded from the evaluation. The reported accuracy measure therefore abstracts away from the issue of incomplete coverage of the lexicon. When we encounter these words in the true MT scenario, we will make no predictions about them, and simply leave them unmodified. In our current experiments, in Russian, 68.2% of all word tokens were in Cyrillic, of which 93.8% were included in our lexicon. In Arabic, 85.5% of all word tokens were in Arabic characters, of which 99.1% were in our lexicon.[8]

Model	**Eng-Rus**	**Eng-Ara**
Random	31.7	16.3
LM	77.6	31.7
Monolingual Word	85.1	69.6
Bilingual Word	87.1	71.9
Monolingual All	87.1	71.6
Bilingual All	**91.5**	**73.3**

Table 5: Accuracy (%) results by model

The results in Table 5 show that the suggested models outperform the language model substantially for both languages. In particular, the contribution of both bilingual and non-lexical features is noteworthy: adding non-lexical features consistently leads to 1.5% to 2% absolute gain in both monolingual and bilingual settings in both language pairs. We obtain a particularly large gain in the Russian bilingual case, in which the absolute gain is more than 4%, translating to 34% error rate reduction. Adding bilingual features has a similar effect of gaining about 2% (and 4% for Russian non-lexical) in accuracy over monolingual models. The overall accuracy is lower in Arabic than in Russian, reflecting the inherent difficulty of the task, as indicated by the random baseline (31.7 in Russian vs. 16.3 in Arabic).

In order to evaluate the effectiveness of the model in alleviating the data sparsity problem in morphological generation, we trained inflection prediction models on various subsets of the training data described in Table 3, and tested their accuracy. The results are given in Figure 2. We can see that with as few as 5,000 training sentences pairs, the model obtains much better accuracy than the language model, which is trained on data that is larger by a few orders of magnitude. We also note that the learning curve

[7] Overall, this feature set approximates the information that is available to a state-of-the-art statistical MT system.

[8] For Arabic, the inflection ambiguity was extremely high: there were on average 39 inflected forms per stem set in our development corpus (per token), as opposed to 7 in Russian. We therefore limited the evaluation of Arabic to those stems that have up to 30 inflected forms, resulting in 17 inflected forms per stem set on average in the development data.

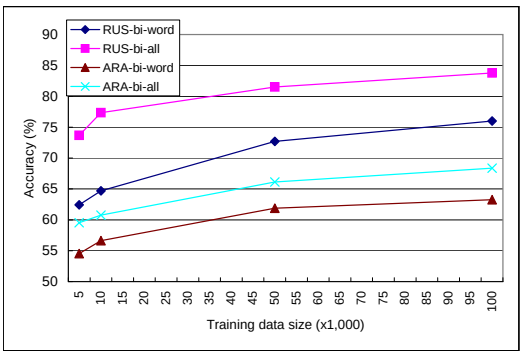

Figure 2: Accuracy, varying training data size

becomes less steep as we use more training data, suggesting that the models are successfully learning generalizations.

We have also manually examined some representative cases where the proposed model failed to make a correct prediction. In both Russian and Arabic, a very common pattern was a mistake in predicting the gender (as well as number and person in Arabic) of pronouns. This may be attributed to the fact that the correct choice of the pronoun requires coreference resolution, which is not available in our model. A more thorough analysis of the results will be helpful to bring further improvements.

8 Conclusions and Future Work

We presented a probabilistic framework for morphological generation given aligned sentence pairs, incorporating morpho-syntactic information from both the source and target sentences. The results, using reference translations, show that the proposed models achieve substantially better accuracy than language models, even with a relatively small amount of training data. Our models using morpho-syntactic information also outperformed models using only lexical information by a wide margin. This result is very promising for achieving our ultimate goal of improving MT output by using a specialized model for target language morphological generation. Though this goal is clearly outside the scope of this paper, we conducted a preliminary experiment where an English-to-Russian MT system was trained on a stemmed version of the aligned data and used to generate stemmed word sequences, which were then inflected using the suggested framework. This simple integration of the proposed model with the MT system improved the BLEU score by 1.7. The most obvious next step of our research, therefore, is to further pursue the integration of the proposed model to the end-to-end MT scenario.

There are multiple paths for obtaining further improvements over the results presented here. These include refinement in feature design, word analysis disambiguation, morphological and syntactic analysis on the source English side (e.g., assigning semantic role tags), to name a few. Another area of investigation is capturing longer-distance agreement phenomena, which can be done by implementing a global statistical model, or by using features from dependency trees more effectively.

Abstract

We present the design and evaluation of a *translator's amenuensis* that uses comparable corpora to propose and rank non-literal solutions to the translation of expressions from the general lexicon. Using distributional similarity and bilingual dictionaries, the method outperforms established techniques for extracting translation equivalents from parallel corpora. The interface to the system is available at: http://corpus.leeds.ac.uk/assist/v05/

1 Introduction

This paper describes a system designed to assist humans in translating expressions that do not necessarily have a literal or compositional equivalent in the target language (TL). In the spirit of (Kay, 1997), it is intended as a *translator's amenuensis* "under the tight control of a human translator … to help increase his productivity and not to supplant him".

One area where human translators particularly appreciate assistance is in the translation of expressions from the general lexicon. Unlike equivalent technical terms, which generally share the same part-of-speech (POS) across languages and are in the ideal case univocal, the contextually appropriate equivalents of general language expressions are often indirect and open to variation. While the transfer module in RBMT may acceptably undergenerate through a many-to-one mapping between source and target expressions, human translators, even in non-literary fields, value legitimate variation. Thus the French expression *il faillit échouer* (lit.: he faltered to fail) may be variously rendered as *he almost/nearly/all but failed; he was on the verge/brink of failing/failure; failure loomed*. All of these translations are indirect in that they involve lexical shifts or POS transformations.

Finding such translations is a hard task that can benefit from automated assistance. 'Mining' such indirect equivalents is difficult, precisely because of the structural mismatch, but also because of the paucity of suitable aligned corpora. The approach adopted here includes the use of comparable corpora in source and target languages, which are relatively easy to create. The challenge is to generate a list of usable solutions and to rank them such that the best are at the top.

Thus the present system is unlike SMT (Och and Ney, 2003), where lexical selection is effected by a translation model based on aligned, parallel corpora, but the novel techniques it has developed are exploitable in the SMT paradigm. It also differs from now traditional uses of comparable corpora for detecting translation equivalents (Rapp, 1999) or extracting terminology (Grefenstette, 2002), which allows a one-to-one correspondence irrespective of the context. Our system addresses difficulties in expressions in the general lexicon, whose translation is context-dependent.

The structure of the paper is as follows. In Section 2 we present the method we use for mining translation equivalents. In Section 3 we present the results of an objective evaluation of the quality of suggestions produced by the system by comparing our output against a parallel corpus. Finally, in Section 4 we present a subjective evaluation focusing on the integration of the system into the workflow of human translators.

2 Methodology

The software acts as a decision support system for translators. It integrates different technologies for

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 136–143,
Prague, Czech Republic, June 2007.

extracting indirect translation equivalents from large comparable corpora. In the following subsections we give the user perspective on the system and describe the methodology underlying each of its sub-tasks.

2.1 User perspective

Unlike traditional dictionaries, the system is a *dynamic translation resource* in that it can successfully find translation equivalents for units which have not been stored in advance, even for idiosyncratic multiword expressions which almost certainly will not figure in a dictionary. While our system can rectify gaps and omissions in static lexicographical resources, its major advantage is that it is able to cope with an open set of translation problems, searching for translation equivalents in comparable corpora in runtime. This makes it more than just an extended dictionary.

Contextual descriptors

From the user perspective the system extracts indirect translation equivalents as sets of *contextual descriptors* – content words that are lexically central in a given sentence, phrase or construction. The choice of these descriptors may determine the general syntactic perspective of the sentence and the use of supporting lexical items. Many translation problems arise from the fact that the mapping between such descriptors is not straightforward.

The system is designed to find possible indirect mappings between sets of descriptors and to verify the acceptability of the mapping into the TL. For example, in the following Russian sentence, the bolded contextual descriptors require indirect translation into English.

Дети посещают ***плохо отремонтированные*** *школы, в которых* ***недостает*** *самого* ***необходимого***
(Children attend ***badly repaired*** *schools, in which [it] is* ***missing*** *the most* ***necessary)***

Combining direct translation equivalents of these words (e.g., translations found in the Oxford Russian Dictionary – ORD) may produce a non-natural English sentence, like the literal translation given above. In such cases human translators usually apply structural and lexical transformations, for instance changing the descriptors' POS and/or replacing them with near-synonyms which fit together in the context of a TL sentence (Munday, 2001: 57-58). Thus, a structural transformation of *плохо отремонтированные* (badly repaired) may give *in poor repair* while a lexical transformation of *недостает самого необходимого* ([it] is missing the most necessary) gives *lacking basic essentials*.

Our system models such transformations of the descriptors and checks the consistency of the resulting sets in the TL.

Using the system

Human translators submit queries in the form of one or more SL descriptors which in their opinion may require indirect translation. When the translators use the system for translating into their native language, the returned descriptors are usually sufficient for them to produce a correct TL construction or phrase around them (even though the descriptors do not always form a naturally sounding expression). When the translators work into a non-native language, they often find it useful to generate concordances for the returned descriptors to verify their usage within TL constructions.

For example, for the sentence above translators may submit two queries: *плохо отремонтированные* (badly repaired) and *недостает необходимого* (missing necessary). For the first query the system returns a list of descriptor pairs (with information on their frequency in the English corpus) ranked by distributional proximity to the original query, which we explain in Section 2.2. At the top of the list come:

```
bad repair = 30        (11.005)
bad maintenance = 16   (5.301)
bad restoration = 2    (5.079)
poor repair = 60       (5.026)…
```

Underlined hyperlinks lead translators to actual contexts in the English corpus, e.g., *poor repair* generates a concordance containing a desirable TL construction which is a structural transformation of the SL query:

in such a	**poor**	state of **repair**
bridge in as	**poor**	a state of **repair** as the highways
building in	**poor**	**repair**.
dwellings are in	**poor**	**repair**;

Similarly, the result of the second query may give the translators an idea about possible lexical transformation:

```
missing need = 14      (5.035)
important missing = 8  (2.930)
missing vital = 8      (2.322)
lack necessary = 204   (1.982)…
essential lack = 86    (0.908)…
```

The concordance for the last pair of descriptors contains the phrase *they lack the three essentials*, which illustrates the transformation. The resulting translation may be the following:

*Children attend schools that are in **poor repair** and **lacking** basic **essentials***

Thus our system supports translators in making decisions about indirect translation equivalents in a number of ways: it suggests possible structural and lexical transformations for contextual descriptors; it verifies which translation variants co-occur in the TL corpus; and it illustrates the use of the transformed TL lexical descriptors in actual contexts.

2.2 Generating translation equivalents

We have generalised the method used in our previous study (Sharoff et al., 2006) for extracting equivalents for continuous multiword expressions (MWEs). Essentially, the method expands the search space for each word and its dictionary translations with entries from automatically computed thesauri, and then checks which combinations are possible in target corpora. These potential translation equivalents are then ranked by their similarity to the original query and presented to the user. The range of retrievable equivalents is now extended from a relatively limited range of two-word constructions which mirror POS categories in SL and TL to a much wider set of co-occurring lexical content items, which may appear in a different order, at some distance from each other, and belong to different POS categories.

The method works best for expressions from the general lexicon, which do not have established equivalents, but not yet for terminology. It relies on a high-quality bilingual dictionary (en-ru ~30k, ru-en ~50K words, combining ORD and the core part of Multitran) and large comparable corpora (~200M En, ~70M Ru) of news texts.

For each of the SL query terms *q* the system generates its *dictionary translation Tr(q)* and its *similarity class S(q)* – a set of words with a similar distribution in a monolingual corpus. Similarity is measured as the cosine between collocation vectors, whose dimensionality is reduced by SVD using the implementation by Rapp (2004). The descriptor and each word in the similarity class are then translated into the TL using ORD or the Multitran dictionary, resulting in $\{Tr(q) \cup Tr(S(q))\}$. On the TL side we also generate similarity classes, but only for dictionary translations of query terms *Tr(q)* (not for *Tr(S(q))*, which can make output too noisy). We refer to the resulting set of TL words as a *translation class T*.

$T = \{Tr(q) \cup Tr(S(q)) \cup S(Tr(q))\}$

Translation classes approximate lexical and structural transformations which can potentially be applied to each of the query terms. Automatically computed similarity classes do not require resources like WordNet, and they are much more suitable for modelling translation transformations, since they often contain a wider range of words of different POS which share the same context, e.g., the similarity class of the word *lack* contains words such as *absence, insufficient, inadequate, lost, shortage, failure, paucity, poor, weakness, inability, need.* This clearly goes beyond the range of traditional thesauri.

For multiword queries, the system performs a consistency check on possible combinations of words from different translation classes. In particular, it computes the Cartesian product for pairs of translation classes T_1 and T_2 to generate the set P of word pairs, where each word (w_1 and w_2) comes from a different translation class:

$P = T_1 \times T_2 = \{(w_1, w_2) \mid w_1 \in T_1 \text{ and } w_2 \in T_2\}$

Then the system checks whether each word pair from the set P exists in the database D of discontinuous content word bi-grams which actually co-occur in the TL corpus:

$P' = P \cap D$

The database contains the set of all bi-grams that occur in the corpus with a frequency ≥ 4 within a window of 5 words (over 9M bigrams for each language). The bi-grams in D and in P are sorted alphabetically, so their order in the query is not important.

Larger N-grams ($N > 2$) in queries are split into combinations of bi-grams, which we found to be an optimal solution to the problem of the scarcity of higher order N-grams in the corpus. Thus, for the query *gain significant importance* the system generates $P'_{1(\text{significant importance})}$, $P'_{2(\text{gain importance})}$, $P'_{3(\text{gain significant})}$ and computes P' as:

$P' = \{(w_1,w_2,w_3) \mid (w_1,w_2) \in P'_1 \ \& \ (w_1, w_3) \in P'_2 \ \& \ (w_2,w_3) \in P'_3\},$

which allows the system to find an indirect equivalent *получить весомое значение* (lit.: receive weighty meaning).

Even though *P'* on average contains about 2% - 4% of the theoretically possible number of bigrams present in *P*, the returned number of potential translation equivalents may still be large and contain much noise. Typically there are several hundred elements in *P'*, of which only a few are really useful for translation. To make the system usable in practice, i.e., to get useful solutions to appear close to the top (preferably on the first screen of the output), we developed methods of ranking and filtering the returned TL contextual descriptor pairs, which we present in the following sections.

2.3 Hypothesis ranking

The system ranks the returned list of contextual descriptors by their distributional proximity to the original query, i.e. it uses scores $cos(v_q, v_w)$ generated for words in similarity classes – the cosine of the angle between the collocation vector for a word and the collocation vector for the query or dictionary translation of the query. Thus, words whose equivalents show similar usage in a comparable corpus receive the highest scores. These scores are computed for each individual word in the output, so there are several ways to combine them to weight words in translation classes and word combinations in the returned list of descriptors.

We established experimentally that the best way to combine similarity scores is to multiply weights *W(T)* computed for each word within its translation class *T*. The weight $W(P'_{(w1,w2)})$ for each pair of contextual descriptors $(w_1, w_2) \in P'$ is computed as:

$$W(P'_{(w1,w2)}) = W(T_{(w1)}) \times W(T_{(w2)});$$

Computing $W(T_{(w)})$, however, is not straightforward either, since some words in similarity classes of different translation equivalents for the query term may be the same, or different words from the similarity class of the original query may have the same translation. Therefore, a word *w* within a translation class may have come by several routes simultaneously, and may have done that several times. For each word *w* in *T* there is a possibility that it arrived in T either because it is in *Tr(q)* or occurs *n* times in *Tr(S(q))* or *k* times in *S(Tr(q))*.

We found that the number of occurrences *n* and *k* of each word *w* in each subset gives valuable information for ranking translation candidates. In our experiments we computed the weight *W(T)* as the sum of similarity scores which *w* receives in each of the subsets. We also discovered that ranking improves if for each query term we compute in addition a larger (and potentially noisy) space of candidates that includes TL similarity classes of translations of the SL similarity class *S(Tr(S(q)))*. These candidates do not appear in the system output, but they play an important role in ranking the displayed candidates. The improvement may be due to the fact that this space is much larger, and may better support relevant candidates since there is a greater chance that appropriate indirect equivalents are found several times within SL and TL similarity classes. The best ranking results were achieved when the original *W(T)* scores were multiplied by 2 and added to the scores for the newly introduced similarity space *S(Tr(S(q)))*:

$$W(T_{(w)}) = 2 \times (1 \text{ if } w \in Tr(q)) + 2 \times \sum(cos(v_q, v_{Tr(w)}) \mid \{w \mid w \in Tr(S(q))\}) + 2 \times \sum(cos(v_{Tr(q)}, v_w) \mid \{w \mid w \in S(Tr(q))\}) + \sum(cos(v_q, v_{Tr(w)}) \times cos(v_{Tr(q)}, v_w) \mid \{w \mid w \in S(Tr(S(q)))\})$$

For example, the system gives the following ranking for the indirect translation equivalents of the Russian phrase *весомое значение* (lit.: weighty meaning) – figures in brackets represent *W(P')* scores for each pair of TL descriptors:

```
1. significant importance = 7 (3.610)
2. significant value = 128    (3.211)
3. measurable value = 6       (2.657)…
8. dramatic importance = 2    (2.028)
9. important significant = 70 (2.014)
10. convincing importance = 6 (1.843)
```

The Russian similarity class for *весомый* (weighty, ponderous) contains: *убедительный* (convincing) (0.469), *значимый* (significant) (0.461), *ощутимый* (notable) (0.452) *драматичный* (dramatic) (0.371). The equivalent of *significant* is not at the top of the similarity class of the Russian query, but it appears at the top of the final ranking of pairs in *P'*, because this hypothesis is supported by elements of the set formed by *S(Tr(S(q)))*; it appears in similarity classes for *notable* (0.353) and *dramatic* (0.315), which contributed these values to the *W(T)* score of *significant*:

W(T(`significant`*))* =

2 × (Tr(значимый)=`significant` (0.461))
+ (Tr(ощутимый)=`notable` (0.452)
× S(`notable`)=`significant` (0.353))
+ (Tr(драматичный)=`dramatic` (0.371)
× S(`dramatic`)= `significant` (0.315))

The word *dramatic* itself is not usable as a translation equivalent in this case, but its similarity

class contains the support for relevant candidates, so it can be viewed as useful noise. On the other hand, the word *convincing* does not receive such support from the hypothesis space, even though its Russian equivalent is ranked higher in the SL similarity class.

2.4 Semantic filtering

Ranking of translation candidates can be further improved when translators use an option to filter the returned list by certain lexical criteria, e.g., to display only those examples that contain a certain lexical item, or to require one of the items to be a dictionary translation of the query term. However, lexical filtering is often too restrictive: in many cases translators need to see a number of related words from the same semantic field or subject domain, without knowing the lexical items in advance. In this section we present the semantic filter, which is based on Russian and English semantic taggers which use the same semantic field taxonomy for both languages.

The semantic filter displays only those items which have specified semantic field tags or tag combinations; it can be applied to one or both words in each translation hypothesis in *P'*. The default setting for the semantic filter is the requirement for both words in the resulting TL candidates to contain any of the semantic field tags from a SL query term.

In the next section we present evaluation results for this default setting (which is applied when the user clicks the *Semantic Filter* button), but human translators have further options – to filter by tags of individual words, to use semantic classes from SL or TL terms, etc.

For example, applying the default semantic filter for the output of the query *плохо отремонтированные* (badly repaired) removes the highlighted items from the list:

```
 1. bad repair = 30        (11.005)
[2. good repair = 154      (8.884) ]
 3. bad rebuild = 6        (5.920)
[4. bad maintenance = 16   (5.301) ]
 5. bad restoration = 2    (5.079)
 6. poor repair = 60       (5.026)
[7. good rebuild = 38      (4.779) ]
 8. bad construction = 14  (4.779)
```

Items 2 and 7 are generated by the system because *good*, *well* and *bad* are in the same similarity cluster for many words (they often share the same collocations). The semantic filter removes examples with *good* and *well* on the grounds that they do not have any of the tags which come from the word *плохо* (badly): in particular, instead of tag `A5-` (Evaluation: Negative) they have tag `A5+` (Evaluation: Positive). Item 4 is removed on the grounds that the words *отремонтированный* (repaired) and *maintenance* do not have any tags in common – they appear ontologically too far apart from the point of view of the semantic tagger.

The core of the system's multilingual semantic tagging is a knowledge base in which single words and MWEs are mapped to their potential semantic field categories. Often a lexical item is mapped to multiple semantic categories, reflecting its potential multiple senses. In such cases, the tags are arranged by the order of likelihood of meanings, with the most prominent first.

3 Objective evaluation

In the *objective evaluation* we tested the performance of our system on a selection of indirect translation problems, extracted from a parallel corpus consisting mostly of articles from English and Russian newspapers (118,497 words in the R-E direction, 589,055 words in the E-R direction). It has been aligned on the sentence level by JAPA (Langlais et al., 1998), and further on the word level by GIZA++ (Och and Ney, 2003).

3.1 Comparative performance

The intuition behind the objective evaluation experiment is that the capacity of our tool to find indirect translation equivalents in comparable corpora can be compared with the results of automatic alignment of parallel texts used in translation models in SMT: one of the major advantages of the SMT paradigm is its ability to reuse indirect equivalents found in parallel corpora (equivalents that may never come up in hand-crafted dictionaries). Thus, automatically generated GIZA++ dictionaries with word alignment contain many examples of indirect translation equivalents.

We use these dictionaries to simulate the generator of translation classes *T*, which we recombine to construct their Cartesian product *P*, similarly to the procedure we use to generate the output of our system. However, the two approaches generate indirect translation equivalence hypotheses on the basis of radically different material: the GIZA dictionary uses evidence from parallel corpora of ex-

isting human translations, while our system recombines translation candidates on the basis of their distributional similarity in monolingual comparable corpora. Therefore we took GIZA as a baseline.

Translation problems for the objective evaluation experiment were manually extracted from two parallel corpora: a section of about 10,000 words of a corpus of English and Russian newspapers, which we also used to train GIZA, and a section of the same length from a corpus of interviews published on the Euronews.net website.

We selected expressions which represented cases of lexical transformations (as illustrated in Section 0), containing at least two content words both in the SL and TL. These expressions were converted into pairs of contextual descriptors – e.g., *recent success, reflect success* – and submitted to the system and to the GIZA dictionary. We compared the ability of our system and of GIZA to find indirect translation equivalents which matched the equivalents used by human translators. The output from both systems was checked to see whether it contained the contextual descriptors used by human translators. We submitted 388 pairs of descriptors extracted from the newspaper translation corpus and 174 pairs extracted from the Euronews interview corpus. Half of these pairs were Russian, and the other half English.

We computed recall figures for 2-word combinations of contextual descriptors and single descriptors within those combinations. We also show the recall of translation variants provided by the ORD on this data set. For example, for the query *недостает необходимого* ([it] is missing necessary [things]) human translators give the solution *lacking essentials*; the lemmatised descriptors are *lack* and *essential*. ORD returns direct translation equivalents *missing* and *necessary*. The GIZA dictionary in addition contains several translation equivalents for the second term (with alignment probabilities) including: *necessary* ~0.332*, need* ~0.226*, essential* ~0.023. Our system returns both descriptors used in human translation as a pair – *lack essential* (ranked 41 without filtering and 22 with the default semantic filter). Thus, for a 2-word combination of the descriptors only the output of our system matched the human solution, which we counted as one hit for the system and no hits for ORD or GIZA. For 1-word descriptors we counted 2 hits for our system (both words in the human solution are matched), and 1 hit for GIZA – it matches the word *essential* ~0.023 (which also illustrates its ability to find indirect translation equivalents).

	2w descriptors		**1w descriptors**	
	news	**interv**	**news**	**interv**
ORD	6.7%	4.6%	32.9%	29.3%
GIZA++	13.9%	3.4%	35.6%	29.0%
Our system	**21.9%**	**19.5%**	**55.8%**	**49.4%**

Table 1 Conservative estimate of recall

It can be seen from **Table 1** that for the newspaper corpus on which it was trained, GIZA covers a wider set of indirect translation variants than ORD. But our recall is even better both for 2-word and 1-word descriptors.

However, note that GIZA's ability to retrieve from the newspaper corpus certain indirect translation equivalents may be due to the fact that it has previously seen them frequently enough to generate a correct alignment and the corresponding dictionary entry.

The Euronews interview corpus was not used for training GIZA. It represents spoken language and is expected to contain more 'radical' transformations. The small decline in ORD figures here can be attributed to the fact that there is a difference in genre between written and spoken texts and consequently between transformation types in them. However, the performance of GIZA drops radically on unseen text and becomes approximately the same as the ORD.

This shows that indirect translation equivalents in the parallel corpus used for training GIZA are too sparse to be learnt one by one and successfully applied to unseen data, since solutions which fit one context do not necessarily suit others.

The performance of our system stays at about the same level for this new type of text; the decline in its performance is comparable to the decline in ORD figures, and can again be explained by the differences in genre.

3.2 Evaluation of hypothesis ranking

As we mentioned, correct ranking of translation candidates improves the usability of the system. Again, the objective evaluation experiment gives only a conservative estimate of ranking, because there may be many more useful indirect solutions further up the list in the output of the system which are legitimate variants of the solutions found in the

parallel corpus. Therefore, evaluation figures should be interpreted in a comparative rather then an absolute sense.

We use ranking by frequency as a baseline for comparing the ranking described in Section 2.3 – by distributional similarity between a candidate and the original query.

Table 2 shows the average rank of human solutions found in parallel corpora and the recall of these solutions for the top 300 examples. Since there are no substantial differences between the figures for the newspaper texts and for the interviews, we report the results jointly for 556 translation problems in both selections (lower rank figures are better).

	Recall	Average rank
2-word descriptors		
frequency (baseline)	16.7%	*rank=93.7*
distributional similarity	19.5%	*rank=**44.4***
sim. + semantic filter	14.4%	*rank=**26.7***
1-word descriptors		
frequency (baseline)	48.2%	*rank=42.7*
distributional similarity	52.8%	*rank=**21.6***
sim. + semantic filter	44.1%	*rank=**11.3***

Table 2 Ranking: frequency, similarity and filter

It can be seen from the table that ranking by similarity yields almost a twofold improvement for the average rank figures compared to the baseline. There is also a small improvement in recall, since there are more relevant examples that appear within the top 300 entries.

The semantic filter once again gives an almost twofold improvement in ranking, since it removes many noisy items. The average is now within the top 30 items, which means that there is a high chance that a translation solution will be displayed on the first screen. The price for improved ranking is decline in recall, since it may remove some relevant lexical transformations if they appear to be ontologically too far apart. But the decline is smaller: about 26.2% for 2-word descriptors and 16.5% for 1-word descriptors. The semantic filter is an optional tool, which can be used to great effect on noisy output: its improvement of ranking outweighs the decline in recall.

Note that the distribution of ranks is not normal, so in **Figure 1** we present frequency polygons for rank groups of 30 (which is the number of items that fit on a single screen, i.e., the number of items in the first group (r030) shows solutions that will be displayed on the first screen). The majority of solutions ranked by similarity appear high in the list (in fact, on the first two or three screens).

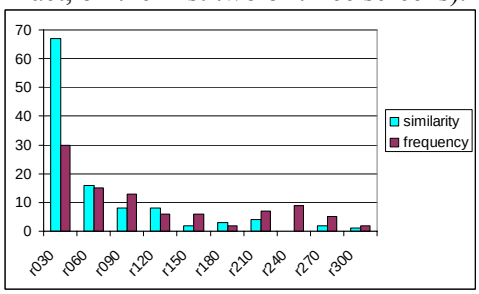

Figure 1 Frequency polygons for ranks

4 Subjective evaluation

The objective evaluation reported above uses a single reference translation and is correspondingly conservative in estimating the coverage of the system. However, many expressions studied have more than one fluent translation. For instance, *in poor repair* is not the only equivalent for the Russian expression *плохо отремонтированные*. It is also possible to translate it as *unsatisfactory condition, bad state of repair, badly in need of repair*, and so on. The objective evaluation shows that the system has been able to find the suggestion used by a particular translator for the problem studied. It does not tell us whether the system has found some other translations suitable for the context. Such legitimate translation variation implies that the performance of a system should be studied on the basis of multiple reference translations, though typically just two reference translations are used (Papineni, et al, 2001). This might be enough for the purposes of a fully automatic MT tool, but in the context of a translator's amanuensis which deals with expressions difficult for human translators, it is reasonable to work with a larger range of acceptable target expressions.

With this in mind we evaluated the performance of the tool with a panel of 12 professional translators. Problematic expressions were highlighted and the translators were asked to find suitable suggestions produced by the tool for these expressions and rank their usability on a scale from 1 to 5 (not acceptable to fully idiomatic, so 1 means that no usable translation was found at all).

Sentences themselves were selected from problems discussed on professional translation forums proz.com and forum.lingvo.ru. Given the range of corpora used in the system (reference and newspa-

per corpora), the examples were filtered to address expressions used in newspapers.

The goal of the subjective evaluation experiment was to establish the usefulness of the system for translators beyond the conservative estimate given by the objective evaluation. The intuition behind the experiment is that if there are several admissible translations for the SL contextual descriptors, and system output matches any of these solutions, then the system has generated something useful. Therefore, we computed recall on sets of human solutions rather than on individual solutions. We matched 210 different human solutions to 36 translation problems. To compute more realistic recall figures, we counted cases when the system output matches any of the human solutions in the set. **Table 3** compares the conservative estimate of the objective evaluation and the more realistic estimate on a single data set.

	2w default	**2w with sem filt**
Conservative	*32.4%; r=53.68*	*21.9%; r=34.67*
Realistic	***75.0%; r=7.48***	***61.1%; r=3.95***

Table 3 Recall and rank for 2-word descriptors

Since the data set is different, the figures for the conservative estimate are higher than those for the objective evaluation data set. However, the table shows the there is a gap between the conservative estimate and the realistic coverage of the translation problems by the system, and that real coverage of indirect translation equivalents is potentially much higher.

Table 4 shows averages (and standard deviation σ) of the usability scores divided in four groups: (1) solutions that are found both by our system and the ORD; (2) solutions found only by our system; (3) solutions found only by ORD (4) solutions found by neither:

	system (+)	**system (–)**
ORD (+)	4.03 (0.42)	3.62 (0.89)
ORD (–)	4.25 (0.79)	3.15 (1.15)

Table 4 Human scores and σ for system output

It can be seen from the table that human users find the system most useful for those problems where the solution does not match any of the direct dictionary equivalents, but is generated by the system.

5 Conclusions

We have presented a method of finding indirect translation equivalents in comparable corpora, and integrated it into a system which assists translators in indirect lexical transfer. The method outperforms established methods of extracting indirect translation equivalents from parallel corpora.

We can interpret these results as an indication that our method, rather than learning individual indirect transformations, models the entire family of transformations entailed by indirect lexical transfer. In other words it learns a translation strategy which is based on the distributional similarity of words in a monolingual corpus, and applies this strategy to novel, previously unseen examples.

The coverage of the tool and additional filtering techniques make it useful for professional translators in automating the search for non-trivial, indirect translation equivalents, especially equivalents for multiword expressions.

Abstract

Efficient decoding has been a fundamental problem in machine translation, especially with an integrated language model which is essential for achieving good translation quality. We develop faster approaches for this problem based on k-best parsing algorithms and demonstrate their effectiveness on both phrase-based and syntax-based MT systems. In both cases, our methods achieve significant speed improvements, often by more than a factor of ten, over the conventional beam-search method at the same levels of search error and translation accuracy.

1 Introduction

Recent efforts in statistical machine translation (MT) have seen promising improvements in output quality, especially the phrase-based models (Och and Ney, 2004) and syntax-based models (Chiang, 2005; Galley et al., 2006). However, efficient decoding under these paradigms, especially with integrated language models (LMs), remains a difficult problem. Part of the complexity arises from the expressive power of the translation model: for example, a phrase- or word-based model with full reordering has exponential complexity (Knight, 1999). The language model also, if fully integrated into the decoder, introduces an expensive overhead for maintaining target-language boundary words for dynamic programming (Wu, 1996; Och and Ney, 2004). In practice, one must prune the search space aggressively to reduce it to a reasonable size.

A much simpler alternative method to incorporate the LM is *rescoring*: we first decode without the LM (henceforth *−LM decoding*) to produce a k-best list of candidate translations, and then rerank the k-best list using the LM. This method runs much faster in practice but often produces a considerable number of search errors since the true best translation (taking LM into account) is often outside of the k-best list.

Cube pruning (Chiang, 2007) is a compromise between rescoring and full-integration: it rescores k subtranslations at each node of the forest, rather than only at the root node as in pure rescoring. By adapting the k-best parsing Algorithm 2 of Huang and Chiang (2005), it achieves significant speed-up over full-integration on Chiang's Hiero system.

We push the idea behind this method further and make the following contributions in this paper:

- We generalize cube pruning and adapt it to two systems very different from Hiero: a phrase-based system similar to Pharaoh (Koehn, 2004) and a tree-to-string system (Huang et al., 2006).
- We also devise a faster variant of cube pruning, called *cube growing*, which uses a lazy version of k-best parsing (Huang and Chiang, 2005) that tries to reduce k to the minimum needed at each node to obtain the desired number of hypotheses at the root.

Cube pruning and cube growing are collectively called *forest rescoring* since they both approximately rescore the packed forest of derivations from −LM decoding. In practice they run an order of

magnitude faster than full-integration with beam search, at the same level of search errors and translation accuracy as measured by BLEU.

2 Preliminaries

We establish in this section a unified framework for translation with an integrated n-gram language model in both phrase-based systems and syntax-based systems based on synchronous context-free grammars (SCFGs). An SCFG (Lewis and Stearns, 1968) is a context-free rewriting system for generating string pairs. Each rule $A \rightarrow \alpha, \beta$ rewrites a pair of nonterminals in both languages, where α and β are the source and target side components, and there is a one-to-one correspondence between the nonterminal occurrences in α and the nonterminal occurrences in β. For example, the following rule

$$\text{VP} \rightarrow \text{PP}\ ^{(1)}\ \text{VP}\ ^{(2)}, \quad \text{VP}\ ^{(2)}\ \text{PP}\ ^{(1)}$$

captures the swapping of VP and PP between Chinese (source) and English (target).

2.1 Translation as Deduction

We will use the following example from Chinese to English for both systems described in this section:

yǔ	*Shālóng*	*jǔxíng*	*le*	*huìtán*
with	Sharon	hold	[*past*]	meeting

'held a meeting with Sharon'

A typical phrase-based decoder generates partial target-language outputs in left-to-right order in the form of *hypotheses* (Koehn, 2004). Each hypothesis has a *coverage vector* capturing the source-language words translated so far, and can be extended into a longer hypothesis by a phrase-pair translating an uncovered segment.

This process can be formalized as a deductive system. For example, the following deduction step grows a hypothesis by the phrase-pair ⟨*yǔ Shālóng*, with Sharon⟩:

$$\frac{(\text{\_\_}\bullet\bullet\bullet) : (w, \text{“held a talk”})}{(\bullet\bullet\bullet\bullet\bullet) : (w + c, \text{“held a talk with Sharon”})} \quad (1)$$

where a • in the coverage vector indicates the source word at this position is "covered" (for simplicity we omit here the ending position of the last phrase which is needed for distortion costs), and where w and $w + c$ are the weights of the two hypotheses, respectively, with c being the cost of the phrase-pair.

Similarly, the decoding problem with SCFGs can also be cast as a deductive (parsing) system (Shieber et al., 1995). Basically, we parse the input string using the source projection of the SCFG while building the corresponding subtranslations in parallel. A possible deduction of the above example is notated:

$$\frac{(\text{PP}_{1,3}) : (w_1, t_1) \qquad (\text{VP}_{3,6}) : (w_2, t_2)}{(\text{VP}_{1,6}) : (w_1 + w_2 + c', t_2 t_1)} \quad (2)$$

where the subscripts denote indices in the input sentence just as in CKY parsing, w_1, w_2 are the scores of the two antecedent items, and t_1 and t_2 are the corresponding subtranslations. The resulting translation $t_2 t_1$ is the inverted concatenation as specified by the target-side of the SCFG rule with the additional cost c' being the cost of this rule.

These two deductive systems represent the search space of decoding without a language model. When one is instantiated for a particular input string, it defines a set of derivations, called a *forest*, represented in a compact structure that has a structure of a graph in the phrase-based case, or more generally, a *hypergraph* in both cases. Accordingly we call items like $(\bullet\bullet\bullet\bullet\bullet)$ and $(\text{VP}_{1,6})$ *nodes* in the forest, and instantiated deductions like

$$\begin{aligned} (\bullet\bullet\bullet\bullet\bullet) \quad &\rightarrow \quad (\text{\_\_}\bullet\bullet\bullet) \text{ with Sharon}, \\ (\text{VP}_{1,6}) \quad &\rightarrow \quad (\text{VP}_{3,6})\ (\text{PP}_{1,3}) \end{aligned}$$

we call *hyperedges* that connect one or more antecedent nodes to a consequent node.

2.2 Adding a Language Model

To integrate with a bigram language model, we can use the dynamic-programming algorithms of Och and Ney (2004) and Wu (1996) for phrase-based and SCFG-based systems, respectively, which we may think of as doing a finer-grained version of the deductions above. Each node v in the forest will be split into a set of augmented items, which we call *+LM items*. For phrase-based decoding, a +LM item has the form $(v\ ^{a})$ where a is the last word of the hypothesis. Thus a +LM version of Deduction (1) might be:

$$\frac{(\text{\_\_}\bullet\bullet\bullet\ ^{\text{talk}}) : (w, \text{“held a talk”})}{(\bullet\bullet\bullet\bullet\bullet\ ^{\text{Sharon}}) : (w', \text{“held a talk with Sharon”})}$$

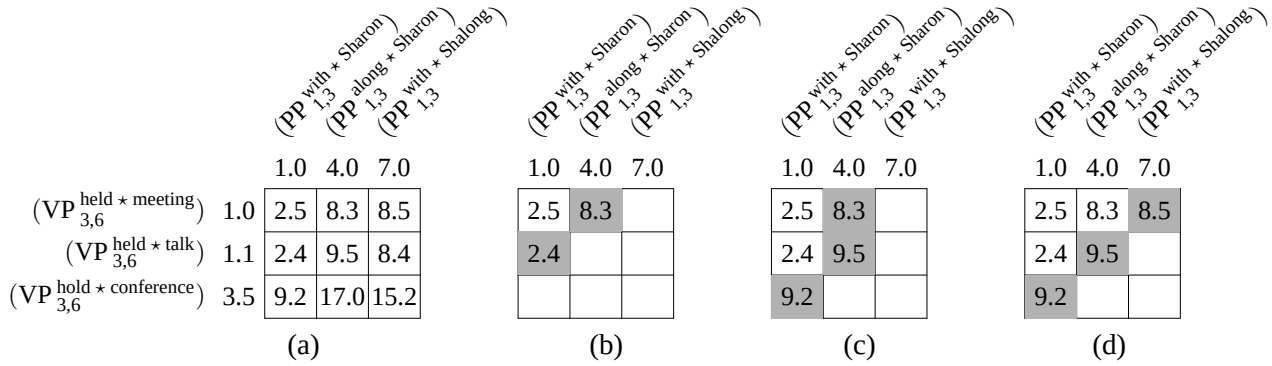

Figure 1: Cube pruning along one hyperedge. (a): the numbers in the grid denote the score of the resulting +LM item, including the combination cost; (b)-(d): the best-first enumeration of the top three items. Notice that the items popped in (b) and (c) are out of order due to the non-monotonicity of the combination cost.

where the score of the resulting +LM item

$$w' = w + c - \log P_{lm}(\text{with} \mid \text{talk})$$

now includes a *combination cost* due to the bigrams formed when applying the phrase-pair.

Similarly, a +LM item in SCFG-based models has the form $(v^{a \star b})$, where a and b are *boundary words* of the hypothesis string, and $\star$ is a placeholder symbol for an elided part of that string, indicating that a possible translation of the part of the input spanned by v starts with a and ends with b. An example +LM version of Deduction (2) is:

$$\frac{(\text{PP}_{1,3}^{\text{with} \star \text{Sharon}})\text{: } (w_1, t_1) \quad (\text{VP}_{3,6}^{\text{held} \star \text{talk}})\text{: } (w_2, t_2)}{(\text{VP}_{1,6}^{\text{held} \star \text{Sharon}})\text{: } (w, t_2 t_1)}$$

where $w = w_1 + w_2 + c' - \log P_{lm}(\text{with} \mid \text{talk})$ with a similar combination cost formed in combining adjacent boundary words of antecedents. This scheme can be easily extended to work with a general n-gram model (Chiang, 2007). The experiments in this paper use trigram models.

The conventional full-integration approach traverses the forest bottom-up and explores all possible +LM deductions along each hyperedge. The theoretical running time of this algorithm is $\mathcal{O}(|F||T|^{(m-1)})$ for phrase-based models, and $\mathcal{O}(|F||T|^{4(m-1)})$ for binary-branching SCFG-based models, where $|F|$ is the size of the forest, and $|T|$ is the number of possible target-side words. Even if we assume a constant number of translations for each word in the input, with a trigram model, this still amounts to $\mathcal{O}(n^{11})$ for SCFG-based models and $\mathcal{O}(2^n n^2)$ for phrase-based models.

3 Cube Pruning

Cube pruning (Chiang, 2007) reduces the search space significantly based on the observation that when the above method is combined with beam search, only a small fraction of the possible +LM items at a node will escape being pruned, and moreover we can select with reasonable accuracy those top-k items without computing all possible items first. In a nutshell, cube pruning works on the −LM forest, keeping at most k +LM items at each node, and uses the k-best parsing Algorithm 2 of Huang and Chiang (2005) to speed up the computation. For simplicity of presentation, we will use concrete SCFG-based examples, but the method applies to the general hypergraph framework in Section 2.

Consider Figure 1(a). Here $k = 3$ and we use $\mathbf{D}(v)$ to denote the top-k +LM items (in sorted order) of node v. Suppose we have computed $\mathbf{D}(u_1)$ and $\mathbf{D}(u_2)$ for the two antecedent nodes $u_1 = (\text{VP}_{3,6})$ and $u_2 = (\text{PP}_{1,3})$ respectively. Then for the consequent node $v = (\text{VP}_{1,6})$ we just need to derive the top-3 from the 9 combinations of $(D_i(u_1), D_j(u_2))$ with $i, j \in [1, 3]$. Since the antecedent items are sorted, it is very likely that the best consequent items in this grid lie towards the upper-left corner. This situation is very similar to k-best parsing and we can adapt the Algorithm 2 of Huang and Chiang (2005) here to explore this grid in a best-first order.

Suppose that the combination costs are negligible, and therefore the weight of a consequent item is just the product of the weights of the antecedent items.

```

Figure 2: Pseudocode for cube pruning.

Then we know that $D_1(v) = (D_1(u_1), D_1(u_2))$, the upper-left corner of the grid. Moreover, we know that $D_2(v)$ is the better of $(D_1(u_1), D_2(u_2))$ and $(D_2(u_1), D_1(u_2))$, the two neighbors of the upper-left corner. We continue in this way (see Figure 1(b)–(d)), enumerating the consequent items best-first while keeping track of a relatively small number of candidates (shaded cells in Figure 1(b), $cand$ in Figure 2) for the next-best item.

However, when we take into account the combination costs, this grid is no longer monotonic in general, and the above algorithm will not always enumerate items in best-first order. We can see this in the first iteration in Figure 1(b), where an item with score 2.5 has been enumerated even though there is an item with score 2.4 still to come. Thus we risk making more search errors than the full-integration method, but in practice the loss is much less significant than the speedup. Because of this disordering, we do not put the enumerated items directly into $\mathbf{D}(v)$; instead, we collect items in a buffer (buf in Figure 2) and re-sort the buffer into $\mathbf{D}(v)$ after it has accumulated k items.[1]

In general the grammar may have multiple rules that share the same source side but have different target sides, which we have treated here as separate hyperedges in the $-$LM forest. In Hiero, these hyperedges are processed as a single unit which we call a *hyperedge bundle*. The different target sides then constitute a third dimension of the grid, forming a cube of possible combinations (Chiang, 2007).

[1] Notice that different combinations might have the same resulting item, in which case we only keep the one with the better score (sometimes called *hypothesis recombination* in MT literature), so the number of items in $\mathbf{D}(v)$ might be less than k.

method	k-best	+LM rescoring...
rescoring	Alg. 3	only at the root node
cube pruning	Alg. 2	on-the-fly at each node
cube growing	Alg. 3	on-the-fly at each node

Table 1: Comparison of the three methods.

Now consider that there are many hyperedges that derive v, and we are only interested the top $+$LM items of v over all incoming hyperedges. Following Algorithm 2, we initialize the priority queue $cand$ with the upper-left corner item from each hyperedge, and proceed as above. See Figure 2 for the pseudocode for cube pruning. We use the notation $\langle e, \mathbf{j} \rangle$ to identify the derivation of v via the hyperedge e and the j_ith best subderivation of antecedent u_i ($1 \leq i \leq |\mathbf{j}|$). Also, we let $\mathbf{1}$ stand for a vector whose elements are all 1, and $\mathbf{b}^i$ for the vector whose members are all 0 except for the ith whose value is 1 (the dimensionality of either should be evident from the context). The heart of the algorithm is lines 10–12. Lines 10–11 move the best derivation $\langle e, \mathbf{j} \rangle$ from $cand$ to buf, and then line 12 pushes its successors $\{\langle e, \mathbf{j} + \mathbf{b}^i \rangle \mid i \in 1 \ldots |e|\}$ into $cand$.

4 Cube Growing

Although much faster than full-integration, cube pruning still computes a fixed amount of $+$LM items at each node, many of which will not be useful for arriving at the 1-best hypothesis at the root. It would be more efficient to compute as few $+$LM items at each node as are needed to obtain the 1-best hypothesis at the root. This new method, called *cube growing*, is a lazy version of cube pruning just as Algorithm 3 of Huang and Chiang (2005), is a lazy version of Algorithm 2 (see Table 1).

Instead of traversing the forest bottom-up, cube growing visits nodes recursively in depth-first order from the root node (Figure 4). First we call LAZYJTHBEST(TOP, 1), which uses the same algorithm as cube pruning to find the 1-best $+$LM item of the root node using the best $+$LM items of

	1.0	4.0	7.0
1.0	2.1	5.1	8.1
1.1	2.2	5.2	8.2
3.5	4.6	7.6	10.6

(a) h-values

1.0	4.0	7.0
2.5	8.3	
2.4		

(b) true costs

Figure 3: Example of cube growing along one hyperedge. (a): the $h(x)$ scores for the grid in Figure 1(a), assuming $h_{combo}(e) = 0.1$ for this hyperedge; (b) cube growing prevents early ranking of the top-left cell (2.5) as the best item in this grid.

the antecedent nodes. However, in this case the best +LM items of the antecedent nodes are not known, because we have not visited them yet. So we recursively invoke LAZYJTHBEST on the antecedent nodes to obtain them as needed. Each invocation of LAZYJTHBEST(v, j) will recursively call itself on the antecedents of v until it is confident that the jth best +LM item for node v has been found.

Consider again the case of one hyperedge e. Because of the nonmonotonicity caused by combination costs, the first +LM item ($\langle e, \mathbf{1} \rangle$) popped from $cand$ is not guaranteed to be the best of all combinations along this hyperedge (for example, the top-left cell of 2.5 in Figure 1 is not the best in the grid). So we cannot simply enumerate items just as they come off of $cand$.[2] Instead, we need to store up popped items in a buffer buf, just as in cube pruning, and enumerate an item only when we are confident that it will never be surpassed in the future. In other words, we would like to have an estimate of the best item not explored yet (analogous to the heuristic function in A* search). If we can establish a lower bound $h_{combo}(e)$ on the combination cost of any +LM deduction via hyperedge e, then we can form a monotonic grid (see Figure 3(a)) of lower bounds on the grid of combinations, by using $h_{combo}(e)$ in place of the true combination cost for each +LM item x in the grid; call this lower bound $h(x)$.

Now suppose that the gray-shaded cells in Figure 3(a) are the members of $cand$. Then the minimum of $h(x)$ over the items in $cand$, in this example, $\min\{2.2, 5.1\} = 2.2$ is a lower bound on the cost of any item in the future for the hyperedge e. Indeed, if $cand$ contains items from multiple hyperedges for a single consequent node, this is still a valid lower bound. More formally:

[2] If we did, then the out-of-order enumeration of +LM items at an antecedent node would cause an entire row or column in the grid to be disordered at the consequent node, potentially leading to a multiplication of search errors.

```
1: procedure LAZYJTHBEST(v, j)
2:     if cand[v] is undefined then
3:         cand[v] ← ∅
4:         FIRE(e, 1, cand) foreach e ∈ IN(v)
5:         buf[v] ← ∅
6:     while |D(v)| < j and |buf[v]| + |D(v)| < k and
       |cand[v]| > 0 do
7:         item ← POP-MIN(cand[v])
8:         PUSH(item, buf[v])
9:         PUSHSUCC(item, cand[v])
10:        bound ← min{h(x) | x ∈ cand[v]}
11:        ENUM(buf[v], D(v), bound)
12:    ENUM(buf[v], D(v), +∞)
13: procedure FIRE(e, j, cand)
14:    e is v → u_1 ... u_|e|
15:    for i in 1 ... |e| do
16:        LAZYJTHBEST(u_i, j_i)
17:        if |D(u_i)| < j_i then return
18:    PUSH(⟨e, j⟩, cand)
19: procedure PUSHSUCC(⟨e, j⟩, cand)
20:    FIRE(e, j + b^i, cand) foreach i in 1 ... |e|
21: procedure ENUM(buf, D, bound)
22:    while |buf| > 0 and MIN(buf) < bound do
23:        append POP-MIN(buf) to D
```

Figure 4: Pseudocode of cube growing.

Lemma 1. *For each node v in the forest, the term*

$$bound = \min_{x \in cand[v]} h(x) \tag{3}$$

is a lower bound on the true cost of any future item that is yet to be explored for v.

Proof. For any item x that is not explored yet, the true cost $c(x) \geq h(x)$, by the definition of h. And there exists an item $y \in cand[v]$ along the same hyperedge such that $h(x) \geq h(y)$, due to the monotonicity of h within the grid along one hyperedge. We also have $h(y) \geq bound$ by the definition of $bound$. Therefore $c(x) \geq bound$. □

Now we can safely pop the best item from buf if its true cost MIN(buf) is better than $bound$ and pass it up to the consequent node (lines 21–23); but otherwise, we have to wait for more items to accumulate in buf to prevent a potential search error, for example, in the case of Figure 3(b), where the top-left cell

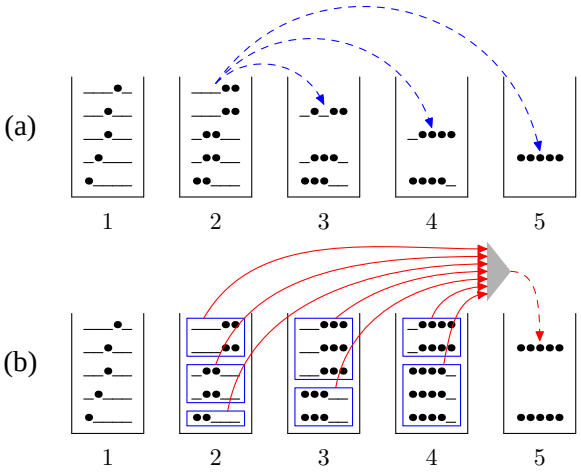

Figure 5: (a) Pharaoh expands the hypotheses in the current bin (#2) into longer ones. (b) In Cubit, hypotheses in previous bins are fed via hyperedge bundles (solid arrows) into a priority queue (shaded triangle), which empties into the current bin (#5).

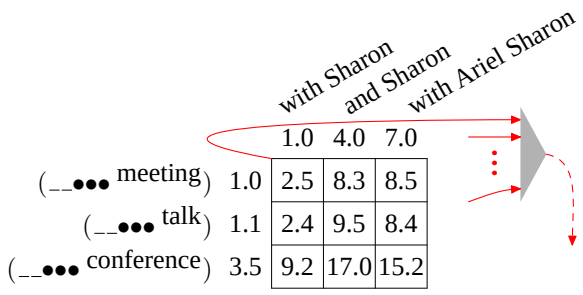

Figure 6: A hyperedge bundle represents all +LM deductions that derives an item in the current bin from the same coverage vector (see Figure 5). The phrases on the top denote the target-sides of applicable phrase-pairs sharing the same source-side.

(2.5) is worse than the current $bound$ of 2.2. The update of $bound$ in each iteration (line 10) can be efficiently implemented by using another heap with the same contents as $cand$ but prioritized by h instead. In practice this is a negligible overhead on top of cube pruning.

We now turn to the problem of estimating the heuristic function h_{combo}. In practice, computing true lower bounds of the combination costs is too slow and would compromise the speed up gained from cube growing. So we instead use a much simpler method that just calculates the minimum combination cost of each hyperedge in the top-i derivations of the root node in $-$LM decoding. This is just an approximation of the true lower bound, and bad estimates can lead to search errors. However, the hope is that by choosing the right value of i, these estimates will be accurate enough to affect the search quality only slightly, which is analogous to "almost admissible" heuristics in A* search (Soricut, 2006).

5 Experiments

We test our methods on two large-scale English-to-Chinese translation systems: a phrase-based system and our tree-to-string system (Huang et al., 2006).

5.1 Phrase-based Decoding

We implemented *Cubit*, a Python clone of the Pharaoh decoder (Koehn, 2004),[3] and adapted cube pruning to it as follows. As in Pharaoh, each bin i contains hypotheses (i.e., +LM items) covering i words on the source-side. But at each bin (see Figure 5), all +LM items from previous bins are first partitioned into $-$LM items; then the hyperedges leading from those $-$LM items are further grouped into hyperedge bundles (Figure 6), which are placed into the priority queue of the current bin.

Our data preparation follows Huang et al. (2006): the training data is a parallel corpus of 28.3M words on the English side, and a trigram language model is trained on the Chinese side. We use the same test set as (Huang et al., 2006), which is a 140-sentence subset of the NIST 2003 test set with 9–36 words on the English side. The weights for the log-linear model are tuned on a separate development set. We set the decoder phrase-table limit to 100 as suggested in (Koehn, 2004) and the distortion limit to 4.

Figure 7(a) compares cube pruning against full-integration in terms of search quality vs. search efficiency, under various pruning settings (threshold beam set to 0.0001, stack size varying from 1 to 200). Search quality is measured by average model cost per sentence (lower is better), and search efficiency is measured by the average number of hypotheses generated (smaller is faster). At each level

[3] In our tests, Cubit always obtains a BLEU score within 0.004 of Pharaoh's (Figure 7(b)). Source code available at `http://www.cis.upenn.edu/~lhuang3/cubit/`

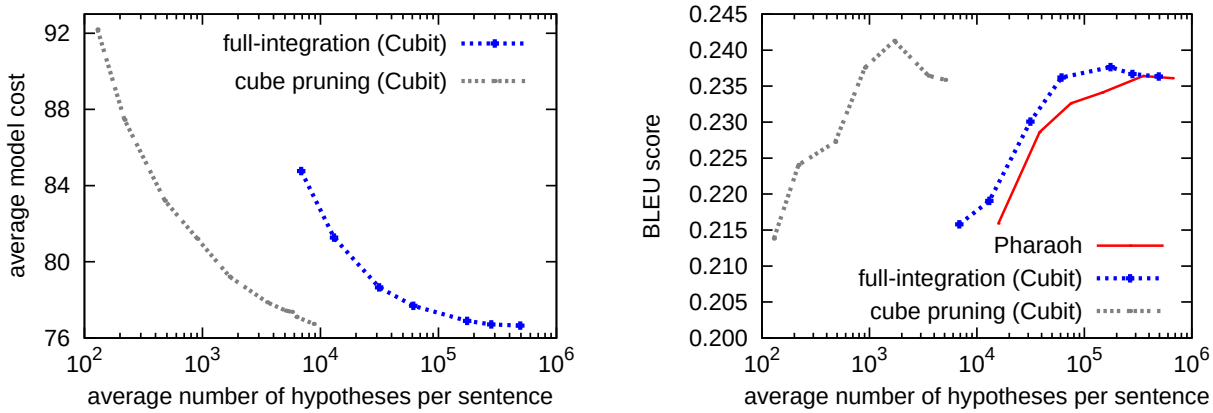

Figure 7: Cube pruning vs. full-integration (with beam search) on phrase-based decoding.

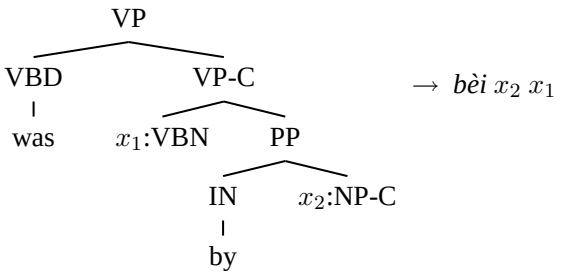
of search quality, the speed-up is always better than a factor of 10. The speed-up at the lowest search-error level is a factor of 32. Figure 7(b) makes a similar comparison but measures search quality by BLEU, which shows an even larger relative speed-up for a given BLEU score, because translations with very different model costs might have similar BLEU scores. It also shows that our full-integration implementation in Cubit faithfully reproduces Pharaoh's performance. Fixing the stack size to 100 and varying the threshold yielded a similar result.

5.2 Tree-to-string Decoding

In tree-to-string (also called *syntax-directed*) decoding (Huang et al., 2006; Liu et al., 2006), the source string is first parsed into a tree, which is then recursively converted into a target string according to transfer rules in a synchronous grammar (Galley et al., 2006). For instance, the following rule translates an English passive construction into Chinese:

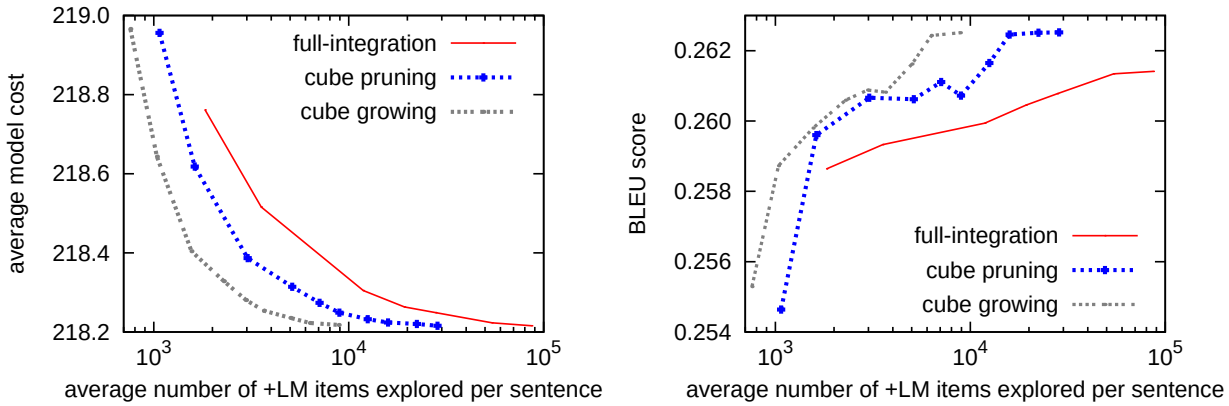


Our tree-to-string system performs slightly better than the state-of-the-art phrase-based system Pharaoh on the above data set. Although different from the SCFG-based systems in Section 2, its derivation trees remain context-free and the search space is still a hypergraph, where we can adapt the methods presented in Sections 3 and 4.

The data set is same as in Section 5.1, except that we also parsed the English-side using a variant of the Collins (1997) parser, and then extracted 24.7M tree-to-string rules using the algorithm of (Galley et al., 2006). Since our tree-to-string rules may have many variables, we first binarize each hyperedge in the forest on the target projection (Huang, 2007). All the three +LM decoding methods to be compared below take these binarized forests as input. For cube growing, we use a non-duplicate k-best method (Huang et al., 2006) to get 100-best unique translations according to −LM to estimate the lower-bound heuristics.[4] This preprocessing step takes on average 0.12 seconds per sentence, which is negligible in comparison to the +LM decoding time.

Figure 8(a) compares cube growing and cube pruning against full-integration under various beam settings in the same fashion of Figure 7(a). At the lowest level of search error, the relative speed-up from cube growing and cube pruning compared with full-integration is by a factor of 9.8 and 4.1, respectively. Figure 8(b) is a similar comparison in terms of BLEU scores and shows an even bigger advantage of cube growing and cube pruning over the baseline.

[4] If a hyperedge is not represented at all in the 100-best −LM derivations at the root node, we use the 1-best −LM derivation of this hyperedge instead. Here, rules that share the same source side but have different target sides are treated as separate hyperedges, not collected into hyperedge bundles, since grouping becomes difficult after binarization.



(a) (b)

Figure 8: Cube growing vs. cube pruning vs. full-integration (with beam search) on tree-to-string decoding.

6 Conclusions and Future Work

We have presented a novel extension of cube pruning called *cube growing*, and shown how both can be seen as general *forest rescoring* techniques applicable to both phrase-based and syntax-based decoding. We evaluated these methods on large-scale translation tasks and observed considerable speed improvements, often by more than a factor of ten. We plan to investigate how to adapt cube growing to phrase-based and hierarchical phrase-based systems.

These forest rescoring algorithms have potential applications to other computationally intensive tasks involving combinations of different models, for example, head-lexicalized parsing (Collins, 1997); joint parsing and semantic role labeling (Sutton and McCallum, 2005); or tagging and parsing with non-local features. Thus we envision forest rescoring as being of general applicability for reducing complicated search spaces, as an alternative to simulated annealing methods (Kirkpatrick et al., 1983).

Statistical Machine Translation through Global Lexical Selection and Sentence Reconstruction

Srinivas Bangalore, Patrick Haffner, Stephan Kanthak
AT&T Labs - Research
180 Park Ave, Florham Park, NJ 07932
{srini,haffner,skanthak}@research.att.com

Abstract

Machine translation of a source language sentence involves selecting appropriate target language words and ordering the selected words to form a well-formed target language sentence. Most of the previous work on statistical machine translation relies on (*local*) associations of target words/phrases with source words/phrases for lexical selection. In contrast, in this paper, we present a novel approach to lexical selection where the target words are associated with the entire source sentence (*global*) without the need to compute local associations. Further, we present a technique for reconstructing the target language sentence from the selected words. We compare the results of this approach against those obtained from a finite-state based statistical machine translation system which relies on local lexical associations.

1 Introduction

Machine translation can be viewed as consisting of two subproblems: (a) lexical selection, where appropriate target language lexical items are chosen for each source language lexical item and (b) lexical reordering, where the chosen target language lexical items are rearranged to produce a meaningful target language string. Most of the previous work on statistical machine translation, as exemplified in (Brown et al., 1993), employs word-alignment algorithm (such as GIZA++ (Och and Ney, 2003)) that provides local associations between source and target words. The source-to-target word alignments are sometimes augmented with target-to-source word alignments in order to improve precision. Further, the word-level alignments are extended to phrase-level alignments in order to increase the extent of local associations. The phrasal associations compile some amount of (*local*) lexical reordering of the target words – those permitted by the size of the phrase. Most of the state-of-the-art machine translation systems use phrase-level associations in conjunction with a target language model to produce sentences. There is relatively little emphasis on (*global*) lexical reordering other than the local reorderings permitted within the phrasal alignments. A few exceptions are the hierarchical (possibly syntax-based) transduction models (Wu, 1997; Alshawi et al., 1998; Yamada and Knight, 2001; Chiang, 2005) and the string transduction models (Kanthak et al., 2005).

In this paper, we present an alternate approach to lexical selection and lexical reordering. For lexical selection, in contrast to the local approaches of associating target to source words, we associate target words to the entire source sentence. The intuition is that there may be lexico-syntactic features of the source sentence (not necessarily a single source word) that might trigger the presence of a target word in the target sentence. Furthermore, it might be difficult to exactly associate a target word to a source word in many situations – (a) when the translations are not exact but paraphrases (b) when the target language does not have one lexical item to express the same concept that is expressed by a source word. Extending word to phrase alignments attempts to address some of these situations while alleviating the noise in word-level alignments.

As a consequence of this global lexical selection approach, we no longer have a tight association between source and target language words. The result of lexical selection is simply a bag of words in the target language and the sentence has to be reconstructed using this bag of words. The words in the bag, however, might be enhanced with rich syntactic information that could aid in reconstructing the target sentence. This approach to lexical selection and

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 152–159,
Prague, Czech Republic, June 2007.

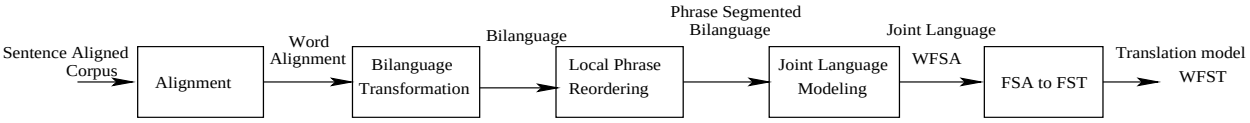

Figure 1: Training phases for our system

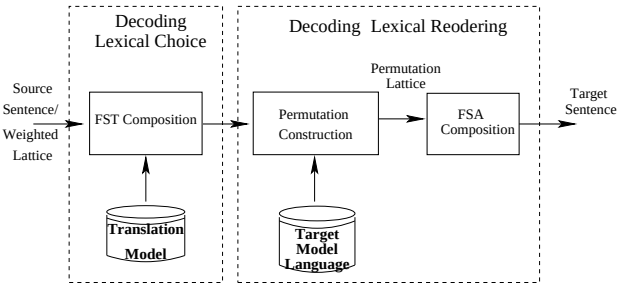

Figure 2: Decoding phases for our system

sentence reconstruction has the potential to circumvent limitations of word-alignment based methods for translation between languages with significantly different word order (e.g. English-Japanese).

In this paper, we present the details of training a global lexical selection model using classification techniques and sentence reconstruction models using permutation automata. We also present a stochastic finite-state transducer (SFST) as an example of an approach that relies on local associations and use it to compare and contrast our approach.

2 SFST Training and Decoding

In this section, we describe each of the components of our SFST system shown in Figure 1. The SFST approach described here is similar to the one described in (Bangalore and Riccardi, 2000) which has subsequently been adopted by (Banchs et al., 2005).

2.1 Word Alignment

The first stage in the process of training a lexical selection model is obtaining an alignment function (f) that given a pair of source ($s_1 s_2 \ldots s_n$) and target ($t_1 t_2 \ldots t_m$) language sentences, maps source language word subsequences into target language word subsequences, as shown below.

$$\forall i \exists j (f(s_i) = t_j \vee f(s_i) = \epsilon) \quad (1)$$

For the work reported in this paper, we have used the GIZA++ tool (Och and Ney, 2003) which implements a string-alignment algorithm. GIZA++ alignment however is asymmetric in that the word mappings are different depending on the direction of alignment – source-to-target or target-to-source. Hence in addition to the functions f as shown in Equation 1 we train another alignment function g :

$$\forall j \exists i (g(t_j) = s_i \vee g(t_j) = \epsilon) \quad (2)$$

English: I need to make a collect call
Japanese: 私は　コレクト　コールを かける　必要があります
Alignment: 1 5 0 3 0 2 4

Figure 3: Example bilingual texts with alignment information

I:私は need:必要があります to:ϵ make:コールを
a:ϵ collect_コレクト call_かける

Figure 4: Bilanguage strings resulting from alignments shown in Figure 3.

2.2 Bilanguage Representation

From the alignment information (see Figure 3), we construct a bilanguage representation of each sentence in the bilingual corpus. The bilanguage string consists of source-target symbol pair sequences as shown in Equation 3. Note that the tokens of a bilanguage could be either ordered according to the word order of the source language or ordered according to the word order of the target language.

$$\begin{aligned} B^f &= b_1^f\, b_2^f\, \ldots\, b_m^f \quad (3) \\ b_i^f &= (s_{i-1}; s_i, f(s_i))\ \ if\ \ f(s_{i-1}) = \epsilon \\ &= (s_i, f(s_{i-1}); f(s_i))\ \ if\ \ s_{i-1} = \epsilon \\ &= (s_i, f(s_i))\ \ otherwise \end{aligned}$$

Figure 4 shows an example alignment and the source-word-ordered bilanguage strings corresponding to the alignment shown in Figure 3.

We also construct a bilanguage using the alignment function g similar to the bilanguage using the alignment function f as shown in Equation 3.

Thus, the bilanguage corpus obtained by combining the two alignment functions is $B = B_f \cup B_g$.

2.3 Bilingual Phrases and Local Reordering

While word-to-word translation only approximates the lexical selection process, phrase-to-phrase mapping can greatly improve the translation of collocations, recurrent strings, etc. Using phrases also allows words within the phrase to be reordered into the correct target language order, thus partially solving the reordering problem. Additionally, SFSTs can take advantage of phrasal correlations to improve the computation of the probability $P(W_S, W_T)$.

The bilanguage representation could result in some source language phrases to be mapped to ϵ

(empty target phrase). In addition to these phrases, we compute subsequences of a given length k on the bilanguage string and for each subsequence we reorder the target words of the subsequence to be in the same order as they are in the target language sentence corresponding to that bilanguage string. This results in a retokenization of the bilanguage into tokens of source-target phrase pairs.

2.4 SFST Model

From the bilanguage corpus B, we train an n-gram language model using standard tools (Goffin et al., 2005). The resulting language model is represented as a weighted finite-state automaton ($S \times T \rightarrow [0,1]$). The symbols on the arcs of this automaton ($s_i\_t_i$) are interpreted as having the source and target symbols (s_i:t_i), making it into a weighted finite-state transducer ($S \rightarrow T \times [0,1]$) that provides a weighted string-to-string transduction from S into T :

$$T^* = \underset{T}{argmax}\ P(s_i, t_i | s_{i-1}, t_{i-1} \ldots s_{i-n-1}, t_{i-n-1})$$

2.5 Decoding

Since we represent the translation model as a weighted finite-state transducer ($TransFST$), the decoding process of translating a new source input (sentence or weighted lattice (I_s)) amounts to a transducer composition ($\circ$) and selection of the best probability path ($BestPath$) resulting from the composition and projecting the target sequence (π_1).

$$T^* = \pi_1(BestPath(I_s \circ TransFST)) \qquad (4)$$

However, we have noticed that on the development corpus, the decoded target sentence is typically shorter than the intended target sentence. This mismatch may be due to the incorrect estimation of the back-off events and their probabilities in the training phase of the transducer. In order to alleviate this mismatch, we introduce a negative word insertion penalty model as a mechanism to produce more words in the target sentence.

2.6 Word Insertion Model

The word insertion model is also encoded as a weighted finite-state automaton and is included in the decoding sequence as shown in Equation 5. The word insertion FST has one state and $|\sum_T|$ number of arcs each weighted with a λ weight representing the word insertion cost. On composition as shown in Equation 5, the word insertion model penalizes or rewards paths which have more words depending on whether λ is positive or negative value.

$$T^* = \pi_1(BestPath(I_s \circ TransFST \circ WIP)) \qquad (5)$$

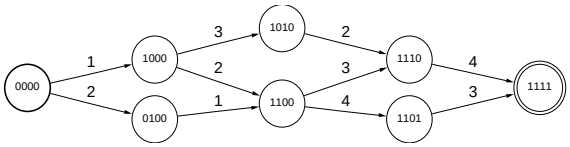

Figure 5: Locally constraint permutation automaton for a sentence with 4 words and window size of 2.

2.7 Global Reordering

Local reordering as described in Section 2.3 is restricted by the window size k and accounts only for different word order within phrases. As permuting non-linear automata is too complex, we apply global reordering by permuting the words of the best translation and weighting the result by an n-gram language model (see also Figure 2):

$$T^* = BestPath(perm(T') \circ LM_t) \qquad (6)$$

Even the size of the minimal permutation automaton of a linear automaton grows exponentially with the length of the input sequence. While decoding by composition simply resembles the principle of memoization (i.e. here: all state hypotheses of a whole sentence are kept in memory), it is necessary to either use heuristic forward pruning or constrain permutations to be within a local window of adjustable size (also see (Kanthak et al., 2005)). We have chosen to constrain permutations here. Figure 5 shows the resulting minimal permutation automaton for an input sequence of 4 words and a window size of 2.

Decoding ASR output in combination with global reordering uses n-best lists or extracts them from lattices first. Each entry of the n-best list is decoded separately and the best target sentence is picked from the union of the n intermediate results.

3 Discriminant Models for Lexical Selection

The approach from the previous section is a generative model for statistical machine translation relying on local associations between source and target sentences. Now, we present our approach for a *global* lexical selection model based on discriminatively trained classification techniques. Discriminant modeling techniques have become the dominant method for resolving ambiguity in speech and other NLP tasks, outperforming generative models. Discriminative training has been used mainly for translation model combination (Och and Ney, 2002) and with the exception of (Wellington et al., 2006; Tillmann and Zhang, 2006), has not been used to directly train parameters of a translation model. We expect discriminatively trained global lexical selection models

to outperform generatively trained local lexical selection models as well as provide a framework for incorporating rich morpho-syntactic information.

Statistical machine translation can be formulated as a search for the best target sequence that maximizes $P(T|S)$, where S is the source sentence and T is the target sentence. Ideally, $P(T|S)$ should be estimated directly to maximize the conditional likelihood on the training data (discriminant model). However, T corresponds to a sequence with a exponentially large combination of possible labels, and traditional classification approaches cannot be used directly. Although Conditional Random Fields (CRF) (Lafferty et al., 2001) train an exponential model at the sequence level, in translation tasks such as ours the computational requirements of training such models are prohibitively expensive.

We investigate two approaches to approximating the string level global classification problem, using different independence assumptions. A comparison of the two approaches is summarized in Table 1.

3.1 Sequential Lexical Choice Model

In the first approach, we formulate a sequential local classification problem as shown in Equations 7. This approach is similar to the SFST approach in that it relies on local associations between the source and target words(phrases). We can use a conditional model (instead of a joint model as before) and the parameters are determined using discriminant training which allows for richer conditioning context.

$$P(T|S) = \prod_{i=1}^{N} P(t_i|\Phi(S,i)) \qquad (7)$$

where $\Phi(S,i)$ is a set of features extracted from the source string S (shortened as Φ in the rest of the section).

3.2 Bag-of-Words Lexical Choice Model

The sequential lexical choice model described in the previous section treats the selection of a lexical choice for a source word in the local lexical context as a classification task. The data for training such models is derived from word alignments obtained by e.g. GIZA++. The decoded target lexical items have to be further reordered, but for closely related languages the reordering could be incorporated into correctly ordered target phrases as discussed previously.

For pairs of languages with radically different word order (e.g. English-Japanese), there needs to be a global reordering of words similar to the case in the SFST-based translation system. Also, for such differing language pairs, the alignment algorithms such as GIZA++ perform poorly.

These observations prompted us to formulate the lexical choice problem *without* the need for word alignment information. We require a sentence aligned corpus as before, but we treat the target sentence as a bag-of-words or BOW assigned to the source sentence. The goal is, given a source sentence, to estimate the probability that we find a given word in the target sentence. This is why, instead of producing a target sentence, what we initially obtain is a target bag of words. Each word in the target vocabulary is detected independently, so we have here a very simple use of binary static classifiers. Training sentence pairs are considered as positive examples when the word appears in the target, and negative otherwise. Thus, the number of training examples equals the number of sentence pairs, in contrast to the sequential lexical choice model which has one training example for each token in the bilingual training corpus. The classifier is trained with n-gram features ($BOgrams(S)$) from the source sentence. During decoding the words with conditional probability greater than a threshold θ are considered as the result of lexical choice decoding.

$$BOW_T^* = \{t|P(t|BOgrams(S)) > \theta\} \qquad (8)$$

For reconstructing the proper order of words in the target sentence we consider all permutations of words in BOW_T^* and weight them by a target language model. This step is similar to the one described in Section 2.7. The BOW approach can also be modified to allow for length adjustments of target sentences, if we add optional deletions in the final step of permutation decoding. The parameter θ and an additional word deletion penalty can then be used to adjust the length of translated outputs. In Section 6, we discuss several issues regarding this model.

4 Choosing the classifier

This section addresses the choice of the classification technique, and argues that one technique that yields excellent performance while scaling well is *binary maximum entropy (Maxent)* with *L1-regularization*.

4.1 Multiclass vs. Binary Classification

The Sequential and BOW models represent two different classification problems. In the sequential model, we have a *multiclass* problem where each class t_i is exclusive, therefore, all the classifier outputs $P(t_i|\Phi)$ must be jointly optimized such that

Table 1: A comparison of the sequential and bag-of-words lexical choice models

	Sequential Lexical Model	**Bag-of-Words Lexical Model**
Output target	Target word for each source position i	Target word given a source sentence
Input features	$BOgram(S, i-d, i+d)$: bag of n-grams in source sentence in the interval $[i-d, i+d]$	$BOgram(S, 0, \|S\|)$: bag of n-grams in source sentence
Probabilities	$P(t_i \| BOgram(S, i-d, i+d))$ Independence assumption between the labels	$P(BOW(T) \| BOgram(S, 0, \|S\|))$
Number of classes	One per target word or phrase	
Training samples	One per source token	One per sentence
Preprocessing	Source/Target *word* alignment	Source/Target *sentence* alignment

$\sum_i P(t_i|\Phi) = 1$. This can be problematic: with one classifier per word in the vocabulary, even allocating the memory during training may exceed the memory capacity of current computers.

In the BOW model, each class can be detected independently, and two different classes can be detected at the same time. This is known as the 1-vs-other scheme. The key advantage over the multiclass scheme is that not all classifiers have to reside in memory at the same time during training which allows for parallelization. Fortunately for the sequential model, we can decompose a multiclass classification problem into separate 1-vs-other problems. In theory, one has to make an additional independence assumption and the problem statement becomes different. Each output label t is projected into a bit string with components $b_j(t)$ where probability of each component is estimated independently:

$$P(b_j(t)|\Phi) = 1 - P(\bar{b}_j(t)|\Phi) = \frac{1}{1 + e^{-(\lambda_j - \lambda_{\bar{j}}) \cdot \Phi}}$$

In practice, despite the approximation, the 1-vs-other scheme has been shown to perform as well as the multiclass scheme (Rifkin and Klautau, 2004). As a consequence, we use the same type of binary classifier for the sequential and the BOW models.

The excellent results recently obtained with the SEARN algorithm (Daume et al., 2007) also suggest that binary classifiers, when properly trained and combined, seem to be capable of matching more complex *structured* output approaches.

4.2 Geometric vs. Probabilistic Interpretation

We separate the most popular classification techniques into two broad categories:

- Geometric approaches maximize the width of a separation margin between the classes. The most popular method is the Support Vector Machine (SVM) (Vapnik, 1998).
- Probabilistic approaches maximize the conditional likelihood of the output class given the input features. This logistic regression is also called Maxent as it finds the distribution with *maximum entropy* that properly estimates the average of each feature over the training data (Berger et al., 1996).

In previous studies, we found that the best accuracy is achieved with non-linear (or kernel) SVMs, at the expense of a high test time complexity, which is unacceptable for machine translation. Linear SVMs and regularized Maxent yield similar performance. In theory, Maxent training, which scales linearly with the number of examples, is faster than SVM training, which scales quadratically with the number of examples. In our first experiments with lexical choice models, we observed that Maxent slightly outperformed SVMs. Using a single threshold with SVMs, some classes of words were over-detected. This suggests that, as theory predicts, SVMs do not properly approximate the posterior probability. We therefore chose to use Maxent as the best probability approximator.

4.3 L1 vs. L2 regularization

Traditionally, Maxent is regularized by imposing a Gaussian prior on each weight: this L2 regularization finds the solution with the smallest possible weights. However, on tasks like machine translation with a very large number of input features, a Laplacian L1 regularization that also attempts to maximize the number of zero weights is highly desirable.

A new L1-regularized Maxent algorithms was proposed for density estimation (Dudik et al., 2004) and we adapted it to classification. We found this algorithm to converge faster than the current state-of-the-art in Maxent training, which is L2-regularized L-BFGS (Malouf, 2002)[1]. Moreover, the number of trained parameters is considerably smaller.

5 Data and Experiments

We have performed experiments on the IWSLT06 Chinese-English training and development sets from

[1]We used the implementation available at http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html

Table 2: Statistics of training and development data from 2005/2006 (* = first of multiple translations only).

	Training (2005)		Dev 2005		Dev 2006	
	Chinese	English	Chinese	English	Chinese	English
Sentences	46,311		506		489	
Running Words	351,060	376,615	3,826	3,897	5,214	6,362*
Vocabulary	11,178	11,232	931	898	1,136	1,134*
Singletons	4,348	4,866	600	538	619	574*
OOVs [%]	-	-	0.6	0.3	0.9	1.0
ASR WER [%]	-	-	-	-	25.2	-
Perplexity	-	-	33	-	86	-
# References	-	-	16		7	

2005 and 2006. The data are traveler task expressions such as seeking directions, expressions in restaurants and travel reservations. Table 2 presents some statistics on the data sets. It must be noted that while the 2005 development set matches the training data closely, the 2006 development set has been collected separately and shows slightly different statistics for average sentence length, vocabulary size and out-of-vocabulary words. Also the 2006 development set contains no punctuation marks in Chinese, but the corresponding English translations have punctuation marks. We also evaluated our models on the Chinese speech recognition output and we report results using 1-best with a word error rate of 25.2%.

For the experiments, we tokenized the Chinese sentences into character strings and trained the models discussed in the previous sections. Also, we trained a punctuation prediction model using Maxent framework on the Chinese character strings in order to insert punctuation marks into the 2006 development data set. The resulting character string with punctuation marks is used as input to the translation decoder. For the 2005 development set, punctuation insertion was not needed since the Chinese sentences already had the true punctuation marks.

In Table 3 we present the results of the three different translation models – FST, Sequential Maxent and BOW Maxent. There are a few interesting observations that can be made based on these results. First, on the 2005 development set, the sequential Maxent model outperforms the FST model, even though the two models were trained starting from the same GIZA++ alignment. The difference, however, is due to the fact that Maxent models can cope with increased lexical context[2] and the parameters of the model are discriminatively trained. The more surprising result is that the BOW Maxent model significantly outperforms the sequential Maxent model. The reason is that the sequential Maxent model relies on the word alignment, which, if erroneous, results in incorrect predictions by the sequential Maxent model. The BOW model does not rely on the word-level alignment and can be interpreted as a discriminatively trained model of dictionary lookup for a target word in the context of a source sentence.

[2]We use 6 words to the left and right of a source word for sequential Maxent, but only 2 preceding source and target words for FST approach.

Table 3: Results (mBLEU) scores for the three different models on the transcriptions for development set 2005 and 2006 and ASR 1-best for development set 2006.

	Dev 2005	Dev 2006	
	Text	Text	ASR 1-best
FST	51.8	19.5	16.5
Seq. Maxent	53.5	19.4	16.3
BOW Maxent	59.9	19.3	16.6

As indicated in the data release document, the 2006 development set was collected differently compared to the one from 2005. Due to this mismatch, the performance of the Maxent models are not very different from the FST model, indicating the lack of good generalization across different genres. However, we believe that the Maxent framework allows for incorporation of linguistic features that could potentially help in generalization across genres. For translation of ASR 1-best, we see a systematic degradation of about 3% in mBLEU score compared to translating the transcription.

In order to compensate for the mismatch between the 2005 and 2006 data sets, we computed a 10-fold average mBLEU score by including 90% of the 2006 development set into the training set and using 10% of the 2006 development set for testing, each time. The average mBLEU score across these 10 runs increased to 22.8.

In Figure 6 we show the improvement of mBLEU scores with the increase in permutation window size. We had to limit to a permutation window size of 10 due to memory limitations, even though the curve has not plateaued. We anticipate using pruning techniques we can increase the window size further.

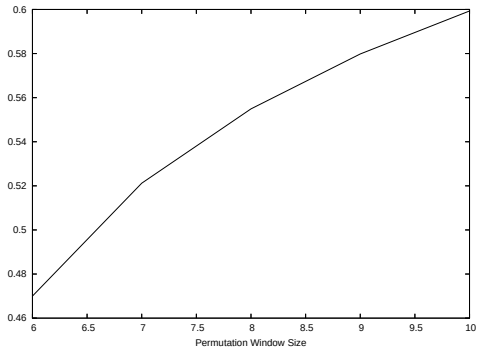

Figure 6: Improvement in mBLEU score with the increase in size of the permutation window

5.1 United Nations and Hansard Corpora

In order to test the scalability of the global lexical selection approach, we also performed lexical selection experiments on the United Nations (Arabic-English) corpus and the Hansard (French-English) corpus using the SFST model and the BOW Maxent model. We used 1,000,000 training sentence pairs and tested on 994 test sentences for the UN corpus. For the Hansard corpus we used the same training and test split as in (Zens and Ney, 2004): 1.4 million training sentence pairs and 5432 test sentences. The vocabulary sizes for the two corpora are mentioned in Table 4. Also in Table 4, are the results in terms of F-measure between the words in the reference sentence and the decoded sentences. We can see that the BOW model outperforms the SFST model on both corpora significantly. This is due to a systematic 10% relative improvement for open class words, as they benefit from a much wider context. BOW performance on close class words is higher for the UN corpus but lower for the Hansard corpus.

Table 4: Lexical Selection results (F-measure) on the Arabic-English UN Corpus and the French-English Hansard Corpus. In parenthesis are F-measures for open and closed class lexical items.

Corpus	Vocabulary		SFST	BOW
	Source	Target		
UN	252,571	53,005	64.6 (60.5/69.1)	69.5 (66.2/72.6)
Hansard	100,270	78,333	57.4 (50.6/67.7)	60.8 (56.5/63.4)

6 Discussion

The BOW approach is promising as it performs reasonably well despite considerable losses in the transfer of information between source and target language. The first and most obvious loss is about word position. The only information we currently use to restore the target word position is the target language model. Information about the grammatical role of a word in the source sentence is completely lost. The language model might fortuitously recover this information if the sentence with the correct grammatical role for the word happens to be the maximum likelihood sentence in the permutation automaton.

We are currently working toward incorporating syntactic information on the target words so as to be able to recover some of the grammatical role information lost in the classification process. In preliminary experiments, we have associated the target lexical items with supertag information (Bangalore and Joshi, 1999). Supertags are labels that provide linear ordering constraints as well as grammatical relation information. Although associating supertags to target words increases the class set for the classifier, we have noticed that the degradation in the F-score is on the order of 3% across different corpora. The supertag information can then be exploited in the sentence construction process. The use of supertags in phrase-based SMT system has been shown to improve results (Hassan et al., 2006).

A less obvious loss is the number of times a word or concept appears in the target sentence. *Function words* like "the" and "of" can appear many times in an English sentence. In the model discussed in this paper, we index each occurrence of the function word with a counter. In order to improve this method, we are currently exploring a technique where the function words serve as attributes (e.g. definiteness, tense, case) on the contentful lexical items, thus enriching the lexical item with morpho-syntactic information.

A third issue concerning the BOW model is the problem of *synonyms* – target words which translate the same source word. Suppose that in the training data, target words t_1 and t_2 are, with equal probability, translations of the same source word. Then, in the presence of this source word, the probability to detect the corresponding target word, which we assume is 0.8, will be, because of discriminant learning, split equally between t_1 and t_2, that is 0.4 and 0.4. Because of this synonym problem, the BOW threshold θ has to be set lower than 0.5, which is observed experimentally. However, if we set the threshold to 0.3, both t_1 and t_2 will be detected in the target sentence, and we found this to be a major source of undesirable insertions.

The BOW approach is different from the parsing based approaches (Melamed, 2004; Zhang and Gildea, 2005; Cowan et al., 2006) where the translation model tightly couples the syntactic and lexical items of the two languages. The decoupling of the

two steps in our model has the potential for generating paraphrased sentences not necessarily isomorphic to the structure of the source sentence.

7 Conclusions

We view machine translation as consisting of lexical selection and lexical reordering steps. These two steps need not necessarily be sequential and could be tightly integrated. We have presented the weighted finite-state transducer model of machine translation where lexical choice and a limited amount of lexical reordering are tightly integrated into a single transduction. We have also presented a novel approach to translation where these two steps are loosely coupled and the parameters of the lexical choice model are discriminatively trained using a maximum entropy model. The lexical reordering model in this approach is achieved using a permutation automaton. We have evaluated these two approaches on the 2005 and 2006 IWSLT development sets and shown that the techniques scale well to Hansard and UN corpora.

Abstract

Dependency-based representations of natural language syntax require a fine balance between structural flexibility and computational complexity. In previous work, several constraints have been proposed to identify classes of dependency structures that are well-balanced in this sense; the best-known but also most restrictive of these is projectivity. Most constraints are formulated on fully specified structures, which makes them hard to integrate into models where structures are composed from lexical information. In this paper, we show how two empirically relevant relaxations of projectivity can be lexicalized, and how combining the resulting lexicons with a regular means of syntactic composition gives rise to a hierarchy of mildly context-sensitive dependency languages.

1 Introduction

Syntactic representations based on word-to-word dependencies have a long tradition in descriptive linguistics. Lately, they have also been used in many computational tasks, such as relation extraction (Culotta and Sorensen, 2004), parsing (McDonald et al., 2005), and machine translation (Quirk et al., 2005).

Especially in recent work on parsing, there is a particular interest in *non-projective* dependency structures, in which a word and its dependents may be spread out over a discontinuous region of the sentence. These structures naturally arise in the syntactic analysis of languages with flexible word order, such as Czech (Veselá et al., 2004). Unfortunately, most formal results on non-projectivity are discouraging: While grammar-driven dependency parsers that are restricted to projective structures can be as efficient as parsers for lexicalized context-free grammar (Eisner and Satta, 1999), parsing is prohibitively expensive when unrestricted forms of non-projectivity are permitted (Neuhaus and Bröker, 1997). Data-driven dependency parsing with non-projective structures is quadratic when all attachment decisions are assumed to be independent of one another (McDonald et al., 2005), but becomes intractable when this assumption is abandoned (McDonald and Pereira, 2006).

In search of a balance between structural flexibility and computational complexity, several authors have proposed constraints to identify classes of non-projective dependency structures that are computationally well-behaved (Bodirsky et al., 2005; Nivre, 2006). In this paper, we focus on two of these proposals: the *gap-degree restriction*, which puts a bound on the number of discontinuities in the region of a sentence covered by a word and its dependents, and the *well-nestedness condition*, which constrains the arrangement of dependency subtrees. Both constraints have been shown to be in very good fit with data from dependency treebanks (Kuhlmann and Nivre, 2006). However, like all other such proposals, they are formulated on fully specified structures, which makes it hard to integrate them into a generative model, where dependency structures are composed from elementary units of lexicalized information. Consequently, little is known about the generative capacity and computational complexity of *languages* over restricted non-projective dependency structures.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 160–167,
Prague, Czech Republic, June 2007.

Contents of the paper In this paper, we show how the gap-degree restriction and the well-nestedness condition can be captured in dependency lexicons, and how combining such lexicons with a regular means of syntactic composition gives rise to an infinite hierarchy of mildly context-sensitive languages.

The technical key to these results is a procedure to encode arbitrary, even non-projective dependency structures into trees (terms) over a signature of local order-annotations. The constructors of these trees can be read as lexical entries, and both the gap-degree restriction and the well-nestedness condition can be couched as syntactic properties of these entries. Sets of gap-restricted dependency structures can be described using regular tree grammars. This gives rise to a notion of *regular dependency languages*, and allows us to establish a formal relation between the structural constraints and mildly context-sensitive grammar formalisms (Joshi, 1985): We show that regular dependency languages correspond to the sets of derivations of lexicalized Linear Context-Free Rewriting Systems (LCFRS) (Vijay-Shanker et al., 1987), and that the gap-degree measure is the structural correspondent of the concept of 'fan-out' in this formalism (Satta, 1992). We also show that adding the well-nestedness condition corresponds to the restriction of LCFRS to Coupled Context-Free Grammars (Hotz and Pitsch, 1996), and that regular sets of well-nested structures with a gap-degree of at most 1 are exactly the class of sets of derivations of Lexicalized Tree Adjoining Grammar (LTAG). This result generalizes previous work on the relation between LTAG and dependency representations (Rambow and Joshi, 1997; Bodirsky et al., 2005).

Structure of the paper The remainder of this paper is structured as follows. Section 2 contains some basic notions related to trees and dependency structures. In Section 3 we present the encoding of dependency structures as order-annotated trees, and show how this encoding allows us to give a lexicalized reformulation of both the gap-degree restriction and the well-nestedness condition. Section 4 introduces the notion of regular dependency languages. In Section 5 we show how different combinations of restrictions on non-projectivity in these languages correspond to different mildly context-sensitive grammar formalisms. Section 6 concludes the paper.

2 Preliminaries

Throughout the paper, we write $[n]$ for the set of all positive natural numbers up to and including n. The set of all strings over a set A is denoted by A^*, the empty string is denoted by ε, and the concatenation of two strings x and y is denoted either by xy, or, where this is ambiguous, by $x \cdot y$.

2.1 Trees

In this paper, we regard trees as terms. We expect the reader to be familiar with the basic concepts related to this framework, and only introduce our particular notation. Let Σ be a set of labels. The set of (finite, unranked) *trees* over Σ is defined recursively by the equation $T_\Sigma := \{\, \sigma(x) \mid \sigma \in \Sigma, x \in T_\Sigma^* \,\}$. The set of *nodes* of a tree $t \in T_\Sigma$ is defined as

$$N(\sigma(t_1 \cdots t_n)) := \{\varepsilon\} \cup \{\, iu \mid i \in [n], u \in N(t_i) \,\}.$$

For two nodes $u, v \in N(t)$, we say that u *governs* v, and write $u \trianglelefteq v$, if v can be written as $v = ux$, for some sequence $x \in \mathbb{N}^*$. Note that the governance relation is both reflexive and transitive. The converse of government is called *dependency*, so $u \trianglelefteq v$ can also be read as 'v depends on u'. The *yield* of a node $u \in N(t)$, $\lfloor u \rfloor$, is the set of all dependents of u in t: $\lfloor u \rfloor := \{\, v \in N(t) \mid u \trianglelefteq v \,\}$. We also use the notations $t(u)$ for the label at the node u of t, and t/u for the subtree of t rooted at u. A *tree language* over Σ is a subset of T_Σ.

2.2 Dependency structures

For the purposes of this paper, a *dependency structure* over Σ is a pair $d = (t, x)$, where $t \in T_\Sigma$ is a tree, and x is a list of the nodes in t. We write D_Σ to refer to the set of all dependency structures over Σ. Independently of the governance relation in d, the list x defines a total order on the nodes in t; we write $u \preceq v$ to denote that u *precedes* v in this order. Note that, like governance, the precedence relation is both reflexive and transitive. A *dependency language* over Σ is a subset of D_Σ.

EXAMPLE. The left half of Figure 1 shows how we visualize dependency structures: circles represent nodes, arrows represent the relation of (immediate) governance, the left-to-right order of the nodes represents their order in the precedence relation, and the dotted lines indicate the labelling. □

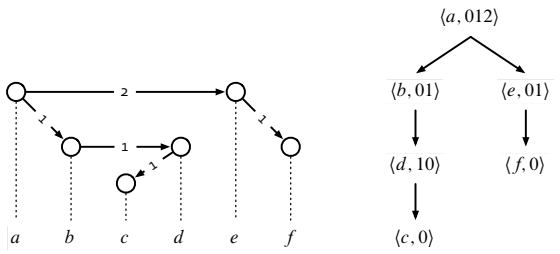

Figure 1: A projective dependency structure

3 Lexicalizing the precedence relation

In this section, we show how the precedence relation of dependency structures can be encoded as, and decoded from, a collection of node-specific order annotations. Under the assumption that the nodes of a dependency structure correspond to lexemic units, this result demonstrates how word-order information can be captured in a dependency lexicon.

3.1 Projective structures

Lexicalizing the precedence relation of a dependency structure is particularly easy if the structure under consideration meets the condition of *projectivity*. A dependency structure is projective, if each of its yields forms an interval with respect to the precedence order (Kuhlmann and Nivre, 2006).

In a projective structure, the interval that corresponds to a yield $\lfloor u \rfloor$ decomposes into the singleton interval $[u, u]$, and the collection of the intervals that correspond to the yields of the immediate dependents of u. To reconstruct the global precedence relation, it suffices to annotate each node u with the relative precedences among the constituent parts of its yield. We represent this 'local' order as a string over the alphabet $\mathbb{N}_0$, where the symbol 0 represents the singleton interval $[u, u]$, and a symbol $i \neq 0$ represents the interval that corresponds to the yield of the ith direct dependent of u. An *order-annotated tree* is a tree labelled with pairs $\langle \sigma, \omega \rangle$, where σ is the label proper, and ω is a local order annotation. In what follows, we will use the functional notations $\sigma(u)$ and $\omega(u)$ to refer to the label and order annotation of u, respectively.

EXAMPLE. Figure 1 shows a projective dependency structure together with its representation as an order-annotated tree. □

We now present procedures for encoding projective dependency structures into order-annotated trees, and for reversing this encoding.

Encoding The representation of a projective dependency structure (t, x) as an order-annotated tree can be computed in a single left-to-right sweep over x. Starting with a copy of the tree t in which every node is annotated with the empty string, for each new node u in x, we update the order annotation of u through the assignment $\omega(u) := \omega(u) \cdot 0$. If $u = vi$ for some $i \in \mathbb{N}$ (that is, if u is an inner node), we also update the order annotation of the parent v of u through the assignment $\omega(v) := \omega(v) \cdot i$.

Decoding To decode an order-annotated tree t, we first linearize the nodes of t into a sequence x, and then remove all order annotations. Linearization proceeds in a way that is very close to a pre-order traversal of the tree, except that the relative position of the root node of a subtree is explicitly specified in the order annotation. Specifically, to linearize an order-annotated tree, we look into the local order $\omega(u)$ annotated at the root node of the tree, and concatenate the linearizations of its constituent parts. A symbol i in $\omega(u)$ represents either the singleton interval $[u, u]$ ($i = 0$), or the interval corresponding to some direct dependent ui of u ($i \neq 0$), in which case we proceed recursively. Formally, the linearization of u is captured by the following three equations:

$$\begin{aligned} \mathrm{lin}(u) &= \mathrm{lin}'(u, \omega(u)) \\ \mathrm{lin}'(u, i_1 \cdots i_n) &= \mathrm{lin}''(u, i_1) \cdots \mathrm{lin}''(u, i_n) \\ \mathrm{lin}''(u, i) &= \textbf{if } i = 0 \textbf{ then } u \textbf{ else } \mathrm{lin}(ui) \end{aligned}$$

Both encoding and decoding can be done in time linear in the number of nodes of the dependency structure or order-annotated tree.

3.2 Non-projective structures

It is straightforward to see that our representation of dependency structures is insufficient if the structures under consideration are non-projective. To witness, consider the structure shown in Figure 2. Encoding this structure using the procedure presented above yields the same order-annotated tree as the one shown in Figure 1, which demonstrates that the encoding is not reversible.

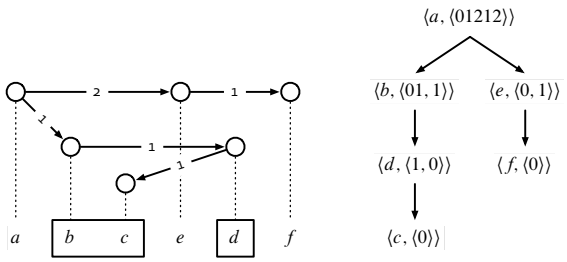

Figure 2: A non-projective dependency structure

Blocks In a non-projective dependency structure, the yield of a node may be spread out over more than one interval; we will refer to these intervals as *blocks*. Two nodes v, w belong to the same block of a node u, if all nodes between v and w are governed by u.

EXAMPLE. Consider the nodes b, c, d in the structures depicted in Figures 1 and 2. In Figure 1, these nodes belong to the same block of b. In Figure 2, the three nodes are spread out over two blocks of b (marked by the boxes): c and d are separated by a node (e) not governed by b. □

Blocks have a recursive structure that is closely related to the recursive structure of yields: the blocks of a node u can be decomposed into the singleton $[u, u]$, and the blocks of the direct dependents of u. Just as a projective dependency structure can be represented by annotating each yield with an order on its constituents, an unrestricted structure can be represented by annotating each block.

Extended order annotations To represent orders on blocks, we extend our annotation scheme as follows. First, instead of a single string, an annotation $\omega(u)$ now is a tuple of strings, where the kth component specifies the order among the constituents of the kth block of u. Second, instead of one, the annotation may now contain multiple occurrences of the same dependent; the kth occurrence of i in $\omega(u)$ represents the kth block of the node ui.

We write $\omega(u)_k$ to refer to the kth component of the order annotation of u. We also use the notation $(i\#k)_u$ to refer to the kth occurrence of i in $\omega(u)$, and omit the subscript when the node u is implicit.

EXAMPLE. In the annotated tree shown in Figure 2, $\omega(b)_1 = (0\#1)(1\#1)$, and $\omega(b)_2 = (1\#2)$. □

Encoding To encode a dependency structure (t, x) as an extended order-annotated tree, we do a post-order traversal of t as follows. For a given node u, let us represent a constituent of a block of u as a triple $i : [v_l, v_r]$, where i denotes the node that contributes the constituent, and v_l and v_r denote the constituent's leftmost and rightmost elements. At each node u, we have access to the singleton block $0 : [u, u]$, and the constituent blocks of the immediate dependents of u. We say that two blocks $i : [v_l, v_r]$, $j : [w_l, w_r]$ can be *merged*, if the node v_r immediately precedes the node w_l. The result of the merger is a new block $ij : [v_l, w_r]$ that represents the information that the two merged constituents belong to the same block of u. By exhaustive merging, we obtain the constituent structure of all blocks of u. From this structure, we can read off the order annotation $\omega(u)$.

EXAMPLE. The yield of the node b in Figure 2 decomposes into $0 : [b, b]$, $1 : [c, c]$, and $1 : [d, d]$. Since b and c are adjacent, the first two of these constituents can be merged into a new block $01 : [b, c]$; the third constituent remains unchanged. This gives rise to the order annotation $\langle 01, 1\rangle$ for b. □

When using a global data-structure to keep track of the constituent blocks, the encoding procedure can be implemented to run in time linear in the number of blocks in the dependency structure. In particular, for projective dependency structures, it still runs in time linear in the number of nodes.

Decoding To linearize the kth block of a node u, we look into the kth component of the order annotated at u, and concatenate the linearizations of its constituent parts. Each occurrence $(i\#k)$ in a component of $\omega(u)$ represents either the node u itself ($i = 0$), or the kth block of some direct dependent ui of u ($i \neq 0$), in which case we proceed recursively:

$$\begin{aligned} \mathrm{lin}(u, k) &= \mathrm{lin}'(u, \omega(u)_k) \\ \mathrm{lin}'(u, i_1 \cdots i_n) &= \mathrm{lin}''(u, i_1) \cdots \mathrm{lin}''(u, i_n) \\ \mathrm{lin}''(u, (i\#k)_u) &= \textbf{if } i = 0 \textbf{ then } u \textbf{ else } \mathrm{lin}(ui, k) \end{aligned}$$

The root node of a dependency structure has only one block. Therefore, to linearize a tree t, we only need to linearize the first block of the tree's root node: $\mathrm{lin}(t) = \mathrm{lin}(\varepsilon, 1)$.

Consistent order annotations Every dependency structure over Σ can be encoded as a tree over the set $\Sigma \times \Omega$, where Ω is the set of all order annotations. The converse of this statement does not hold: to be interpretable as a dependency structure, tree structure and order annotation in an order-annotated tree must be *consistent*, in the following sense.

PROPERTY C1: Every annotation $\omega(u)$ in a tree t contains all and only the symbols in the collection $\{0\} \cup \{\, i \mid ui \in N(t) \,\}$, i.e., one symbol for u, and one symbol for every direct dependent of u.

PROPERTY C2: The number of occurrences of a symbol $i \neq 0$ in $\omega(u)$ is identical to the number of components in the annotation of the node ui. Furthermore, the number of components in the annotation of the root node is 1.

With this notion of consistency, we can prove the following technical result about the relation between dependency structures and annotated trees. We write $\pi_\Sigma(s)$ for the tree obtained from a tree $s \in T_{\Sigma\times\Omega}$ by re-labelling every node u with $\sigma(u)$.

PROPOSITION 1. For every dependency structure (t, x) over Σ, there exists a tree s over $\Sigma \times \Omega$ such that $\pi_\Sigma(s) = t$ and $\mathrm{lin}(s) = x$. Conversely, for every consistently order-annotated tree $s \in T_{\Sigma\times\Omega}$, there exists a uniquely determined dependency structure (t, x) with these properties. □

3.3 Local versions of structural constraints

The encoding of dependency structures as order-annotated trees allows us to reformulate two constraints on non-projectivity originally defined on fully specified dependency structures (Bodirsky et al., 2005) in terms of syntactic properties of the order annotations that they induce:

Gap-degree The *gap-degree* of a dependency structure is the maximum over the number of discontinuities in any yield of that structure.

EXAMPLE. The structure depicted in Figure 2 has gap-degree 1: the yield of b has one discontinuity, marked by the node e, and this is the maximal number of discontinuities in any yield of the structure. □

Since a discontinuity in a yield is delimited by two blocks, and since the number of blocks of a node u equals the number of components in the order annotation of u, the following result is obvious:

PROPOSITION 2. A dependency structure has gap-degree k if and only if the maximal number of components among the annotations $\omega(u)$ is $k + 1$. □

In particular, a dependency structure is projective iff all of its annotations consist of just one component.

Well-nestedness The well-nestedness condition constrains the arrangement of subtrees in a dependency structure. Two subtrees $t/u_1, t/u_2$ *interleave*, if there are nodes $v_l^1, v_r^1 \in t/u_1$ and $v_l^2, v_r^2 \in t/u_2$ such that $v_l^1 \prec v_l^2 \prec v_r^1 \prec v_r^2$. A dependency structure is *well-nested*, if no two of its disjoint subtrees interleave. We can prove the following result:

PROPOSITION 3. A dependency structure is well-nested if and only if no annotation $\omega(u)$ contains a substring $i \cdots j \cdots i \cdots j$, for $i, j \in \mathbb{N}$. □

EXAMPLE. The dependency structure in Figure 1 is well-nested, the structure depicted in Figure 2 is not: the subtrees rooted at the nodes b and e interleave. To see this, notice that $b \prec e \prec d \prec f$. Also notice that $\omega(a)$ contains the substring 1212. □

4 Regular dependency languages

The encoding of dependency structures as order-annotated trees gives rise to an encoding of dependency languages as tree languages. More specifically, dependency languages over a set Σ can be encoded as tree languages over the set $\Sigma \times \Omega$, where Ω is the set of all order annotations. Via this encoding, we can study dependency languages using the tools and results of the well-developed formal theory of tree languages. In this section, we discuss dependency languages that can be encoded as regular tree languages.

4.1 Regular tree grammars

The class of regular tree languages, REGT for short, is a very natural class with many characterizations (Gécseg and Steinby, 1997): it is generated by regular tree grammars, recognized by finite tree automata, and expressible in monadic second-order logic. Here we use the characterization in terms of grammars. Regular tree grammars are natural candidates for the formalization of dependency lexicons, as each rule in such a grammar can be seen as the specification of a word and the syntactic categories or grammatical functions of its immediate dependents.

Formally, a *(normalized) regular tree grammar* is a construct $G = (N_G, \Sigma_G, S_G, P_G)$, in which N_G and Σ_G are finite sets of non-terminal and terminal symbols, respectively, $S_G \in N_G$ is a dedicated start symbol, and P_G is a finite set of productions of the form $A \to \sigma(A_1 \cdots A_n)$, where $\sigma \in \Sigma_G$, $A \in N_G$, and $A_i \in N_G$, for every $i \in [n]$. The *(direct) derivation relation* associated to G is the binary relation $\Rightarrow_G$ on the set $T_{\Sigma_G \cup N_G}$ defined as follows:

$$\frac{t \in T_{\Sigma_G \cup N_G} \qquad t/u = A \qquad (A \to s) \in P_G}{t \Rightarrow_G t[u \mapsto s]}$$

Informally, each step in a derivation replaces a non-terminal-labelled leaf by the right-hand side of a matching production. The *tree language* generated by G is the set of all terminal trees that can eventually be derived from the trivial tree formed by its start symbol: $L(G) = \{\, t \in T_{\Sigma_G} \mid S_G \Rightarrow_G^* t \,\}$.

4.2 Regular dependency grammars

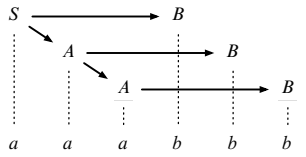
We call a dependency language *regular*, if its encoding as a set of trees over $\Sigma \times \Omega$ forms a regular tree language, and write REGD for the class of all regular dependency languages. For every regular dependency language L, there is a regular tree grammar with terminal alphabet $\Sigma \times \Omega$ that generates the encoding of L. Similar to the situation with individual structures, the converse of this statement does not hold: the consistency properties mentioned above impose corresponding syntactic restrictions on the rules of grammars G that generate the encoding of L.

PROPERTY C1′: The ω-component of every production $A \to \langle \sigma, \omega \rangle (A_1 \cdots A_n)$ in G contains all and only symbols in the set $\{0\} \cup \{\, i \mid i \in [n] \,\}$.

PROPERTY C2′: For every non-terminal $X \in N_G$, there is a uniquely determined integer d_X such that for every production $A \to \langle \sigma, \omega \rangle (A_1 \cdots A_n)$ in G, d_{A_i} gives the number of occurrences of i in ω, d_A gives the number of components in ω, and $d_{S_G} = 1$.

It turns out that these properties are in fact sufficient to characterize the class of regular tree grammars that generate encodings of dependency languages. In but slight abuse of terminology, we will refer to such grammars as *regular dependency grammars*.

EXAMPLE. Figure 3 shows a regular tree grammar that generates a set of non-projective dependency structures with string language $\{\, a^n b^n \mid n \geq 1 \,\}$. □



$S \to \langle a, \langle 01 \rangle \rangle (B) \mid \langle a, \langle 0121 \rangle \rangle (A, B)$
$A \to \langle a, \langle 0, 1 \rangle \rangle (B) \mid \langle a, \langle 01, 21 \rangle \rangle (A, B)$
$B \to \langle b, \langle 0 \rangle \rangle$

Figure 3: A grammar for a language in REGD(1)

5 Structural constraints and formal power

In this section, we present our results on the generative capacity of regular dependency languages, linking them to a large class of mildly context-sensitive grammar formalisms.

5.1 Gap-restricted dependency languages

A dependency language L is called *gap-restricted*, if there is a constant $c_L \geq 0$ such that no structure in L has a gap-degree higher than c_L. It is plain to see that every regular dependency language is gap-restricted: the gap-degree of a structure is directly reflected in the number of components of its order annotations, and every regular dependency grammar makes use of only a finite number of these annotations. We write REGD(k) to refer to the class of regular dependency languages with a gap-degree bounded by k.

Linear Context-Free Rewriting Systems Gap-restricted dependency languages are closely related to Linear Context-Free Rewriting Systems (LCFRS) (Vijay-Shanker et al., 1987), a class of formal systems that generalizes several mildly context-sensitive grammar formalisms. An LCFRS consists of a regular tree grammar G and an interpretation of the terminal symbols of this grammar as linear, non-erasing functions into tuples of strings. By these functions, each tree in $L(G)$ can be evaluated to a string.

EXAMPLE. Here is an example for a function:

$$f(\langle x_1^1, x_1^2 \rangle, \langle x_2^1 \rangle) \;=\; \langle a x_1^1, x_2^1 x_1^2 \rangle$$

This function states that in order to compute the pair of strings that corresponds to a tree whose root node is labelled with the symbol f, one first has to compute the pair of strings corresponding to the first child

of the root node ($\langle x_1^1, x_1^2 \rangle$) and the single string corresponding to the second child ($\langle x_2^1 \rangle$), and then concatenate the individual components in the specified order, preceded by the terminal symbol a. □

We call a function *lexicalized*, if it contributes exactly one terminal symbol. In an LCFRS in which all functions are lexicalized, there is a one-to-one correspondence between the nodes in an evaluated tree and the positions in the string that the tree evaluates to. Therefore, tree and string implicitly form a dependency structure, and we can speak of the *dependency language* generated by a lexicalized LCFRS.

Equivalence We can prove that every regular dependency grammar can be transformed into a lexicalized LCFRS that generates the same dependency language, and vice versa. The basic insight in this proof is that every order annotation in a regular dependency grammar can be interpreted as a compact description of a function in the corresponding LCFRS. The number of components in the order-annotation, and hence, the gap-degree of the resulting dependency language, corresponds to the *fan-out* of the function: the highest number of components among the arguments of the function (Satta, 1992).[1] A technical difficulty is caused by the fact that LCFRS can swap components: $f(\langle x_1^1, x_1^2 \rangle) = \langle a x_1^2, x_1^1 \rangle$. This commutativity needs to be compiled out during the translation into a regular dependency grammar.

We write LLCFRL(k) for the class of all dependency languages generated by lexicalized LCFRS with a fan-out of at most k.

PROPOSITION 4. $\text{REGD}(k) = \text{LLCFRL}(k+1)$ □

In particular, the class REGD(0) of regular dependency languages over projective structures is exactly the class of dependency languages generated by lexicalized context-free grammars.

EXAMPLE. The gap-degree of the language generated by the grammar in Figure 3 is bounded by 1. The rules for the non-terminal A can be translated into the following functions of an equivalent LCFRS:

$$f_{\langle a,\langle 0,1\rangle\rangle}(\langle x_1^1 \rangle) = \langle a, x_1^1 \rangle$$
$$f_{\langle a,\langle 01,21\rangle\rangle}(\langle x_1^1, x_1^2 \rangle, \langle x_2^1 \rangle) = \langle a x_1^1, x_2^1 x_1^2 \rangle$$

The fan-out of these functions is 2. □

[1] More precisely, gap-degree = fan-out − 1.

5.2 Well-nested dependency languages

The absence of the substring $i \cdots j \cdots i \cdots j$ in the order annotations of well-nested dependency structures corresponds to a restriction to 'well-bracketed' compositions of sub-structures. This restriction is central to the formalism of Coupled-Context-Free Grammar (CCFG) (Hotz and Pitsch, 1996).

It is straightforward to see that every CCFG can be translated into an equivalent LCFRS. We can also prove that every LCFRS obtained from a regular dependency grammar with well-nested order annotations can be translated back into an equivalent CCFG. We write $\text{REGD}_{wn}(k)$ for the well-nested subclass of REGD(k), and LCCFL(k) for the class of all dependency languages generated by lexicalized CCFGs with a fan-out of at most k.

PROPOSITION 5. $\text{REGD}_{wn}(k) = \text{LCCFL}(k+1)$ □

As a special case, Coupled-Context-Free Grammars with fan-out 2 are equivalent to Tree Adjoining Grammars (TAGS) (Hotz and Pitsch, 1996). This enables us to generalize a previous result on the class of dependency structures generated by lexicalized TAGS (Bodirsky et al., 2005) to the class of generated dependency languages, LTAL.

PROPOSITION 6. $\text{REGD}_{wn}(1) = \text{LTAL}$ □

6 Conclusion

In this paper, we have presented a lexicalized reformulation of two structural constraints on non-projective dependency representations, and shown that combining dependency lexicons that satisfy these constraints with a regular means of syntactic composition yields classes of mildly context-sensitive dependency languages. Our results make a significant contribution to a better understanding of the relation between the phenomenon of non-projectivity and notions of formal power.

The close link between restricted forms of non-projective dependency languages and mildly context-sensitive grammar formalisms provides a promising starting point for future work. On the practical side, it should allow us to benefit from the experience in building parsers for mildly context-sensitive formalisms when addressing the task of efficient non-projective dependency parsing, at least in the frame-

work of grammar-driven parsing. This may eventually lead to a better trade-off between structural flexibility and computational efficiency than that obtained with current systems. On a more theoretical level, our results provide a basis for comparing a variety of formally rather distinct grammar formalisms with respect to the sets of dependency structures that they can generate. Such a comparison may be empirically more adequate than one based on traditional notions of generative capacity (Kallmeyer, 2006).

Abstract

This paper shows how to use the Unfold-Fold transformation to transform Projective Bilexical Dependency Grammars (PBDGs) into ambiguity-preserving weakly equivalent Context-Free Grammars (CFGs). These CFGs can be parsed in $O(n^3)$ time using a CKY algorithm with appropriate indexing, rather than the $O(n^5)$ time required by a naive encoding. Informally, using the CKY algorithm with such a CFG mimics the steps of the Eisner-Satta $O(n^3)$ PBDG parsing algorithm. This transformation makes all of the techniques developed for CFGs available to PBDGs. We demonstrate this by describing a maximum posterior parse decoder for PBDGs.

1 Introduction

Projective Bilexical Dependency Grammars (PBDGs) have attracted attention recently for two reasons. First, because they capture bilexical head-to-head dependencies they are capable of producing extremely high-quality parses: state-of-the-art discriminatively trained PBDG parsers rival the accuracy of the very best statistical parsers available today (McDonald, 2006). Second, Eisner-Satta $O(n^3)$ PBDG parsing algorithms are extremely fast (Eisner, 1996; Eisner and Satta, 1999; Eisner, 2000).

This paper investigates the relationship between Context-Free Grammar (CFG) parsing and the Eisner/Satta PBDG parsing algorithms, including their extension to second-order PBDG parsing (McDonald, 2006; McDonald and Pereira, 2006). Specifically, we show how to use an off-line preprocessing step, the Unfold-Fold transformation, to transform a PBDG into an equivalent CFG that can be parsed in $O(n^3)$ time using a version of the CKY algorithm with suitable indexing (Younger, 1967), and extend this transformation so that it captures second-order PBDG dependencies as well. The transformations are ambiguity-preserving, i.e., there is a one-to-one mapping between dependency parses and CFG parses, so it is possible to map the CFG parses back to the PBDG parses they correspond to.

The PBDG to CFG reductions make techniques developed for CFGs available to PBDGs as well. For example, incremental CFG parsing algorithms can be used with the CFGs produced by this transform, as can the Inside-Outside estimation algorithm (Lari and Young, 1990) and more exotic methods such as estimating adjoined hidden states (Matsuzaki et al., 2005; Petrov et al., 2006). As an example application, we describe a maximum posterior parse decoder for PBDGs in Section 8.

The Unfold-Fold transformation is a calculus for transforming functional and logic programs into equivalent but (hopefully) faster programs (Burstall and Darlington, 1977). We use it here to transform CFGs encoding dependency grammars into other CFGs that are more efficiently parsable. Since CFGs can be expressed as Horn-clause logic programs (Pereira and Shieber, 1987) and the Unfold-Fold transformation is provably correct for such programs (Sato, 1992; Pettorossi and Proeitti, 1992), it follows that its application to CFGs is provably correct as well. The Unfold-Fold transformation is used here to derive the CFG schemata presented in sections 5–7. A system that uses these schemata (such as the one described in section 8) can implement

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 168–175,
Prague, Czech Republic, June 2007.

these schemata directly, so the Unfold-Fold transformation plays a theoretical role in this work, justifying the resulting CFG schemata.

The closest related work we are aware of is McAllester (1999), which also describes a reduction of PBDGs to efficiently-parsable CFGs and directly inspired this work. However, the CFGs produced by McAllester's transformation include epsilon-productions so they require a specialized CFG parsing algorithm, while the CFGs produced by the transformations described here have binary productions so they can be parsed with standard CFG parsing algorithms. Further, our approach extends to second-order PBDG parsing, while McAllester only discusses first-order PBDGs.

The rest of this paper is structured as follows. Section 2 defines projective dependency graphs and grammars and Section 3 reviews the "naive" encoding of PBDGs as CFGs with an $O(n^5)$ parse time, where n is the length of the string to be parsed. Section 4 introduces the "split-head" CFG encoding of PBDGs, which has an $O(n^4)$ parse time and serves as the input to the Unfold-Fold transform. Section 5 uses the Unfold-Fold transform to obtain a weakly-equivalent CFG encoding of PBDGs which can be parsed in $O(n^3)$ time, and presents timing results showing that the transformation does speed parsing. Sections 6 and 7 apply Unfold-Fold in slightly more complex ways to obtain CFG encodings of PBDGs that also make second-order dependencies available in $O(n^3)$ time parsable CFGs. Section 8 applies a PBDG to CFG transform to obtain a maximum posterior decoding parser for PBDGs.

2 Projective bilexical dependency parses and grammars

Let Σ be a finite set of $terminals$ (e.g., words), and let 0 be the *root terminal* not in Σ. If $w = (w_1, \ldots, w_n) \in \Sigma^\star$, let $w^\star = (0, w_1, \ldots, w_n)$, i.e., $w^\star$ is obtained by prefixing w with 0. A *dependency parse* G for w is a tree whose root is labeled 0 and whose other n vertices are labeled with each of the n terminals in w. If G contains an arc from u to v then we say that v is a *dependent* of u, and if G contains a path from u to v then we say that v is a *descendant* of u. If v is dependent of u that also precedes u in $w^\star$ then we say that v is a *left dependent* of u (right dependent and left and right descendants are defined similarly).

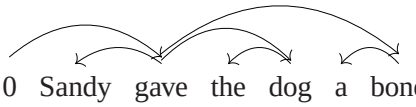

Figure 1: A projective dependency parse for the sentence "Sam gave the dog a bone".

A dependency parse G is *projective* iff whenever there is a path from u to v then there is also a path from u to every word between u and v in $w^\star$ as well. Figure 1 depicts a projective dependency parse for the sentence "Sam gave the dog a bone".

A projective dependency grammar defines a set of projective dependency parses. A *Projective Bilexical Dependency Grammar* (PBDG) consists of two relations $\overleftarrow{\ }$ and $\overrightarrow{\ }$, both defined over $(\Sigma \cup \{0\}) \times \Sigma$. A PBDG generates a projective dependency parse G iff $u \overrightarrow{\ } v$ for all right dependencies (u, v) in G and $v \overleftarrow{\ } u$ for all left dependencies (u, v) in G. The language generated by a PBDG is the set of strings that have projective dependency parses generated by the grammar. The following dependency grammar generates the dependency parse in Figure 1.

$$\begin{array}{cc} 0 \overrightarrow{\ } \text{gave} & \text{Sandy} \overleftarrow{\ } \text{gave} \\ \text{gave} \overrightarrow{\ } \text{dog} & \text{the} \overleftarrow{\ } \text{dog} \\ \text{gave} \overrightarrow{\ } \text{bone} & \text{a} \overleftarrow{\ } \text{bone} \end{array}$$

This paper does not consider stochastic dependency grammars directly, but see Section 8 for an application involving them. However, it is straightforward to associate weights with dependencies, and since the dependencies are preserved by the transformations, obtain a weighted CFG. Standard methods for converting weighted CFGs to equivalent PCFGs can be used if required (Chi, 1999). Alternatively, one can transform a corpus of dependency parses into a corpus of the corresponding CFG parses, and estimate CFG production probabilities directly from that corpus.

3 A naive encoding of PBDGs

There is a well-known method for encoding a PBDG as a CFG in which each terminal $u \in \Sigma$ is associated with a corresponding nonterminal X_u that expands to u and all of u's descendants. The nonterminals of the naive encoding CFG consist of the start symbol S and symbols X_u for each terminal $u \in \Sigma$, and

the productions of the CFG are the instances of the following schemata:

$$\begin{array}{rcll} \mathrm{S} & \rightarrow & \mathrm{X}_u & \text{where } 0 \curvearrowright u \\ \mathrm{X}_u & \rightarrow & u & \\ \mathrm{X}_u & \rightarrow & \mathrm{X}_v\ \mathrm{X}_u & \text{where } v \curvearrowleft u \\ \mathrm{X}_u & \rightarrow & \mathrm{X}_u\ \mathrm{X}_v & \text{where } u \curvearrowright v \end{array}$$

The dependency annotations associated with each production specify how to interpret a local tree generated by that production, and permit us to map a CFG parse to the corresponding dependency parse. For example, the top-most local tree in Figure 2 was generated by the production $\mathrm{S} \rightarrow \mathrm{X}_{\mathrm{gave}}$, and indicate that in this parse $0 \curvearrowright \mathrm{gave}$.

Given a terminal vocabulary of size m the CFG contains $O(m^2)$ productions, so it is impractical to enumerate all possible productions for even modest vocabularies. Instead productions relevant to a particular sentence are generated on the fly.

The naive encoding CFG in general requires $O(n^5)$ parsing time with a conventional CKY parsing algorithm, since tracking the head annotations u and v multiplies the standard $O(n^3)$ CFG parse time requirements by an additional factor proportional to the $O(n^2)$ productions expanding X_u.

An additional problem with the naive encoding is that the resulting CFG in general exhibits spurious ambiguities, i.e., a single dependency parse may correspond to more than one CFG parse, as shown in Figure 2. Informally, this is because the CFG permits left and the right dependencies to be arbitrarily intermingled.

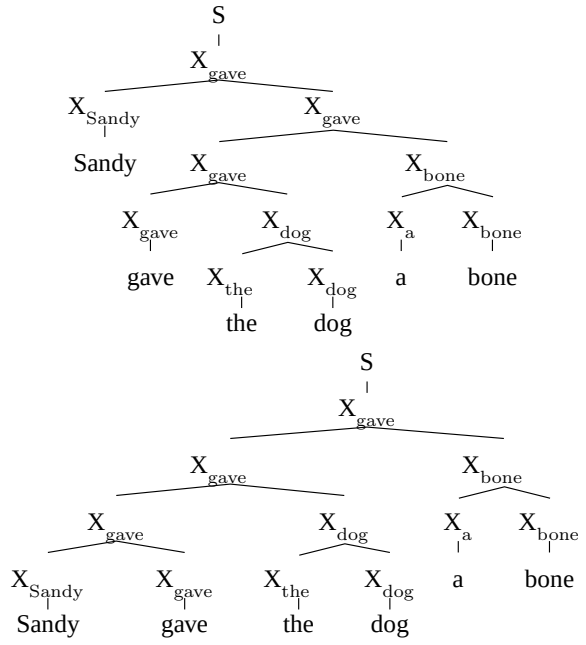

Figure 2: Two parses using the naive CFG encoding that both correspond to the dependency parse of Figure 1.

4 Split-head encoding of PBDGs

There are several ways of removing the spurious ambiguities in the naive CFG encoding just described. This section presents a method we call the "split-head encoding", which removes the ambiguities and serves as starting point for the grammar transforms described below.

The split-head encoding represents each word u in the input string w by *two* unique terminals u_l and u_r in the CFG parse. A split-head CFG's terminal vocabulary is $\Sigma' = \{u_l, u_r : u \in \Sigma\}$, where Σ is the set of terminals of the PBDG. A PBDG parse with yield $w = (u_1, \ldots, u_n)$ is transformed to a split-head CFG parse with yield $w' = (u_{1,l}, u_{1,r}, \ldots, u_{n,l}, u_{n,r})$, so $|w'| = 2|w|$.

The split-head CFG for a PBDG is given by the following schemata:

$$\begin{array}{rcll} \mathrm{S} & \rightarrow & \mathrm{X}_u & \text{where } 0 \curvearrowright u \\ \mathrm{X}_u & \rightarrow & \mathrm{L}_u\ {}_u\mathrm{R} & \text{where } u \in \Sigma \\ \mathrm{L}_u & \rightarrow & u_l & \\ \mathrm{L}_u & \rightarrow & \mathrm{X}_v\ \mathrm{L}_u & \text{where } v \curvearrowleft u \\ {}_u\mathrm{R} & \rightarrow & u_r & \\ {}_u\mathrm{R} & \rightarrow & {}_u\mathrm{R}\ \mathrm{X}_v & \text{where } u \curvearrowright v \end{array}$$

The dependency parse shown in Figure 1 corresponds to the split-head CFG parse shown in Figure 3. Each X_u expands to two new categories, L_u and ${}_u\mathrm{R}$. L_u consists of u_l and all of u's left descendants, while ${}_u\mathrm{R}$ consists of u_r and all of u's right descendants. The spurious ambiguity present in the naive encoding does not arise in the split-head encoding because the left and right dependents of a head are assembled independently and cannot intermingle.

As can be seen by examining the split-head schemata, the *rightmost* descendant of L_u is either L_u or u_l, which guarantees that the rightmost terminal dominated by L_u is always u_l; similarly the *leftmost* terminal dominated by ${}_u\mathrm{R}$ is always u_r. Thus

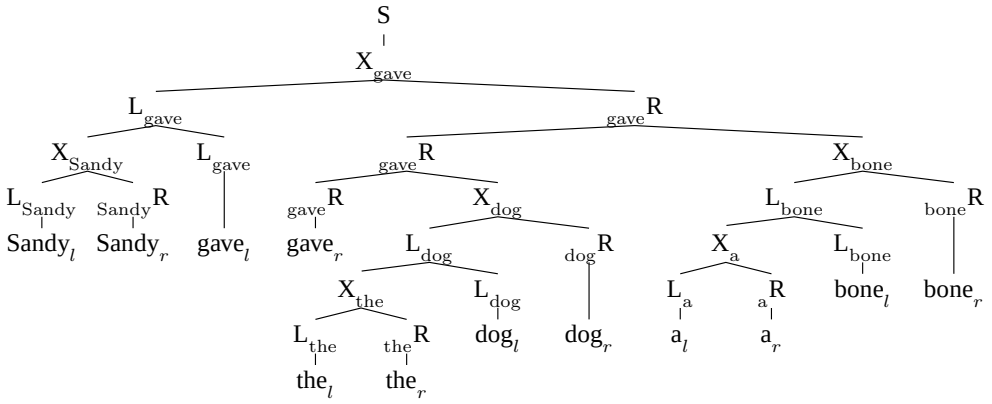

Figure 3: The split-head parse corresponding to the dependency graph depicted in Figure 1. Notice that u_l is always the rightmost descendant of L_u and u_r is always the leftmost descendant of ${}_u\mathrm{R}$, which means that these indices are redundant given the constituent spans.

these subscript indices are redundant given the string positions of the constituents, which means we do not need to track the index u in L_u and ${}_u\mathrm{R}$ but can parse with just the two categories L and R, and determine the index from the constituent's span when required.

It is straight-forward to extend the split-head CFG to encode the additional state information required by the head automata of Eisner and Satta (1999); this corresponds to splitting the non-terminals L_u and ${}_u\mathrm{R}$. For simplicity we work with PBDGs in this paper, but all of the Unfold-Fold transformations described below extend to split-head grammars with the additional state structure required by head automata.

Implementation note: it is possible to directly parse the "undoubled" input string w by modifying both the CKY algorithm and the CFGs described in this paper. Modify L_u and ${}_u\mathrm{R}$ so they both ultimately expand to the same terminal u, and special-case the implementation of production $\mathrm{X}_u \rightarrow \mathrm{L}_u\ {}_u\mathrm{R}$ and all productions derived from it to permit L_u and ${}_u\mathrm{R}$ to overlap by the terminal u.

The split-head formulation explains what initially seem unusual properties of existing PBDG algorithms. For example, one of the standard "sanity checks" for the Inside-Outside algorithm—that the outside probability of each terminal is equal to the sentence's inside probability—fails for these algorithms. In fact, the outside probability of each terminal is *double* the sentence's inside probability because these algorithms implicitly collapse the two terminals u_l and u_r into a single terminal u.

5 A $O(n^3)$ split-head grammar

The split-head encoding described in the previous section requires $O(n^4)$ parsing time because the index v on X_v is not redundant. We can obtain an equivalent grammar that only requires $O(n^3)$ parsing time by transforming the split-head grammar using Unfold-Fold. We describe the transformation on L_u; the transformation of ${}_u\mathrm{R}$ is symmetric.

We begin with the definition of L_u in the split-head grammar above ("|" separates the right-hand sides of productions).

$$\mathrm{L}_u \;\rightarrow\; u_l \;\mid\; \mathrm{X}_v\ \mathrm{L}_u \quad \text{where } v \curvearrowleft u$$

Our first transformation step is to unfold X_v in L_u, i.e., replace X_v by its expansion, producing the following definition for L_u (ignore the underlining for now).

$$\mathrm{L}_u \;\rightarrow\; u_l \;\mid\; \mathrm{L}_v\ \underline{{}_v\mathrm{R}\ \mathrm{L}_u} \quad \text{where } v \curvearrowleft u$$

This removes the offending X_v in L_u, but the resulting definition of L_u contains ternary productions and so still incurs $O(n^4)$ parse time. To address this we define new nonterminals ${}_x\mathrm{M}_y$ for each $x, y \in \Sigma$:

$${}_x\mathrm{M}_y \;\rightarrow\; {}_x\mathrm{R}\ \mathrm{L}_y$$

and fold the underlined children in L_u into ${}_v\mathrm{M}_u$:

$$\begin{aligned} {}_x\mathrm{M}_y &\rightarrow {}_x\mathrm{R}\ \mathrm{L}_y && \text{where } x, y \in \Sigma \\ \mathrm{L}_u &\rightarrow u_l \mid \mathrm{L}_v\ {}_v\mathrm{M}_u && \text{where } v \curvearrowleft u \end{aligned}$$

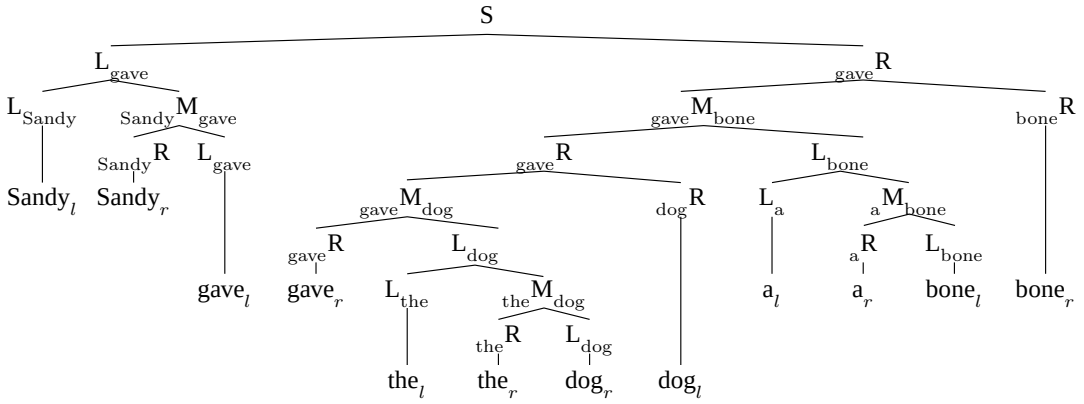

Figure 4: The $O(n^3)$ split-head parse corresponding to the dependency graph of Figure 1.

The $O(n^3)$ split-head grammar is obtained by unfolding the occurence of X_u in the S production and dropping the X_u schema as X_u no longer appears on the right-hand side of any production. The resulting $O(n^3)$ split-head grammar schemata are as follows:

$$
\begin{array}{rcll}
\mathrm{S} & \rightarrow & \mathrm{L}_u \ {}_u\mathrm{R} & \text{where } 0 \curvearrowright u \\
\mathrm{L}_u & \rightarrow & u_l & \\
\mathrm{L}_u & \rightarrow & \mathrm{L}_v \ {}_v\mathrm{M}_u & \text{where } v \curvearrowleft u \\
{}_u\mathrm{R} & \rightarrow & u_r & \\
{}_u\mathrm{R} & \rightarrow & {}_u\mathrm{M}_v \ {}_v\mathrm{R} & \text{where } u \curvearrowright v \\
{}_x\mathrm{M}_y & \rightarrow & {}_x\mathrm{R} \ \mathrm{L}_y & \text{where } x, y \in \Sigma
\end{array}
$$

As before, the dependency annotations on the production schemata permit us to map CFG parses to the corresponding dependency parse. This grammar requires $O(n^3)$ parsing time to parse because the indices are redundant given the constituent's string positions for the reasons described in section 4. Specifically, the rightmost terminal of L_u is always u_l, the leftmost terminal of ${}_u\mathrm{R}$ is always u_r and the leftmost and rightmost terminals of ${}_v\mathrm{M}_u$ are v_l and u_r respectively.

The $O(n^3)$ split-head grammar is closely related to the $O(n^3)$ PBDG parsing algorithm given by Eisner and Satta (1999). Specifically, the steps involved in parsing with this grammar using the CKY algorithm are essentially the same as those performed by the Eisner/Satta algorithm. The primary difference is that the Eisner/Satta algorithm involves two separate categories that are collapsed into the single category M here.

To confirm their relative performance we implemented stochastic CKY parsers for the three CFG schemata described so far. The production schemata were hard-coded for speed, and the implementation trick described in section 4 was used to avoid doubling the terminal string. We obtained dependency weights from our existing discriminatively-trained PBDG parser (not cited to preserve anonymity). We compared the parsers' running times on section 24 of the Penn Treebank. Because all three CFGs implement the same dependency grammar their Viterbi parses have the same dependency accuracy, namely 0.8918. We precompute the dependency weights, so the times include just the dynamic programming computation on a 3.6GHz Pentium 4.

CFG schemata	sentences parsed / second
Naive $O(n^5)$ CFG	45.4
$O(n^4)$ CFG	406.2
$O(n^3)$ CFG	3580.0

6 An $O(n^3)$ adjacent-head grammar

This section shows how to further transform the $O(n^3)$ grammar described above into a form that encodes second-order dependencies between adjacent dependent heads in much the way that a Markov PCFG does (McDonald, 2006; McDonald and Pereira, 2006). We provide a derivation for the L_u constituents; there is a parallel derivation for ${}_u\mathrm{R}$.

We begin by unfolding X_v in the definition of L_u in the split-head grammar, producing as before:

$$\mathrm{L}_u \ \rightarrow \ u_l \ | \ \mathrm{L}_v \ \underline{{}_v\mathrm{R} \ \mathrm{L}_u}$$

Now introduce a new nonterminal ${}_v\mathrm{M}_u^{\mathrm{L}}$, which is a specialized version of M requiring that v is a left-dependent of u, and fold the underlined constituents

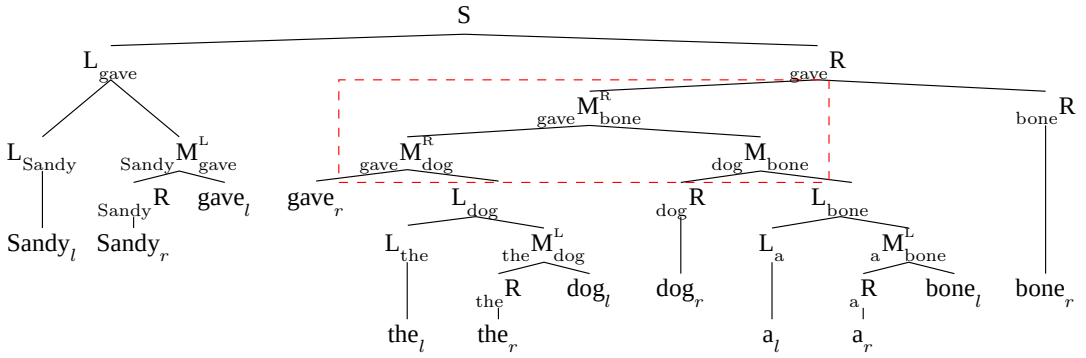

Figure 5: The $O(n^3)$ adjacent-head parse corresponding to the dependency graph of Figure 1. The boxed local tree indicates *bone* is the dependent of *give* following the dependent *dog*, i.e., $give \overset{\curvearrowright}{\curvearrowleft} dog \overset{\curvearrowright}{\curvearrowleft} bone$.

into ${}_v\mathrm{M}^{\mathrm{L}}_u$.

$$\begin{array}{rcll} {}_v\mathrm{M}^{\mathrm{L}}_u & \rightarrow & {}_v\mathrm{R}\ \mathrm{L}_u & \text{where } v \curvearrowleft u \\ \mathrm{L}_u & \rightarrow & u_l \mid \mathrm{L}_v\ {}_v\mathrm{M}^{\mathrm{L}}_u & \text{where } v \curvearrowleft u \end{array}$$

Now unfold L_u in the definition of ${}_v\mathrm{M}^{\mathrm{L}}_u$, producing:

$${}_v\mathrm{M}^{\mathrm{L}}_u \rightarrow {}_v\mathrm{R}\ u_l \mid \underline{{}_v\mathrm{R}\ \mathrm{L}_{v'}}\ {}_{v'}\mathrm{M}^{\mathrm{L}}_u; \quad v \overset{\curvearrowleft}{\curvearrowright} v' \overset{\curvearrowleft}{\curvearrowright} u$$

Note that in the first production expanding ${}_v\mathrm{M}^{\mathrm{L}}_u$, v is the *closest* left dependent of u, and in the second production v and v' are *adjacent* left-dependents of u. ${}_v\mathrm{M}^{\mathrm{L}}_u$ has a ternary production, so we introduce ${}_x\mathrm{M}_y$ as before to fold the underlined constituents into.

$$\begin{array}{rcll} {}_x\mathrm{M}_y & \rightarrow & {}_x\mathrm{R}\ \mathrm{L}_y & \text{where } x, y \in \Sigma \\ {}_v\mathrm{M}^{\mathrm{L}}_u & \rightarrow & {}_v\mathrm{R}\ u_l \mid {}_v\mathrm{M}_{v'}\ {}_{v'}\mathrm{M}^{\mathrm{L}}_u; & v \overset{\curvearrowleft}{\curvearrowright} v' \overset{\curvearrowleft}{\curvearrowright} u \end{array}$$

The resulting grammar schema is as below, and a sample parse is given in Figure 5.

$$\begin{array}{rcll} \mathrm{S} & \rightarrow & \mathrm{L}_u\ {}_u\mathrm{R} & \text{where } 0 \curvearrowright u \\ \mathrm{L}_u & \rightarrow & u_l & u \text{ has no left dependents} \\ \mathrm{L}_u & \rightarrow & \mathrm{L}_v\ {}_v\mathrm{M}^{\mathrm{L}}_u & v \text{ is } u\text{'s last left dep.} \\ {}_v\mathrm{M}^{\mathrm{L}}_u & \rightarrow & {}_v\mathrm{R}\ u_l & v \text{ is } u\text{'s closest left dep.} \\ {}_v\mathrm{M}^{\mathrm{L}}_u & \rightarrow & {}_v\mathrm{M}_{v'}\ {}_{v'}\mathrm{M}^{\mathrm{L}}_u & v \overset{\curvearrowleft}{\curvearrowright} v' \overset{\curvearrowleft}{\curvearrowright} u \\ {}_u\mathrm{R} & \rightarrow & u_r & u \text{ has no right dependents} \\ {}_u\mathrm{R} & \rightarrow & {}_u\mathrm{M}^{\mathrm{R}}_v\ {}_v\mathrm{R} & v \text{ is } u\text{'s last right dep.} \\ {}_u\mathrm{M}^{\mathrm{R}}_v & \rightarrow & u_r\ \mathrm{L}_v & v \text{ is } u\text{'s closest right dep.} \\ {}_u\mathrm{M}^{\mathrm{R}}_v & \rightarrow & {}_u\mathrm{M}^{\mathrm{R}}_{v'}\ {}_{v'}\mathrm{M}_v & u \overset{\curvearrowright}{\curvearrowleft} v' \overset{\curvearrowright}{\curvearrowleft} v \\ {}_x\mathrm{M}_y & \rightarrow & {}_x\mathrm{R}\ \mathrm{L}_y & \text{where } x, y \in \Sigma \end{array}$$

As before, the indices on the nonterminals are redundant, as the heads are always located at an edge of each constituent, so they need not be computed or stored and the CFG can be parsed in $O(n^3)$ time. The steps involved in CKY parsing with this grammar correspond closely to those of the McDonald (2006) second-order PBDG parsing algorithm.

7 An $O(n^3)$ dependent-head grammar

This section shows a different application of Unfold-Fold can capture head-to-head-to-head dependencies, i.e., "vertical" second-order dependencies, rather than the "horizontal" ones captured by the transformation described in the previous section. Because we expect these vertical dependencies to be less important linguistically than the horizontal ones, we only sketch the transformation here.

The derivation differs from the one in Section 6 in that the dependent ${}_v\mathrm{R}$, rather than the head L_u, is unfolded in the initial definition of ${}_v\mathrm{M}^{\mathrm{L}}_u$. This results in a grammar that tracks vertical, rather than horizontal, second-order dependencies. Since left-hand and right-hand derivations are assembled separately in a split-head grammar, the grammar in fact only tracks zig-zag type dependencies (e.g., where a grandparent has a right dependent, which in turn has a left dependent).

The resulting grammar is given below, and a sample parse using this grammar is shown in Figure 6. Because the subscripts are redundant they can be omitted and the resulting CFG can be parsed in

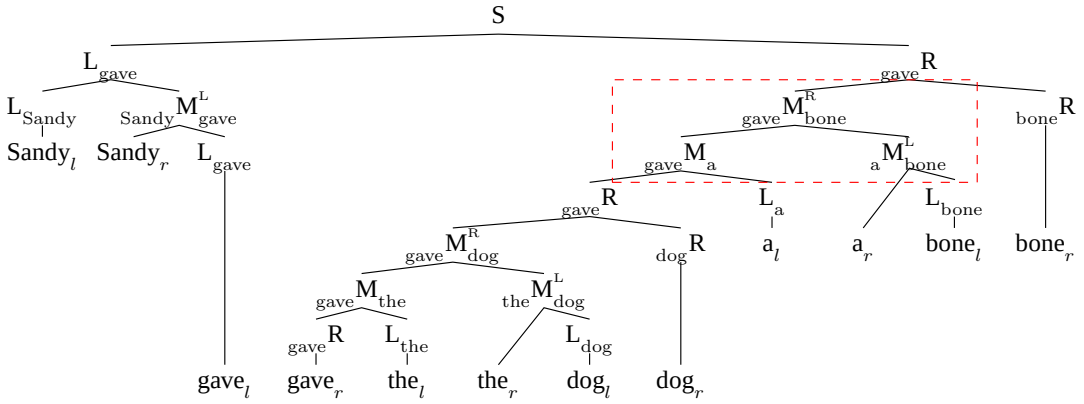

Figure 6: The n^3 dependent-head parse corresponding to the dependency graph of Figure 1. The boxed local tree indicates that *a* is a left-dependent of *bone*, which is in turn a right-dependent of *gave*, i.e., *gave* ← *a* → *bone* .

$O(n^3)$ time using the CKY algorithm.

$$
\begin{array}{rcll}
\mathrm{S} & \rightarrow & \mathrm{L}_{u\ u}\mathrm{R} & \text{where } 0 \curvearrowright u \\
\mathrm{L}_{u} & \rightarrow & u_l & \\
\mathrm{L}_{u} & \rightarrow & \mathrm{L}_{v\ v}\mathrm{M}^{\mathrm{L}}_{u} & \text{where } v \curvearrowleft u \\
{}_{v}\mathrm{M}^{\mathrm{L}}_{u} & \rightarrow & v_r\ \mathrm{L}_{u} & \text{where } v \curvearrowleft u \\
{}_{v}\mathrm{M}^{\mathrm{L}}_{u} & \rightarrow & {}_{v}\mathrm{M}^{\mathrm{R}}_{w\ w}\mathrm{M}_{u} & \text{where } v \leftrightarrows w \ u \\
{}_{u}\mathrm{R} & \rightarrow & u_r & \\
{}_{u}\mathrm{R} & \rightarrow & {}_{u}\mathrm{M}^{\mathrm{R}}_{v\ v}\mathrm{R} & \text{where } u \curvearrowright v \\
{}_{u}\mathrm{M}^{\mathrm{R}}_{v} & \rightarrow & {}_{u}\mathrm{R}\ v_l & \text{where } u \curvearrowright v \\
{}_{u}\mathrm{M}^{\mathrm{R}}_{v} & \rightarrow & {}_{u}\mathrm{M}_{w\ w}\mathrm{M}^{\mathrm{L}}_{v} & \text{where } u \ \overset{\curvearrowright}{\leftrightarrows}\ w \ u \\
{}_{x}\mathrm{M}_{y} & \rightarrow & {}_{x}\mathrm{R}\ \mathrm{L}_{y} & \text{where } x, y \in \Sigma
\end{array}
$$

8 Maximum posterior decoding

As noted in the introduction, one consequence of the PBDG to CFG reductions presented in this paper is that CFG parsing and estimation techniques are now available for PBDGs as well. As an example application, this section describes Maximum Posterior Decoding (MPD) for PBDGs.

Goodman (1996) observed that the Viterbi parse is in general not the optimal parse for evaluation metrics such as f-score that are based on the number of correct constituents in a parse. He showed that MPD improves f-score modestly relative to Viterbi decoding for PCFGs.

Since dependency parse accuracy is just the proportion of dependencies in the parse that are correct, Goodman's observation should hold for PBDG parsing as well. MPD for PBDGs selects the parse that maximizes the sum of the marginal probabilities of each of the dependencies in the parse. Such a decoder might plausibly produce parses that score better on the dependency accuracy metric than Viterbi parses.

MPD is straightforward given the PBDG to CFG reductions described in this paper. Specifically, we use the Inside-Outside algorithm to compute the posterior probability of the CFG constituents corresponding to each PBDG dependency, and then use the Viterbi algorithm to find the parse tree that maximizes the sum of these posterior probabilities.

We implemented MPD for first-order PBDGs using dependency weights from our existing discriminatively-trained PBDG parser (not cited to preserve anonymity). These weights are estimated by an online procedure as in McDonald (2006), and are not intended to define a probability distribution. In an attempt to heuristically correct for this, in this experiment we used $\exp(\alpha w_{u,v})$ as the weight of the dependency between head u and dependent v, where $w_{u,v}$ is the weight provided by the discriminatively-trained model and α is an adjustable scaling parameter tuned to optimize MPD accuracy on development data.

Unfortunately we found no significant difference between the accuracy of the MPD and Viterbi parses. Optimizing MPD on the development data (section 24 of the PTB) set the scale factor $\alpha = 0.21$ and produced MPD parses with an accuracy of 0.8921, which is approximately the same as the Viterbi accuracy of 0.8918. On the blind test data (section 23) the two accuracies are essentially iden-

tical (0.8997).

There are several possible explanations for the failure of MPD to produce more accurate parses than Viterbi decoding. Perhaps MPD requires weights that define a probability distribution (e.g., a MaxEnt model). It is also possible that discriminative training adjusts the weights in a way that ensures that the Viterbi parse is close to the maximum posterior parse. This was the case in our experiment, and if this is true with discriminative training in general, then maximum posterior decoding will not have much to offer to discriminative parsing.

9 Conclusion

This paper shows how to use the Unfold-Fold transform to translate PBDGs into CFGs that can be parsed in $O(n^3)$ time. A key component of this is the split-head construction, where each word u in the input is split into two terminals u_l and u_r of the CFG parse. We also showed how to systematically transform the split-head CFG into grammars which track second-order dependencies. We provided one grammar which captures horizontal second-order dependencies (McDonald, 2006), and another which captures vertical second-order head-to-head-to-head dependencies.

The grammars described here just scratch the surface of what is possible with Unfold-Fold. Notice that both of the second-order grammars have more nonterminals than the first-order grammar. If one is prepared to increase the number of nonterminals still further, it may be possible to track additional information about constituents (although if we insist on $O(n^3)$ parse time we will be unable to track the interaction of more than three heads at once).

Parsing and Generation as Datalog Queries

Makoto Kanazawa

kanazawa@nii.ac.jp

Abstract

We show that the problems of parsing and surface realization for grammar formalisms with "context-free" derivations, coupled with Montague semantics (under a certain restriction) can be reduced in a uniform way to Datalog query evaluation. As well as giving a polynomial-time algorithm for computing all derivation trees (in the form of a shared forest) from an input string or input logical form, this reduction has the following complexity-theoretic consequences for all such formalisms: (i) the decision problem of recognizing grammaticality (surface realizability) of an input string (logical form) is in LOGCFL; and (ii) the search problem of finding one logical form (surface string) from an input string (logical form) is in functional LOGCFL. Moreover, the generalized supplementary magic-sets rewriting of the Datalog program resulting from the reduction yields efficient Earley-style algorithms for both parsing and generation.

1 Introduction

The representation of context-free grammars (augmented with features) in terms of definite clause programs is well-known. In the case of a bare-bone CFG, the corresponding program is in the function-free subset of logic programming, known as *Datalog*. For example, determining whether a string John found a unicorn belongs to the language of the CFG in Figure 1 is equivalent to deciding whether the Datalog program in Figure 2 together with the *database* in (1) can derive the *query* "?– S(0, 4)."

(1) John(0, 1). found(1, 2). a(2, 3). unicorn(3, 4).

S → NP VP	V → found
VP → V NP	V → caught
V → V Conj V	Conj → and
NP → Det N	Det → a
NP → John	N → unicorn

Figure 1: A CFG.

S(i, j) :– NP(i, k), VP(k, j).	V(i, j) :– found(i, j).
VP(i, j) :– V(i, k), NP(k, j).	V(i, j) :– caught(i, j).
V(i, j) :– V(i, k), Conj(k, l), V(l, j).	Conj(i, j) :– and(i, j).
NP(i, j) :– Det(i, k), N(k, j).	Det(i, j) :– a(i, j).
NP(i, j) :– John(i, j).	N(i, j) :– unicorn(i, j).

Figure 2: The Datalog representation of a CFG.

By *naive* (or *seminaive*) bottom-up evaluation (see, e.g., Ullman, 1988), the answer to such a query can be computed in polynomial time in the size of the database for any Datalog program. By recording rule instances rather than derived facts, a packed representation of the complete set of Datalog derivation trees for a given query can also be obtained in polynomial time by the same technique. Since a Datalog derivation tree uniquely determines a grammar derivation tree, this gives a reduction of context-free recognition and parsing to query evaluation in Datalog.

In this paper, we show that a similar reduction to Datalog is possible for more powerful grammar formalisms with "context-free" derivations, such as *(multi-component) tree-adjoining grammars* (Joshi and Schabes, 1997; Weir, 1988), *IO macro grammars* (Fisher, 1968), and *(parallel) multiple context-free grammars* (Seki et al., 1991). For instance, the TAG in Figure 3 is represented by the Datalog program in Figure 4. Moreover, the method of reduc-

tion extends to the problem of tactical generation (surface realization) for these grammar formalisms coupled with Montague semantics (under a certain restriction). Our method essentially relies on the encoding of different formalisms in terms of *abstract categorial grammars* (de Groote, 2001).

The reduction to Datalog makes it possible to apply to parsing and generation sophisticated evaluation techniques for Datalog queries; in particular, an application of *generalized supplementary magic-sets* rewriting (Beeri and Ramakrishnan, 1991) automatically yields Earley-style algorithms for both parsing and generation. The reduction can also be used to obtain a tight upper bound, namely *LOGCFL*, on the computational complexity of the problem of recognition, both for grammaticality of input strings and for surface realizability of input logical forms.

With regard to parsing and recognition of input strings, polynomial-time algorithms and the LOGCFL upper bound on the computational complexity are already known for the grammar formalisms covered by our results (Engelfriet, 1986); nevertheless, we believe that our reduction to Datalog offers valuable insights. Concerning generation, our results seem to be entirely new.[1]

2 Context-free grammars on λ-terms

Consider an augmentation of the grammar in Figure 1 with Montague semantics, where the left-hand side of each rule is annotated with a λ-term that tells how the meaning of the left-hand side is composed from the meanings of the right-hand side nonterminals, represented by upper-case variables $X_1, X_2, \ldots$ (Figure 5).[2]

$\mathsf{S}(X_1 X_2) \rightarrow \mathsf{NP}(X_1)\ \mathsf{VP}(X_2)$
$\mathsf{VP}(\lambda x.X_2(\lambda y.X_1 y x)) \rightarrow \mathsf{V}(X_1)\ \mathsf{NP}(X_2)$
$\mathsf{V}(\lambda y x.X_2(X_1 y x)(X_3 y x)) \rightarrow \mathsf{V}(X_1)\ \mathsf{Conj}(X_2)\ \mathsf{V}(X_3)$
$\mathsf{NP}(X_1 X_2) \rightarrow \mathsf{Det}(X_1)\ \mathsf{N}(X_2)$
$\mathsf{NP}(\lambda u.u\ \mathbf{John}^{e}) \rightarrow \mathsf{John}$
$\mathsf{V}(\mathbf{find}^{e\rightarrow e\rightarrow t}) \rightarrow \mathsf{found}$
$\mathsf{V}(\mathbf{catch}^{e\rightarrow e\rightarrow t}) \rightarrow \mathsf{caught}$
$\mathsf{Conj}(\wedge^{t\rightarrow t\rightarrow t}) \rightarrow \mathsf{and}$
$\mathsf{Det}(\lambda uv.\exists^{(e\rightarrow t)\rightarrow t}(\lambda y.\wedge^{t\rightarrow t\rightarrow t}(uy)(vy))) \rightarrow \mathsf{a}$
$\mathsf{N}(\mathbf{unicorn}^{e\rightarrow t}) \rightarrow \mathsf{unicorn}$

Figure 5: A context-free grammar with Montague semantics.

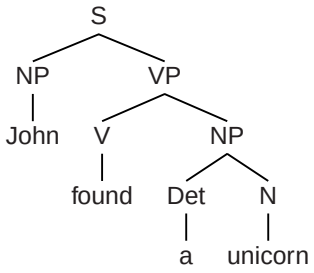

Figure 6: A derivation tree.

The meaning of a sentence is computed from its derivation tree. For example, John found a unicorn has the derivation tree in Figure 6, and the grammar rules assign its root node the λ-term

$$(\lambda u.u\ \mathbf{John})(\lambda x.(\lambda uv.\exists(\lambda y.\wedge(uy)(vy)))\ \mathbf{unicorn}\ (\lambda y.\mathbf{find}\ y\ x)),$$

which β-reduces to the λ-term

(2) $\exists(\lambda y.\wedge(\mathbf{unicorn}\ y)(\mathbf{find}\ y\ \mathbf{John}))$

encoding the first-order logic formula representing the meaning of the sentence (i.e., its logical form).

Thus, computing the logical form(s) of a sentence involves parsing and λ-term normalization. To find a sentence expressing a given logical form, it suffices

[1] We only consider *exact generation*, not taking into account the problem of logical form equivalence, which will most likely render the problem of generation computationally intractable (Moore, 2002).

[2] We follow standard notational conventions in typed λ-calculus. Thus, an application $M_1 M_2 M_3$ (written without parentheses) associates to the left, $\lambda x.\lambda y.M$ is abbreviated to $\lambda xy.M$, and $\alpha \rightarrow \beta \rightarrow \gamma$ stands for $\alpha \rightarrow (\beta \rightarrow \gamma)$. We refer the reader to Hindley, 1997 or Sørensen and Urzyczyn, 2006 for standard notions used in simply typed λ-calculus.

$\mathsf{S}(X_1X_2)$:– $\mathsf{NP}(X_1), \mathsf{VP}(X_2)$.
$\mathsf{VP}(\lambda x.X_2(\lambda y.X_1yx))$:– $\mathsf{V}(X_1), \mathsf{NP}(X_2)$.
$\mathsf{V}(\lambda yx.X_2(X_1yx)(X_3yx))$:– $\mathsf{V}(X_1), \mathsf{Conj}(X_2), \mathsf{V}(X_3)$.
$\mathsf{NP}(X_1X_2)$:– $\mathsf{Det}(X_1), \mathsf{N}(X_2)$.
$\mathsf{NP}(\lambda u.u\ \mathbf{John}^{e})$.
$\mathsf{V}(\mathbf{find}^{e\to e\to t})$.
$\mathsf{V}(\mathbf{catch}^{e\to e\to t})$.
$\mathsf{Conj}(\wedge^{t\to t\to t})$.
$\mathsf{Det}(\lambda uv.\exists^{(e\to t)\to t}(\lambda y.\wedge^{t\to t\to t}(uy)(vy)))$.
$\mathsf{N}(\mathbf{unicorn}^{e\to t})$.

Figure 7: A CFLG.

to find a derivation tree whose root node is associated with a λ-term that β-reduces to the given logical form; the desired sentence can simply be read off from the derivation tree. At the heart of both tasks is the computation of the derivation tree(s) that yield the input. In the case of generation, this may be viewed as parsing the input λ-term with a "context-free" grammar that generates a set of λ-terms (in normal form) (Figure 7), which is obtained from the original CFG with Montague semantics by stripping off terminal symbols. Determining whether a given logical form is surface realizable with the original grammar is equivalent to recognition with the resulting *context-free λ-term grammar* (CFLG).

In a CFLG such as in Figure 7, constants appearing in the λ-terms have preassigned types indicated by superscripts. There is a mapping σ from nonterminals to their types ($\sigma = \{\mathsf{S} \mapsto t, \mathsf{NP} \mapsto (e \to t) \to t, \mathsf{VP} \mapsto e{\to}t, \mathsf{V} \mapsto e{\to}e{\to}t, \mathsf{Conj} \mapsto t{\to}t{\to}t, \mathsf{Det} \mapsto (e{\to}t){\to}(e{\to}t){\to}t, \mathsf{N} \mapsto e{\to}t\}$). A rule that has A on the left-hand side and $B_1, \ldots, B_n$ as right-hand side nonterminals has its left-hand side annotated with a well-formed λ-term M that has type $\sigma(A)$ under the type environment $X_1 : \sigma(B_1), \ldots, X_n : \sigma(B_n)$ (in symbols, $X_1 : \sigma(B_1), \ldots, X_n : \sigma(B_n) \vdash M : \sigma(A)$).

What we have called a context-free λ-term grammar is nothing but an alternative notation for an *abstract categorial grammar* (de Groote, 2001) whose abstract vocabulary is second-order, with the restriction to *linear* λ-terms removed.[3] In the linear case, Salvati (2005) has shown the recognition/parsing complexity to be PTIME, and exhibited an algorithm similar to Earley parsing for TAGs. Second-order

[3] A λ-term is a *λI-term* if each occurrence of λ binds at least one occurrence of a variable. A λI-term is *linear* if no subterm contains more than one free occurrence of the same variable.

$S(\lambda y.X_1(\lambda z.z)y)$:– $A(X_1)$.
$A(\lambda xy.\mathsf{a}^{o\to o}(X_1(\lambda z.\mathsf{b}^{o\to o}(x(\mathsf{c}^{o\to o}z)))(\mathsf{d}^{o\to o}y)))$:– $A(X_1)$.
$A(\lambda xy.xy)$.

Figure 8: The CFLG encoding a TAG.

linear ACGs are known to be expressive enough to encode well-known mildly context-sensitive grammar formalisms in a straightforward way, including TAGs and multiple context-free grammars (de Groote, 2002; de Groote and Pogodalla, 2004).

For example, the linear CFLG in Figure 8 is an encoding of the TAG in Figure 3, where $\sigma(S) = o{\to}o$ and $\sigma(A) = (o \to o) \to o \to o$ (see de Groote, 2002 for details of this encoding). In encoding a string-generating grammar, a CFLG uses o as the type of string position and $o \to o$ as the type of string. Each terminal symbol is represented by a constant of type $o \to o$, and a string $a_1 \ldots a_n$ is encoded by the λ-term $\lambda z.a_1^{o\to o}(\ldots(a_n^{o\to o}z)\ldots)$, which has type $o \to o$.

A string-generating grammar coupled with Montague semantics may be represented by a *synchronous CFLG*, a pair of CFLGs with matching rule sets (de Groote 2001). The transduction between strings and logical forms in either direction consists of parsing the input λ-term with the source-side grammar and normalizing the λ-term(s) constructed in accordance with the target-side grammar from the derivation tree(s) output by parsing.

3 Reduction to Datalog

We show that under a weaker condition than linearity, a CFLG can be represented by a Datalog program, obtaining a tight upper bound (LOGCFL) on the recognition complexity. Due to space limitation, our presentation here is kept at an informal level; formal definitions and rigorous proof of correctness will appear elsewhere.

We use the grammar in Figure 7 as an example, which is represented by the Datalog program in Figure 9. Note that all λ-terms in this grammar are *almost linear* in the sense that they are λI-terms where any variable occurring free more than once in any subterm must have an atomic type. Our construction is guaranteed to be correct only when this condition is met.

Each Datalog rule is obtained from the corresponding grammar rule in the following way. Let

$\mathsf{S}(p_1)$:– $\mathsf{NP}(p_1, p_2, p_3), \mathsf{VP}(p_2, p_3)$.
$\mathsf{VP}(p_1, p_4)$:– $\mathsf{V}(p_2, p_4, p_3), \mathsf{NP}(p_1, p_2, p_3)$.
$\mathsf{V}(p_1, p_4, p_3)$:–
    $\mathsf{V}(p_2, p_4, p_3), \mathsf{Conj}(p_1, p_5, p_2), \mathsf{V}(p_5, p_4, p_3)$.
$\mathsf{NP}(p_1, p_4, p_5)$:– $\mathsf{Det}(p_1, p_4, p_5, p_2, p_3), \mathsf{N}(p_2, p_3)$.
$\mathsf{NP}(p_1, p_1, p_2)$:– $\mathbf{John}(p_2)$.
$\mathsf{V}(p_1, p_3, p_2)$:– $\mathbf{find}(p_1, p_3, p_2)$.
$\mathsf{V}(p_1, p_3, p_2)$:– $\mathbf{catch}(p_1, p_3, p_2)$.
$\mathsf{Conj}(p_1, p_3, p_2)$:– $\wedge(p_1, p_3, p_2)$.
$\mathsf{Det}(p_1, p_5, p_4, p_3, p_4)$:– $\exists(p_1, p_2, p_4), \wedge(p_2, p_5, p_3)$.
$\mathsf{N}(p_1, p_2)$:– $\mathbf{unicorn}(p_1, p_2)$.

Figure 9: The Datalog representation of a CFLG.

M be the λ-term annotating the left-hand side of the grammar rule. We first obtain a *principal* (i.e., most general) *typing* of M.[4] In the case of the second rule, this is

$$X_1 : p_3 \to p_4 \to p_2,\ X_2 : (p_3 \to p_2) \to p_1 \vdash \lambda x.X_2(\lambda y.X_1 y x) : p_4 \to p_1.$$

We then remove $\to$ and parentheses from the types in the principal typing and write the resulting sequences of atomic types in reverse.[5] We obtain the Datalog rule by replacing X_i and M in the grammar rule with the sequence coming from the type paired with X_i and M, respectively. Note that atomic types in the principal typing become variables in the Datalog rule. When there are constants in the λ-term M, they are treated like free variables. In the case of the second-to-last rule, the principal typing is

$$\exists : (p_4 \to p_2) \to p_1,\ \wedge : p_3 \to p_5 \to p_2 \vdash \lambda uv.\exists(\lambda y.\wedge(uy)(vy)) : (p_4 \to p_3) \to (p_4 \to p_5) \to p_1.$$

If the same constant occurs more than once, distinct occurrences are treated as distinct free variables.

The construction of the database representing the input λ-term is similar, but slightly more complex. A simple case is the λ-term (2), where each constant occurs just once. We compute its principal typing, treating constants as free variables.[6]

$$\exists : (4 \to 2) \to 1,\ \wedge : 3 \to 5 \to 2,\ \mathbf{unicorn} : 4 \to 3,\ \mathbf{find} : 4 \to 6 \to 5,\ \mathbf{John} : 6 \vdash \exists(\lambda y.\wedge(\mathbf{unicorn}\, y)(\mathbf{find}\, y\ \mathbf{John})) : 1.$$

[4]To be precise, we must first convert M to its *η-long form* relative to the type assigned to it by the grammar. For example, X_1X_2 in the first rule is converted to $X_1(\lambda x.X_2 x)$.

[5]The reason for reversing the sequences of atomic types is to reconcile the λ-term encoding of strings with the convention of listing string positions from left to right in databases like (1).

[6]We assume that the input λ-term is in η-long normal form.

We then obtain the corresponding database (3) and query (4) from the antecedent and succedent of this judgment, respectively. Note that here we are using $1, 2, 3, \ldots$ as atomic types, which become database constants.

(3) $\exists(1,2,4).\ \wedge(2,5,3).\ \mathbf{unicorn}(3,4).\ \mathbf{find}(5,6,4).\ \mathbf{John}(6).$

(4) ?– $\mathsf{S}(1)$.

When the input λ-term contains more than one occurrence of the same constant, it is not always correct to simply treat them as distinct free variables, unlike in the case of λ-terms annotating grammar rules. Consider the λ-term (5) (John found and caught a unicorn):

(5) $\exists(\lambda y.\wedge(\mathbf{unicorn}\, y)(\wedge(\mathbf{find}\, y\ \mathbf{John})(\mathbf{catch}\, y\ \mathbf{John})))$.

Here, the two occurrences of **John** must be treated as the same variable. The principal typing is (6) and the resulting database is (7).

(6) $\exists : (4 \to 2) \to 1,\ \wedge_1 : 3 \to 5 \to 2,\ \mathbf{unicorn} : 4 \to 3,\ \wedge_2 : 6 \to 8 \to 5,\ \mathbf{find} : 4 \to 7 \to 6,\ \mathbf{John} : 7, \mathbf{catch} : 4 \to 7 \to 8 \vdash \exists(\lambda y.\wedge_1(\mathbf{unicorn}\, y)(\wedge_2(\mathbf{find}\, y\ \mathbf{John})(\mathbf{catch}\, y\ \mathbf{John}))) : 1.$

(7) $\exists(1,2,4).\ \wedge(2,5,3).\ \wedge(5,8,6).\ \mathbf{unicron}(3,4).\ \mathbf{find}(6,7,4).\ \mathbf{John}(7).\ \mathbf{catch}(8,7,4).$

It is not correct to identify the two occurrences of $\wedge$ in this example. The rule is to identify distinct occurrences of the same constant just in case they occur in the same position within α-equivalent subterms of an atomic type. This is a necessary condition for those occurrences to originate as one and the same occurrence in the non-normal λ-term at the root of the derivation tree. (As a preprocessing step, it is also necessary to check that distinct occurrences of a bound variable satisfy the same condition, so that the given λ-term is β-equal to some almost linear λ-term.[7])

[7]Note that the way we obtain a database from an input λ-term generalizes the standard database representation of a string: from the λ-term encoding $\lambda z.a_1^{o\to o}(\ldots(a_n^{o\to o} z)\ldots)$ of a string $a_1 \ldots a_n$, we obtain the database $\{a_1(0,1), \ldots, a_n(n-1,n)\}$.

4 Correctness of the reduction

We sketch some key points in the proof of correctness of our reduction. The λ-term N obtained from the input λ-term by replacing occurrences of constants by free variables in the manner described above is the normal form of some almost linear λ-term N'. The *leftmost reduction* from an almost linear λ-term to its normal form must be *non-deleting* and *almost non-duplicating* in the sense that when a β-redex $(\lambda x.P)Q$ is contracted, Q is not deleted, and moreover it is not duplicated unless the type of x is atomic. We can show that the *Subject Expansion Theorem* holds for such β-reduction, so the principal typing of N is also the principal typing of N'. By a slight generalization of a result by Aoto (1999), this typing $\Gamma \vdash N' : \alpha$ must be *negatively non-duplicated* in the sense that each atomic type has at most one negative occurrence in it. By Aoto and Ono's (1994) generalization of the *Coherence Theorem* (see Mints, 2000), it follows that every λ-term P such that $\Gamma' \vdash P : \alpha$ for some $\Gamma' \subseteq \Gamma$ must be $\beta\eta$-equal to N' (and consequently to N).

Given the one-one correspondence between the grammar rules and the Datalog rules, a Datalog derivation tree uniquely determines a grammar derivation tree (see Figure 10 as an example). This relation is not one-one, because a Datalog derivation tree contains database constants from the input database. This extra information determines a typing of the λ-term P at the root of the grammar derivation tree (with occurrences of constants in the λ-term corresponding to distinct facts in the database regarded as distinct free variables):

$\mathbf{John} : 6$, $\mathbf{find} : 4 \to 6 \to 5$, $\exists : (4 \to 2) \to 1$,
$\wedge : 3 \to 5 \to 2$, $\mathbf{unicorn} : 4 \to 3 \vdash$
$(\lambda u.u\ \mathbf{John})$
$(\lambda x.(\lambda uv.\exists(\lambda y.\wedge(uy)(vy)))\ \mathbf{unicorn}\ (\lambda y.\mathbf{find}\ y\ x)) : 1.$

The antecedent of this typing must be a subset of the antecedent of the principal typing of the λ-term N from which the input database was obtained. By the property mentioned at the end of the preceding paragraph, it follows that the grammar derivation tree is a derivation tree for the input λ-term.

Conversely, consider the λ-term P (with distinct occurrences of constants regarded as distinct free variables) at the root of a grammar derivation tree for the input λ-term. We can show that there is a substitution θ which maps the free variables of P to the free variables of the λ-term N used to build the input database such that θ sends the normal form of P to N. Since P is an almost linear λ-term, the leftmost reduction from $P\theta$ to N is non-deleting and almost non-duplicating. By the Subject Expansion Theorem, the principal typing of N is also the principal typing of $P\theta$, and this together with the grammar derivation tree determines a Datalog derivation tree.

5 Complexity-theoretic consequences

Let us call a rule $A(M) :- B_1(X_1), \ldots, B_n(X_n)$ in a CFLG an *ϵ-rule* if $n = 0$ and M does not contain any constants. We can eliminate ϵ-rules from an almost linear CFLG by the same method that Kanazawa and Yoshinaka (2005) used for linear grammars, noting that for any Γ and α, there are only finitely many almost linear λ-terms M such that $\Gamma \vdash M : \alpha$. If a grammar has no ϵ-rule, any derivation tree for the input λ-term N that has a λ-term P at its root node corresponds to a Datalog derivation tree whose number of leaves is equal to the number of occurrences of constants in P, which cannot exceed the number of occurrences of constants in N.

A Datalog program $\mathbf{P}$ is said to have the *polynomial fringe property* relative to a class $\mathcal{D}$ of databases if there is a polynomial $p(n)$ such that for every database D in $\mathcal{D}$ of n facts and every query q such that $\mathbf{P} \cup D$ derives q, there is a derivation tree for q whose fringe (i.e., sequence of leaves) is of length at most $p(n)$. For such $\mathbf{P}$ and $\mathcal{D}$, it is known that $\{ (D, q) \mid D \in \mathcal{D}, \mathbf{P} \cup D \text{ derives } q \}$ is in the complexity class *LOGCFL* (Ullman and Van Gelder, 1988; Kanellakis, 1988).

We state without proof that the database-query pair (D, q) representing an input λ-term N can be computed in logspace. By padding D with extra useless facts so that the size of D becomes equal to the number of occurrences of constants in N, we obtain a logspace reduction from the set of λ-terms generated by an almost linear CFLG to a set of the form $\{ (D, q) \mid D \in \mathcal{D}, \mathbf{P} \cup D \vdash q \}$, where $\mathbf{P}$ has the polynomial fringe property relative to $\mathcal{D}$. This shows that the problem of recognition for an almost linear CFLG is in LOGCFL.

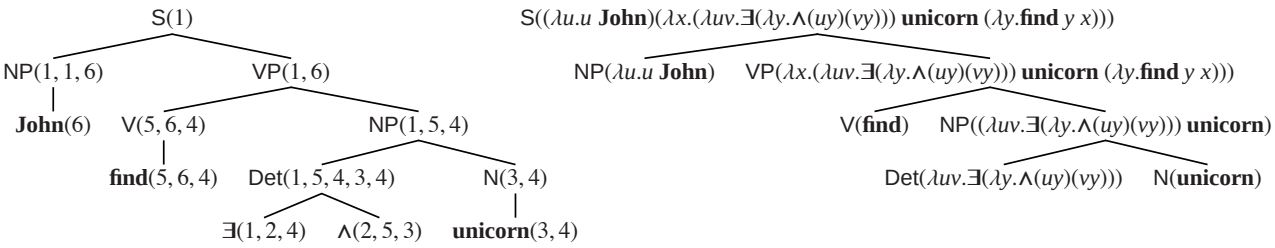

Figure 10: A Datalog derivation tree (left) and the corresponding grammar derivation tree (right)

By the main result of Gottlob et al. (2002), the related search problem of finding one derivation tree for the input λ-term is in *functional LOGCFL*, i.e., the class of functions that can be computed by a logspace-bounded Turing machine with a LOGCFL oracle. In the case of a synchronous almost linear CFLG, the derivation tree found from the source λ-term can be used to compute a target λ-term. Thus, to the extent that transduction back and forth between strings and logical forms can be expressed by a synchronous almost linear CFLG, the search problem of finding one logical form of an input sentence and that of finding one surface realization of an input logical form are both in functional LOGCFL.[8] As a consequence, there are efficient parallel algorithms for these problems.

6 Regular sets of trees as input

Almost linear CFLGs can represent a substantial fragment of a Montague semantics for English and such "linear" grammar formalisms as (multi-component) tree-adjoining grammars (both as string grammars and as tree grammars) and multiple context-free grammars. However, IO macro grammars and parallel multiple context-free grammars cannot be directly represented because representing string copying requires multiple occurrences of a variable of type $o \to o$. This problem can be solved by switching from strings to trees. We convert the input string into the regular set of binary trees whose yield equals the input string (using c as the sole symbol of rank 2), and turn the grammar into a tree grammar, replacing all instances of string concatenation in the grammar with the tree operation $t_1, t_2 \mapsto c(t_1, t_2)$. This way, a string grammar is turned into a tree grammar that generates a set of trees whose image under the yield function is the language of the string grammar. (In the case of an IO macro grammar, the result is an *IO context-free tree grammar* (Engelfriet, 1977).) String copying becomes tree copying, and the resulting grammar can be represented by an almost linear CFLG and hence by a Datalog program. The regular set of all binary trees that yield the input string is represented by a database that is constructed from a deterministic bottom-up finite tree automaton recognizing it. Determinism is important for ensuring correctness of this reduction. Since the database can be computed from the input string in logspace, the complexity-theoretic consequences of the last section carry over here.

7 Magic sets and Earley-style algorithms

Magic-sets rewriting of a Datalog program allows bottom-up evaluation to avoid deriving useless facts by mimicking top-down evaluation of the original program. The result of the *generalized supplementary magic-sets* rewriting of Beeri and Ramakrishnan (1991) applied to the Datalog program representing a CFG essentially coincides with the *deduction system* (Shieber et al., 1995) or *uninstantiated parsing system* (Sikkel, 1997) for Earley parsing. By applying the same rewriting method to Datalog programs representing almost linear CFLGs, we can obtain efficient parsing and generation algorithms for various grammar formalisms with context-free derivations.

We illustrate this approach with the program in Figure 4, following the presentation of Ullman

[8] If the target-side grammar is not linear, the normal form of the target λ-term cannot be explicitly computed because its size may be exponential in the size of the source λ-term. Nevertheless, a typing that serves to uniquely identify the target λ-term can be computed from the derivation tree in logspace. Also, if the target-side grammar is linear and string-generating, the target string can be explicitly computed from the derivation tree in logspace (Salvati, 2007).

(1989a; 1989b). We assume the query to take the form "?– $S(0, x)$.", so that the input database can be processed incrementally. The program is first made *safe* by eliminating the possibility of deriving non-ground atoms:

$S(p_1, p_3)$:– $A(p_1, p_3, p_2, p_2)$.
$A(p_1, p_8, p_4, p_5)$:– $A(p_2, p_7, p_3, p_6)$, $\mathsf{a}(p_1, p_2)$, $\mathsf{b}(p_3, p_4)$, $\mathsf{c}(p_5, p_6)$, $\mathsf{d}(p_7, p_8)$.
$A(p_1, p_8, p_4, p_5)$:– $\mathsf{a}(p_1, p_2)$, $\mathsf{b}(p_2, p_4)$, $\mathsf{c}(p_5, p_6)$, $\mathsf{d}(p_6, p_8)$.

The *subgoal rectification* removes duplicate arguments from subgoals, creating new predicates as needed:

$S(p_1, p_3)$:– $B(p_1, p_3, p_2)$.
$A(p_1, p_8, p_4, p_5)$:– $A(p_2, p_7, p_3, p_6)$, $\mathsf{a}(p_1, p_2)$, $\mathsf{b}(p_3, p_4)$, $\mathsf{c}(p_5, p_6)$, $\mathsf{d}(p_7, p_8)$.
$A(p_1, p_8, p_4, p_5)$:– $\mathsf{a}(p_1, p_2)$, $\mathsf{b}(p_2, p_4)$, $\mathsf{c}(p_5, p_6)$, $\mathsf{d}(p_6, p_8)$.
$B(p_1, p_8, p_4)$:– $A(p_2, p_7, p_3, p_6)$, $\mathsf{a}(p_1, p_2)$, $\mathsf{b}(p_3, p_4)$, $\mathsf{c}(p_4, p_6)$, $\mathsf{d}(p_7, p_8)$.
$B(p_1, p_8, p_4)$:– $\mathsf{a}(p_1, p_2)$, $\mathsf{b}(p_2, p_4)$, $\mathsf{c}(p_4, p_6)$, $\mathsf{d}(p_6, p_8)$.

We then attach to predicates *adornments* indicating the free/bound status of arguments in top-down evaluation, reordering subgoals so that as many arguments as possible are marked as bound:

$S^{bf}(p_1, p_3)$:– $B^{bff}(p_1, p_3, p_2)$.
$B^{bff}(p_1, p_8, p_4)$:– $\mathsf{a}^{bf}(p_1, p_2)$, $A^{bfff}(p_2, p_7, p_3, p_6)$, $\mathsf{b}^{bf}(p_3, p_4)$, $\mathsf{c}^{bb}(p_4, p_6)$, $\mathsf{d}^{bf}(p_7, p_8)$.
$B^{bff}(p_1, p_8, p_4)$:– $\mathsf{a}^{bf}(p_1, p_2)$, $\mathsf{b}^{bf}(p_2, p_4)$, $\mathsf{c}^{bf}(p_4, p_6)$, $\mathsf{d}^{bf}(p_6, p_8)$.
$A^{bfff}(p_1, p_8, p_4, p_5)$:– $\mathsf{a}^{bf}(p_1, p_2)$, $A^{bfff}(p_2, p_7, p_3, p_6)$, $\mathsf{b}^{bf}(p_3, p_4)$, $\mathsf{c}^{bb}(p_5, p_6)$, $\mathsf{d}^{bf}(p_7, p_8)$.
$A^{bfff}(p_1, p_8, p_4, p_5)$:– $\mathsf{a}^{bf}(p_1, p_2)$, $\mathsf{b}^{bf}(p_2, p_4)$, $\mathsf{c}^{ff}(p_5, p_6)$, $\mathsf{d}^{bf}(p_6, p_8)$.

The generalized supplementary magic-sets rewriting finally gives the following rule set:

r_1 : $m\_B(p_1)$:– $m\_S(p_1)$.
r_2 : $S(p_1, p_3)$:– $m\_B(p_1)$, $B(p_1, p_3, p_2)$.
r_3 : $sup_{2.1}(p_1, p_2)$:– $m\_B(p_1)$, $\mathsf{a}(p_1, p_2)$.
r_4 : $sup_{2.2}(p_1, p_7, p_3, p_6)$:– $sup_{2.1}(p_1, p_2)$, $A(p_2, p_7, p_3, p_6)$.
r_5 : $sup_{2.3}(p_1, p_7, p_6, p_4)$:– $sup_{2.2}(p_1, p_7, p_3, p_6)$, $\mathsf{b}(p_3, p_4)$.
r_6 : $sup_{2.4}(p_1, p_7, p_4)$:– $sup_{2.3}(p_1, p_7, p_6, p_4)$, $\mathsf{c}(p_4, p_6)$.
r_7 : $B(p_1, p_8, p_4)$:– $sup_{2.4}(p_1, p_7, p_4)$, $\mathsf{d}(p_7, p_8)$.
r_8 : $sup_{3.1}(p_1, p_2)$:– $m\_B(p_1)$, $\mathsf{a}(p_1, p_2)$.
r_9 : $sup_{3.2}(p_1, p_4)$:– $sup_{3.1}(p_1, p_2)$, $\mathsf{b}(p_2, p_4)$.
r_{10} : $sup_{3.3}(p_1, p_4, p_6)$:– $sup_{3.2}(p_1, p_4)$, $\mathsf{c}(p_4, p_6)$.
r_{11} : $B(p_1, p_8, p_4)$:– $sup_{3.3}(p_1, p_4, p_6)$, $\mathsf{d}(p_6, p_8)$.
r_{12} : $m\_A(p_2)$:– $sup_{2.1}(p_1, p_2)$.
r_{13} : $m\_A(p_2)$:– $sup_{4.1}(p_1, p_2)$.
r_{14} : $sup_{4.1}(p_1, p_2)$:– $m\_A(p_1)$, $\mathsf{a}(p_1, p_2)$.
r_{15} : $sup_{4.2}(p_1, p_7, p_3, p_6)$:– $sup_{4.1}(p_1, p_2)$, $A(p_2, p_7, p_3, p_6)$.
r_{16} : $sup_{4.3}(p_1, p_7, p_6, p_4)$:– $sup_{4.2}(p_1, p_7, p_3, p_6)$, $\mathsf{b}(p_3, p_4)$.
r_{17} : $sup_{4.4}(p_1, p_7, p_4, p_5)$:– $sup_{4.3}(p_1, p_7, p_6, p_4)$, $\mathsf{c}(p_5, p_6)$.
r_{18} : $A(p_1, p_8, p_4, p_5)$:– $sup_{4.4}(p_1, p_7, p_4, p_5)$, $\mathsf{d}(p_7, p_8)$.
r_{19} : $sup_{5.1}(p_1, p_2)$:– $m\_A(p_1)$, $\mathsf{a}(p_1, p_2)$.
r_{20} : $sup_{5.2}(p_1, p_4)$:– $sup_{5.1}(p_1, p_2)$, $\mathsf{b}(p_2, p_4)$.
r_{21} : $sup_{5.3}(p_1, p_4, p_5, p_6)$:– $sup_{5.2}(p_1, p_4)$, $\mathsf{c}(p_5, p_6)$.
r_{22} : $A(p_1, p_8, p_4, p_5)$:– $sup_{5.3}(p_1, p_4, p_5, p_6)$, $\mathsf{d}(p_6, p_8)$.

The following version of chart parsing adds control structure to this deduction system:

1. (INIT) Initialize the chart to the empty set, the agenda to the singleton $\{m\_S(0)\}$, and n to 0.
2. Repeat the following steps:
   (a) Repeat the following steps until the agenda is exhausted:
      i. Remove a fact from the agenda, called the *trigger*.
      ii. Add the trigger to the chart.
      iii. Generate all facts that are immediate consequences of the trigger together with all facts in the chart, and add to the agenda those generated facts that are neither already in the chart nor in the agenda.
   (b) (SCAN) Remove the next fact from the input database and add it to the agenda, incrementing n. If there is no more fact in the input database, go to step 3.
3. If $S(0, n)$ is in the chart, accept; otherwise reject.

The following is the trace of the algorithm on input string aabbccdd:

1.	$m\_S(0)$	INIT	14.	$\mathsf{c}(4, 5)$	SCAN
2.	$m\_B(0)$	$r_1, 1$	15.	$sup_{5.3}(1, 3, 4, 5)$	$r_{21}, 12, 14$
3.	$\mathsf{a}(0, 1)$	SCAN	16.	$\mathsf{c}(6, 5)$	SCAN
4.	$sup_{2.1}(0, 1)$	$r_3, 2, 3$	17.	$sup_{5.3}(1, 3, 5, 6)$	$r_{21}, 12, 16$
5.	$sup_{3.1}(0, 1)$	$r_8, 2, 3$	18.	$\mathsf{d}(6, 7)$	SCAN
6.	$m\_A(1)$	$r_{12}, 4$	19.	$A(1, 7, 3, 5)$	$r_{22}, 17, 18$
7.	$\mathsf{a}(1, 2)$	SCAN	20.	$sup_{2.2}(0, 7, 3, 5)$	$r_4, 4, 19$
8.	$sup_{4.1}(1, 2)$	$r_{14}, 6, 7$	21.	$sup_{2.3}(0, 7, 5, 4)$	$r_5, 13, 20$
9.	$sup_{5.1}(1, 2)$	$r_{19}, 6, 7$	22.	$sup_{2.4}(0, 7, 4)$	$r_6, 14, 21$
10.	$m\_A(2)$	$r_{13}, 8$	23.	$\mathsf{d}(7, 8)$	SCAN
11.	$\mathsf{b}(2, 3)$	SCAN	24.	$B(0, 8, 4)$	$r_7, 22, 23$
12.	$sup_{5.2}(1, 3)$	$r_{20}, 9, 11$	25.	$S(0, 8)$	$r_2, 2, 24$
13.	$\mathsf{b}(3, 4)$	SCAN			

Note that unlike existing Earley-style parsing algorithms for TAGs, the present algorithm is an instantiation of a general schema that applies to parsing with more powerful grammar formalisms as well as to generation with Montague semantics.

8 Conclusion

Our reduction to Datalog brings sophisticated techniques for Datalog query evaluation to the problems

of parsing and generation, and establishes a tight bound on the computational complexity of recognition for a wide range of grammars. In particular, it shows that the use of higher-order λ-terms for semantic representation need not be avoided for the purpose of achieving computational tractability.

Optimizing Grammars for Minimum Dependency Length

Abstract

We examine the problem of choosing word order for a set of dependency trees so as to minimize total dependency length. We present an algorithm for computing the optimal layout of a single tree as well as a numerical method for optimizing a grammar of orderings over a set of dependency types. A grammar generated by minimizing dependency length in unordered trees from the Penn Treebank is found to agree surprisingly well with English word order, suggesting that dependency length minimization has influenced the evolution of English.

1 Introduction

Dependency approaches to language assume that every word in a sentence is the dependent of one other word (except for one word, which is the global head of the sentence), so that the words of a sentence form an acyclic directed graph. An important principle of language, supported by a wide range of evidence, is that there is preference for dependencies to be short. This has been offered as an explanation for numerous psycholinguistic phenomena, such as the greater processing difficulty of object relative clauses versus subject relative clauses (Gibson, 1998). Dependency length minimization is also a factor in ambiguity resolution: listeners prefer the interpretation with shorter dependencies. Statistical parsers make use of features that capture dependency length (e.g. an adjacency feature in Collins (1999), more explicit length features in McDonald et al. (2005) and Eisner and Smith (2005)) and thus learn to favor parses with shorter dependencies.

In this paper we attempt to measure the extent to which basic English word order chooses to minimize dependency length, as compared to average dependency lengths under other possible grammars. We first present a linear-time algorithm for finding the ordering of a single dependency tree with shortest total dependency length. Then, given that word order must also be determined by grammatical relations, we turn to the problem of specifying a grammar in terms of constraints over such relations. We wish to find the set of ordering constraints on dependency types that minimizes a corpus's total dependency length. Even assuming that dependency trees must be projective, this problem is NP-complete,[1] but we find that numerical optimization techniques work well in practice. We reorder unordered dependency trees extracted from corpora and compare the results to English in terms of both the resulting dependency length and the strings that are produced. The optimized order constraints show a high degree of similarity to English, suggesting that dependency length minimization has influenced the word order choices of basic English grammar.

2 The Dependency Length Principle

This idea that dependency length minimization may be a general principle in language has been discussed by many authors. One example concerns the

[1] English has crossing (non-projective) dependencies, but they are believed to be very infrequent. McDonald et al. (2005) report that even in Czech, commonly viewed as a non-projective language, fewer than 2% of dependencies violate the projectivity constraint.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 184–191,
Prague, Czech Republic, June 2007.

well-known principle that languages tend to be predominantly "head-first" (in which the head of each dependency is on the left) or "head-last" (where it is on the right). Frazier (1985) suggests that this might serve the function of keeping heads and dependents close together. In a situation where each word has exactly one dependent, it can be seen that a "head-first" arrangement achieves minimal dependency length, as each link has a length of one.

We will call a head-first dependency "right-branching" and a head-last dependency "left-branching"; a language in which most or all dependencies have the same branching direction is a "same-branching" language.

Another example of dependency length minimization concerns situations where a head has multiple dependents. In such cases, dependency length will be minimized if the shorter dependent is placed closer to the head. Hawkins (1994) has shown that this principle is reflected in grammatical rules across many languages. It is also reflected in situations of choice; for example, in cases where a verb is followed by a prepositional phrase and a direct object NP, the direct object NP will usually be placed first (closer to the verb) but if it is longer than the PP, it is often placed second.

While one might suppose that a "same-branching" language is optimal for dependency-length minimization, this is not in fact the case. If a word has several dependents, placing them all on the same side causes them to get in the way of each other, so that a more 'balanced" configuration – with some dependents on each side – has lower total dependency length. It is particularly desirable for one or more one-word dependent phrases to be "opposite-branching" (in relation to the prevailing branching direction of the language); opposite-branching of a long phrase tends to cause a long dependency from the head of the phrase to the external head.

Exactly this pattern has been observed by Dryer (1992) in natural languages. Dryer argues that, while most languages have a predominant branching direction, phrasal (multi-word) dependents tend to adhere to this prevailing direction much more consistently than one-word dependents, which frequently branch opposite to the prevailing direction of the language. English reflects this pattern quite strongly: While almost all phrasal dependents are right-branching (prepositional phrases, objects of prepositions and verbs, relative clauses, etc.), some 1-word categories are left-branching, notably determiners, noun modifiers, adverbs (sometimes), and attributive adjectives.

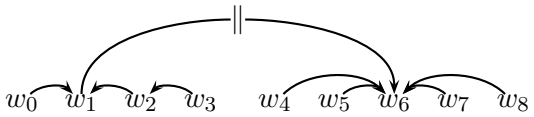

Figure 1: Separating a dependency link into two pieces at a subtree boundary.

This linguistic evidence strongly suggests that languages have been shaped by principles of dependency length minimization. One might wonder how close natural languages are to being optimal in this regard. To address this question, we extract unordered dependency graphs from English and consider different algorithms, which we call Dependency Linearization Algorithms (DLAs), for ordering the words; our goal is to find the algorithm that is optimal with regard to dependency length minimization. We begin with an "unlabeled" DLA, which simply minimizes dependency length without requiring consistent ordering of syntactic relations. We then consider the more realistic case of a "labeled" DLA, which is required to have syntactically consistent ordering.

Once we find the optimal DLA, two questions can be asked. First, how close is dependency length in English to that of this optimal DLA? Secondly, how similar is the optimal DLA to English in terms of the actual rules that arise?

3 The Optimal Unlabeled DLA

Finding linear arrangements of graphs that minimize total edge length is a classic problem, NP-complete for general graphs but with an $O(n^{1.6})$ algorithm for trees (Chung, 1984). However, the traditional problem description does not take into account the projectivity constraint of dependency grammar. This constraint simplifies the problem; in this section we show that a simple linear-time algorithm is guaranteed to find an optimal result.

A natural strategy would be to apply dynamic programming over the tree structure, observing that to-

tal dependency length of a linearization can be broken into the sum of links below any node w in the tree, and the sum of links outside the node, by which we mean all links not connected to dependents of the node. These two quantities interact only through the position of w relative to the rest of its descendants, meaning that we can use this position as our dynamic programming state, compute the optimal layout of each subtree given each position of the head within the subtree, and combine subtrees bottom-up to compute the optimal linearization for the entire sentence.

This can be further improved by observing that the total length of the outside links depends on the position of w only because it affects the length of the link connecting w to its parent. All other outside links either cross above all words under w, and depend only on the total size of w's subtree, or are entirely on one side of w's subtree. The link from w to its parent is divided into two pieces, whose lengths add up to the total length of the link, by slicing the link where it crosses the boundary from w's subtree to the rest of the sentence. In the example in Figure 1, the dependency from w_1 to w_6 has total length five, and is divided in to two components of length 2.5 at the boundary of w_1's subtree. The length of the piece over w's subtree depends on w's position within that subtree, while the other piece does not depend on the internal layout of w's subtree. Thus the total dependency length for the entire sentence can be divided into:

1. the length of all links within w's subtree plus the length of the first piece of w's link to its parent, i.e. the piece that is above descendants of w.

2. the length of the remaining piece of w's link to its parent plus the length of all links outside w.

where the second quantity can be optimized independently of the internal layout of w's subtree. While the link from w to its parent may point either to the right or left, the optimal layout for w's subtree given that w attaches to its left must be the mirror image of the optimal layout given that w attaches to its right. Thus, only one case need be considered, and the optimal layout for the entire sentence can be computed from the bottom up using just one dynamic programming state for each node in the tree.

We now go on to show that, in computing the ordering of the d_i children of a given node, not all $d_i!$ possibilities need be considered. In fact, one can simply order the children by adding them in increasing order of size, going from the head outwards, and alternating between adding to the left and right edges of the constituent.

The first part of this proof is the observation that, as we progress from the head outward, to either the left or the right, the head's child subtrees must be placed in increasing order of size. If any two adjacent children appear with the smaller one further from the head, we can swap the positions of these two children, reducing the total dependency length of the tree. No links crossing over the two children will change in length, and no links within either child will change. Thus only the length of the links from the two children will change, and as the link connecting the outside child now crosses over a shorter intermediate constituent, the total length will decrease.

Next, we show that the two longest children must appear on opposite sides of the head in the optimal linearization. To see this, consider the case where both child i (the longest child) and child $i-1$ (the second longest child) appear on the same side of the head. From the previous result, we know that $i-1$ and i must be the outermost children on their side. If there are no children on the other side of the head, the tree can be improved by moving either i or $i-1$ to the other side. If there is a child on the other side of the head, it must be smaller than both i and $i-1$, and the tree can be improved by swapping the position of the child from the other side and child $i-1$.

Given that the two largest children are outermost and on opposite sides of the head, we observe that the sum of the two links connecting these children to the head does not depend on the arrangement of the first $i-2$ children. Any rearrangement that decreases the length of the link to the left of the head must increase the length of the link to the right of the head by the same amount. Thus, the optimal layout of all i children can be found by placing the two largest children outermost and on opposite sides, the next two largest children next outermost and on op-

DLA	Length
Optimal	33.7
Random	76.1
Observed	47.9

Table 1: Dependency lengths for unlabeled DLAs.

posite sides, and so on until only one or zero children are left. If there are an odd number of children, the side of the final (smallest) child makes no difference, because the other children are evenly balanced on the two sides so the last child will have the same dependency-lengthening effect whichever side it is on.

Our pairwise approach implies that there are many optimal linearizations, $2^{\lfloor i/2 \rfloor}$ in fact, but one simple and optimal approach is to alternate sides as in Figure 2, putting the smallest child next to the head, the next smallest next to the head on the opposite side, the next outside the first on the first side, and so on.

So far we have not considered the piece of the link from the head to its parent that is over the head's subtree. The argument above can be generalized by considering this link as a special child, longer than the longest real child. By making the special child the longest child, we will be guaranteed that it will be placed on the outside, as is necessary for a projective tree. As before, the special child and the longest real child must be placed outermost and on opposite sides, the next two longest children immediately within the first two, and so on.

Using the algorithm from the previous section, it is possible to efficiently compute the optimal dependency length from English sentences. We take sentences from the Wall Street Journal section of the Penn Treebank, extract the dependency trees using the head-word rules of Collins (1999), consider them to be unordered dependency trees, and linearize them to minimize dependency length. Automatically extracting dependencies from the Treebank can lead to some errors, in particular with complex compound nouns. Fortunately, compound nouns tend to occur at the leaves of the tree, and the head rules are reliable for the vast majority of structures.

Results in Table 1 show that observed dependency lengths in English are between the minimum achievable given the unordered dependencies and the length we would find given a random ordering, and are much closer to the minimum. This already suggests that minimizing dependency length has been a factor in the development of English. However, the optimal "language" to which English is being compared has little connection to linguistic reality. Essentially, this model represents a free word-order language: Head-modifier relations are oriented without regard to the grammatical relation between the two words. In fact, however, word order in English is relatively rigid, and a more realistic experiment would be to find the optimal algorithm that reflects consistent syntactic word order rules. We call this a "labeled" DLA, as opposed to the "unlabeled" DLA presented above.

4 Labeled DLAs

In this section, we consider linearization algorithms that assume fixed word order for a given grammatical relation, but choose the order such as to minimize dependency length over a large number of sentences. We represent grammatical relations simply by using the syntactic categories of the highest constituent headed by (maximal projection of) the two words in the dependency relation. Due to sparse data concerns, we removed all function tags such as TMP (temporal), LOC (locative), and CLR (closely related) from the treebank. We made an exception for the SBJ (subject) tag, as we thought it important to distinguish a verb's subject and object for the purposes of choosing word order. Looking at a head and its set of dependents, the complete ordering of all dependents can be modeled as a context-free grammar rule over a nonterminal alphabet of maximal projection categories. A fixed word-order language will have only one rule for each set of nonterminals appearing in the right-hand side.

Searching over all such DLAs would be exponentially expensive, but a simple approximation of the

DLA	Dep. len. / % correct order
random	76.1 / 40.5
extracted from optimal	61.6 / 55.4
weights from English	50.9 / 82.2
optimized weights	42.5 / 64.9

Table 2: Results for different methods of linearizing unordered trees from section 0 of the Wall Street Journal corpus. Each result is given as average dependency length in words, followed by the percentage of heads (with at least one dependent) having all dependents correctly ordered.

optimal labeled DLA can found using the following procedure:

1. Compute the optimal layout of all sentences in the corpus using the unlabeled DLA.

2. For each combination of a head type and a set of child types, count the occurrences of each ordering.

3. Take the most frequent ordering for each set as the order in the new DLA.

In the first step we used the alternating procedure from the previous section, with a modification for the fixed word-order scenario. In order to make the order of a subtree independent of the direction in which it attaches to its parent, dependents were placed in order of length on alternating sides of the head from the inside out, always starting with the shortest dependent immediately to the left of the head.

Results in Table 2 (first two lines) show that a DLA using rules extracted from the optimal layout matches English significantly better than a random DLA, indicating that dependency length can be used as a general principle to predict word order.

4.1 An Optimized Labeled DLA

While the DLA presented above is a good deal better than random (in terms of minimizing dependency length), there is no reason to suppose that it is optimal. In this section we address the issue of finding the optimal labeled DLA.

If we model a DLA as a set of context-free grammar rules over dependency types, specifying a fixed ordering for any set of dependency types attaching to a given head, the space of DLAs is enormous, and the problem of finding the optimal DLA is a difficult one. One way to break the problem down is to model the DLA as a set of weights for each type of dependency relation. Under this model the word order is determined by placing all dependents of a word in order of increasing weight from left to right. This reduces the number of parameters of the model to T, if there are T dependency types, from T^k if a word may have up to k dependents. It also allows us to naturally capture statements such as "a noun phrase consists of a determiner, then (possibly) some adjectives, the head noun, and then (possibly) some prepositional phrases", by, for example, setting the weight for NP→DT to -2, NP→JJ to -1, and NP→PP to 1. We assume the head itself has a weight of zero, meaning negatively weighted dependents appear to the head's left, and positively weighted dependents to the head's right.

4.1.1 A DLA Extracted from English

As a test of whether this model is adequate to represent English word order, we extracted weights for the Wall Street Journal corpus, used them to reorder the same set of sentences, and tested how often words with at least one dependent were assigned the correct order. We extracted the weights by assigning, for each dependency relation in the corpus, an integer according to its position relative to the head, -1 for the first dependent to the left, -2 for the second to the left, and so on. We averaged these numbers across all occurrences of each dependency type. The dependency types consisted of the syntactic categories of the maximal projections of the two words in the dependency relation.

Reconstructing the word order of each sentence from this weighted DLA, we find that 82% of all words with at least one dependent have all dependents ordered correctly (third line of Table 2). This is significantly higher than the heuristic discussed in the previous section, and probably as good as can be expected from such a simple model, particularly in light of the fact that there is some choice in the word order for most sentences (among adjuncts for example) and that this model does not take the lengths of

the individual constituents into account at all.

We now wish to find the set of weights that minimize the dependency length of the corpus. While the size of the search space is still too large to search exhaustively, numerical optimization techniques can be applied to find an approximate solution.

4.1.2 NP-Completeness

The problem of finding the optimum weighted DLA for a set of input trees can be shown to be NP-complete by reducing from the problem of finding a graph's minimum Feedback Arc Set, one of the 21 classic problems of Karp (1972). The input to the Feedback Arc Set problem is a directed graph, for which we wish to find an ordering of vertices such that the smallest number of edges point from later to earlier vertices in the ordering. Given an instance of this problem, we can create a set of dependency trees such that each feedback arc in the original graph causes total dependency length to increase by one, if we identify each dependency type with a vertex in the original problem, and choose weights for the dependency types according to the vertex order.[2]

4.1.3 Local Search

Our search procedure is to optimize one weight at a time, holding all others fixed, and iterating through the set of weights to be set. The objective function describing the total dependency length of the corpus is piecewise constant, as the dependency length will not change until one weight crosses another, causing two dependents to reverse order, at which point the total length will discontinuously jump. Non-differentiability implies that methods based on gradient ascent will not apply. This setting is reminiscent of the problem of optimizing feature weights for reranking of candidate machine translation outputs, and we employ an optimization technique similar to that used by Och (2003) for machine translation. Because the objective function only changes at points where one weight crosses another's value, the set of segments of weight values with different values of the objective function can be exhaustively enumerated. In fact, the only significant points are the values of other weights for dependency types which occur in the corpus attached to the same head as the dependency being optimized. We build a table of interacting dependencies as a preprocessing step on the data, and then when optimizing a weight, consider the sequence of values between consecutive interacting weights. When computing the total corpus dependency length at a new weight value, we can further speed up computation by reordering only those sentences in which a dependency type is used, by building an index of where dependency types occur as another preprocessing step.

[2] We omit details due to space.

	Test Data	
Training Data	WSJ	Swbd
WSJ	42.5 / 64.9	12.5 / 63.6
Swbd	43.9 / 59.8	12.2 / 58.7

Table 3: Domain effects on dependency length minimization: each result is formatted as in Table 2.

This optimization process is not guaranteed to find the global maximum (for this reason we call the resulting DLA "optimized" rather than "optimal"). The procedure is guaranteed to converge simply from the fact that there are a finite number of objective function values, and the objective function must increase at each step at which weights are adjusted.

We ran this optimization procedure on section 2 through 21 of the Wall Street Journal portion of the Penn Treebank, initializing all weights to random numbers between zero and one. This initialization makes all phrases head-initial to begin with, and has the effect of imposing a directional bias on the resulting grammar. When optimization converges, we obtain a set of weights which achieves an average dependency length of 40.4 on the training data, and 42.5 on held-out data from section 0 (fourth line of Table 2). While the procedure is unsupervised with respect to the English word order (other than the head-initial bias), it is supervised with respect to dependency length minimization; for this reason we report all subsequent results on held-out data. While random initializations lead to an initial average dependency length varying from 60 to 73 with an average of 66 over ten runs, all runs were within $\pm.5$ of one another upon convergence. When the order of words' dependents was compared to the real word order on held-out data, we find that 64.9% of words

Training Sents	Dep. len. / % correct order
100	13.70 / 54.38
500	12.81 / 57.75
1000	12.59 / 58.01
5000	12.34 / 55.33
10000	12.27 / 55.92
50000	12.17 / 58.73

Table 4: Average dependency length and rule accuracy as a function of training data size, on Switchboard data.

with at least one dependent have the correct order.

4.2 Domain Variation

Written and spoken language differ significantly in their structure, and one of the most striking differences is the much greater average sentence length of formal written language. The Wall Street Journal is not representative of typical language use. Language was not written until relatively recently in its development, and the Wall Street Journal in particular represents a formal style with much longer sentences than are used in conversational speech. The change in the lengths of sentences and their constituents could make the optimized DLA in terms of dependency length very different for the two genres.

In order to test this effect, we performed experiments using both the Wall Street Journal (written) and Switchboard (conversational speech) portions of the Penn Treebank, and compared results with different training and test data. For Switchboard, we used the first 50,000 sentences of sections 2 and 3 as the training data, and all of section 4 as the test data.

We find relatively little difference in dependency length as we vary training data between written and spoken English, as shown in Table 3. For the accuracy of the resulting word order, however, training on Wall Street Journal outperforms Switchboard even when testing on Switchboard, perhaps because the longer sentences in WSJ provide more information for the optimization procedure to work with.

4.3 Learning Curve

How many sentences are necessary to learn a good set of dependency weights? Table 4 shows results for Switchboard as we increase the number of sentences provided as input to the weight optimization procedure. While the average dependency length on held-out test data slowly decreases with more data, the percentage of correctly ordered dependents is less well-behaved. It turns out that even 100 sentences are enough to learn a DLA that is nearly as good as one derived from a much larger dataset.

Label	Interpretation	Weight
S→NP	verb - object NP	0.037
S→NP-SBJ	verb - subject NP	-0.022
S→PP	verb - PP	0.193
NP→DT	object noun - determiner	-0.070
NP-SBJ→DT	subject noun - determiner	-0.052
NP→PP	obj noun - PP	0.625
NP-SBJ→PP	subj noun - PP	0.254
NP→SBAR	obj noun - rel. clause	0.858
NP-SBJ→SBAR	subject noun - rel. clause	-0.110
NP→JJ	obj noun - adjective	0.198
NP-SBJ→JJ	subj noun - adjective	-0.052

Table 5: Sample weights from optimized DLA. Negatively weighted dependents appear to the left of their head.

4.4 Comparing the Optimized DLA to English

We have seen that the optimized DLA matches English text much better than a random DLA and that it achieves only a slightly lower dependency length than English. It is also of interest to compare the optimized DLA to English in more detail. First we examine the DLA's tendency towards "opposite-branching 1-word phrases". English reflects this principle to a striking degree: on the WSJ test set, 79.4 percent of left-branching phrases are 1-word, compared to only 19.4 percent of right-branching phrases. The optimized DLA also reflects this pattern, though somewhat less strongly: 75.5 percent of left-branching phrases are 1-word, versus 36.7 percent of right-branching phrases.

We can also compare the optimized DLA to English with regard to specific rules. As explained earlier, the optimal DLA's rules are expressed in the form of weights assigned to each relation, with positive weights indicating right-branching placement. Table 5 shows some important rules. The middle column shows the syntactic situation in which the relation normally occurs. We see, first of all, that object NPs are to the right of the verb and subject NPs are to the left, just like in English. PPs are also the right of verbs; the fact that the weight is greater than for NPs indicates that they are placed further to the right, as they normally are in English. Turning

to the internal structure of noun phrases, we see that determiners are to the left of both object and subject nouns; PPs are to the right of both object and subject nouns. We also find some differences with English, however. Clause modifiers of nouns (these are mostly relative clauses) are to the right of object nouns, as in English, but to the left of subject nouns; adjectives are to the left of subject nouns, as in English, but to the right of object nouns. Of course, these differences partly arise from the fact that we treat NP and NP-SBJ as distinct whereas English does not (with regard to their internal structure).

5 Conclusion

In this paper we have presented a dependency linearization algorithm which is optimized for minimizing dependency length, while still maintaining consistent positioning for each grammatical relation. The fact that English is so much lower than the random DLAs in dependency length gives suggests that dependency length minimization is an important general preference in language. The output of the optimized DLA also proves to be much more similar to English than a random DLA in word order. An informal comparison of some important rules between English and the optimal DLA reveals a number of striking similarities, though also some differences.

The fact that the optimized DLA's ordering matches English on only 65% of words shows, not surprisingly, that English word order is determined by other factors in addition to dependency length minimization. In some cases, ordering choices in English are underdetermined by syntactic rules. For example, a manner adverb may be placed either before the verb or after ("He ran quickly / he quickly ran"). Here the optimized DLA requires a consistent ordering while English does not. One might suppose that such syntactic choices in English are guided at least partly by dependency length minimization, and indeed there is evidence for this; for example, people tend to put the shorter of two PPs closer to the verb (Hawkins, 1994). But there are also other factors involved – for example, the tendency to put "given" discourse elements before "new" ones, which has been shown to play a role independent of length (Arnold et al., 2000).

In other cases, the optimized DLA allows more fine-grained choices than English. For example, the optimized DLA treats NP and NP-SBJ as different; this allows it to have different syntactic rules for the two cases – a possibility that it sometimes exploits, as seen above. No doubt this partly explains why the optimized DLA achieves lower dependency length than English.

Abstract

Large corpora of parsed sentences with semantic role labels (e.g. PropBank) provide training data for use in the creation of high-performance automatic semantic role labeling systems. Despite the size of these corpora, individual verbs (or rolesets) often have only a handful of instances in these corpora, and only a fraction of English verbs have even a single annotation. In this paper, we describe an approach for dealing with this sparse data problem, enabling accurate semantic role labeling for novel verbs (rolesets) with only a single training example. Our approach involves the identification of syntactically similar verbs found in PropBank, the alignment of arguments in their corresponding rolesets, and the use of their corresponding annotations in PropBank as surrogate training data.

1 Generalizing Semantic Role Annotations

A recent release of the PropBank (Palmer et al., 2005) corpus of semantic role annotations of Treebank parses contained 112,917 labeled instances of 4,250 rolesets corresponding to 3,257 verbs, as illustrated by this example for the verb *buy*.

[$_{arg0}$ Chuck] [$_{buy.01}$ bought] [$_{arg1}$ a car] [$_{arg2}$ from Jerry] [$_{arg3}$ for $1000].

Annotations similar to these have been used to create automated semantic role labeling systems (Pradhan et al., 2005; Moschitti et al., 2006) for use in natural language processing applications that require only shallow semantic parsing. As with all machine-learning approaches, the performance of these systems is heavily dependent on the availability of adequate amounts of training data. However, the number of annotated instances in PropBank varies greatly from verb to verb; there are 617 annotations for the *want* roleset, only 7 for *desire*, and 0 for any sense of the verb *yearn*. Do we need to keep annotating larger and larger corpora in order to generate accurate semantic labeling systems for verbs like *yearn*?

A better approach may be to generalize the data that exists already to handle novel verbs. It is reasonable to suppose that there must be a number of verbs within the PropBank corpus that behave nearly exactly like *yearn* in the way that they relate to their constituent arguments. Rather than annotating new sentences that contain the verb *yearn*, we could simply find these similar verbs and use their annotations as surrogate training data.

This paper describes an approach to generalizing semantic role annotations across different verbs, involving two distinct steps. The first step is to order all of the verbs with semantic role annotations according to their syntactic similarity to the target verb, followed by the second step of aligning argument labels between different rolesets. To evaluate this approach we developed a simple automated semantic role labeling algorithm based on the frequency of parse-tree paths, and then compared its performance when using real and surrogate training data from PropBank.

Prague, Czech Republic, June 2007.

2 Parse Tree Paths

A key concept in understanding our approach to both automated semantic role annotation and generalization is the notion of a *parse tree path*. Parse tree paths were used for semantic role labeling by Gildea and Jurafsky (2002) as descriptive features of the syntactic relationship between predicates and their arguments in the parse tree of a sentence. Predicates are typically assumed to be specific target words (verbs), and arguments are assumed to be spans of words in the sentence that are dominated by nodes in the parse tree. A parse tree path can be described as a sequence of transitions up from the target word then down to the node that dominates the argument span (e.g. Figure 1).

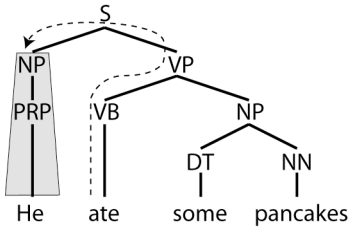

Figure 1: An example parse tree path from the predicate *ate* to the argument NP *He*, represented as ↑VB↑VP↑S↓NP

Parse tree paths are particularly interesting for automated semantic role labeling because they generalize well across syntactically similar sentences. For example, the parse tree path in Figure 1 would still correctly identify the "eater" argument in the given sentence if the personal pronoun "he" were swapped with a markedly different noun phrase, e.g. "the attendees of the annual holiday breakfast."

3 A Simple Semantic Role Labeler

To explore issues surrounding the generalization of semantic role annotations across verbs, we began by authoring a simple automated semantic role labeling algorithm that assigns labels according to the frequency of the parse tree paths seen in training data. To construct a labeler for a specific roleset, training data consisting of parsed sentences with role-labeled parse tree constituents are analyzed to identify all of the parse tree paths between predicates and arguments, which are then tabulated and sorted by frequency. For example, Table 1 lists the 10 most frequent pairs of arguments and parse tree paths for the *want.01* roleset in a recent release of PropBank.

Count	Argument	Parse tree path
189	ARG0	↑VBP↑VP↑S↓NP
159	ARG1	↑VBP↑VP↓S
125	ARG0	↑VBZ↑VP↑S↓NP
110	ARG1	↑VBZ↑VP↓S
102	ARG0	↑VB↑VP↑VP↑S↓NP
98	ARG1	↑VB↑VP↓S
96	ARG0	↑VBD↑VP↑S↓NP
79	ARGM	↑VB↑VP↑VP↓RB
76	ARG1	↑VBD↑VP↓S
43	ARG1	↑VBP↑VP↓NP

Table 1. Top 10 most frequent parse tree paths for arguments of the PropBank want.01 roleset, based on 617 annotations

To automatically assign role labels to an unlabeled parse tree, each entry in the table is considered in order of highest frequency. Beginning from the target word in the sentence (e.g. *wants*) a check is made to determine if the entry includes a possible parse tree path in the parse tree of the sentence. If so, then the constituent is assigned the role label of the entry, and all subsequent entries in the table that have the same argument label or lead to subconstituents of the labeled node are invalidated. Only subsequent entries that assign core arguments of the roleset (e.g. ARG0, ARG1) are invalidated, allowing for multiple assignments of non-core labels (e.g. ARGM) to a test sentence. In cases where the path leads to more than one node in a sentence, the leftmost path is selected. This process then continues down the list of valid table entries, assigning additional labels to unlabeled parse tree constituents, until the end of the table is reached.

This approach also offers a simple means of dealing with multiple-constituent arguments, which occasionally appear in PropBank data. In these cases, the data is listed as unique entries in the frequency table, where each of the parse tree paths to the multiple constituents are listed as a set. The labeling algorithm will assign the argument of the entry only if all parse tree paths in the set are present in the sentence.

The expected performance of this approach to semantic role labeling was evaluated using the PropBank data using a leave-one-out cross-validation experimental design. Precision and recall scores were calculated for each of the 3,086

rolesets with at least two annotations. Figure 2 graphs the average precision, recall, and F-score for rolesets according to the number of training examples of the roleset in the PropBank corpus. An additional curve in Figure 2 plots the percentage of these PropBank rolesets that have the given amount of training data or more. For example, F-scores above 0.7 are first reached with 62 training examples, but only 8% of PropBank rolesets have this much training data available.

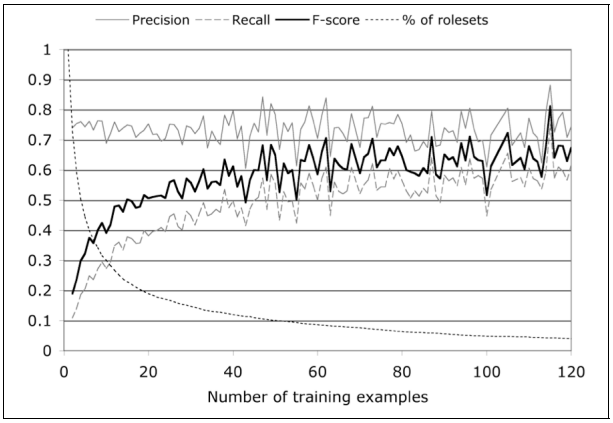

Figure 2. Performance of our semantic role labeling approach on PropBank rolesets

4 Identifying Syntactically Similar Verbs

A key part of generalizing semantic role annotations is to calculate the syntactic similarity between verbs. The expectation here is that verbs that appear in syntactically similar contexts are going to behave similarly in the way that they relate to their arguments. In this section we describe a fully automated approach to calculating the syntactic similarity between verbs.

Our approach is strictly empirical; the similarity of verbs is determined by examining the syntactic contexts in which they appear in a large text corpus. Our approach is analogous to previous work in extracting collocations from large text corpora using syntactic information (Lin, 1998). In our work, we utilized the GigaWord corpus of English newswire text (Linguistic Data Consortium, 2003), consisting of nearly 12 gigabytes of textual data. To prepare this corpus for analysis, we extracted the body text from each of the 4.1 million entries in the corpus and applied a maximum-entropy algorithm to identify sentence boundaries (Reynar and Ratnaparkhi, 1997).

Next we executed a four-step analysis process for each of the 3,257 verbs in the PropBank corpus. In the first step, we identified each of the sentences in the prepared GigaWord corpus that contained any inflection of the given verb. To automatically identify all verb inflections, we utilized the English DELA electronic dictionary (Courtois, 2004), which contained all but 21 of the PropBank verbs (for which we provided the inflections ourselves), with old-English verb inflections removed. We extracted GigaWord sentences containing these inflections by using the GNU *grep* program and a template regular expression for each inflection list. The results of these searches were collected in 3,257 files (one for each verb). The largest of these files was for inflections of the verb *say* (15.9 million sentences), and the smallest was for the verb *namedrop* (4 sentences).

The second step was to automatically generate syntactic parse trees for the GigaWord sentences found for each verb. It was our original intention to parse all of the found sentences, but we found that the slow speed of contemporary syntactic parsers made this impractical. Instead, we focused our efforts on the first 100 sentences found for each of the 3,257 verbs with 100 or fewer tokens: a total of 324,461 sentences (average of 99.6 per verb). For this task we utilized the August 2005 release of the Charniak parser with the default speed/accuracy settings (Charniak, 2000), which required roughly 360 hours of processor time on a 2.5 GHz PowerPC G5.

The third step was to characterize the syntactic context of the verbs based on where they appeared within the parse trees. For this purpose, we utilized parse tree paths as a means of converting tree structures into a flat, feature-vector representation. For each sentence, we identified all *possible* parse tree paths that begin from the verb inflection and terminate at a constituent that does not include the verb inflection. For example, the syntactic context of the verb in Figure 1 can be described by the following five parse tree paths:

1. ↑VB↑VP↑S↓NP
2. ↑VB↑VP↑S↓NP↓PRP
3. ↑VB↑VP↓NP
4. ↑VB↑VP↓NP↓DT
5. ↑VB↑VP↓NP↓NN

Possible parse tree paths were identified for every parsed sentence for a given verb, and the frequencies of each unique path were tabulated

into a feature vector representation. Parse tree paths where the first node was not a Treebank part-of-speech tag for a verb were discarded, effectively filtering the non-verb homonyms of the set of inflections. The resulting feature vectors were normalized by dividing the values of each feature by the number of verb instances used to generate the parse tree paths; the value of each feature indicates the proportion of observed inflections in which the parse tree path is possible. As a representative example, 95 verb forms of *abandon* were found in the first 100 GigaWord sentences containing any inflection of this verb. For this verb, 4,472 possible parse tree paths were tabulated into 3,145 unique features, 2501 of which occurred only once.

The fourth step was to compute the distance between a given verb and each of the 3,257 feature vector representations describing the syntactic context of PropBank verbs. We computed and compared the performance of a wide variety of possible vector-based distance metrics, including Euclidean, Manhattan, and Chi-square (with un-normalized frequency counts), but found that the ubiquitous cosine measure was least sensitive to variations in sample size between verbs. To facilitate a comparative performance evaluation (section 6), pairwise cosine distance measures were calculated between each pair of PropBank verbs and sorted into individual files, producing 3,257 lists of 3,257 verbs ordered by similarity.

Table 2 lists the 25 most syntactically similar pairs of verbs among all PropBank verbs. There are a number of notable observations in this list. First is the extremely high similarity between *bind* and *bound*. This is partly due to the fact that they share an inflection (*bound* is the irregular past tense form of *bind*), so the first 100 instances of GigaWord sentences for each verb overlap significantly, resulting in overlapping feature vector representations. Although this problem appears to be restricted to this one pair of verbs, it could be avoided in the future by using the part-of-speech tag in the parse tree to help distinguish between verb lemmas.

A second observation of Table 2 is that several verbs appear multiple times in this list, yielding sets of verbs that all have high syntactic similarity. Three of these sets account for 19 of the verbs in this list:

1. plunge, tumble, dive, jump, fall, fell, dip
2. assail, chide, lambaste
3. buffet, embroil, lock, superimpose, whipsaw, pluck, whisk, mar, ensconce

The appearance of these sets suggests that our method of computing syntactic similarity could be used to identify distinct clusters of verbs that behave in very similar ways. In future work, it would be particularly interesting to compare empirically-derived verb clusters to verb classes derived from theoretical considerations (Levin, 1993), and to the automated verb classification techniques that use these classes (Joanis and Stevenson, 2003).

A third observation of Table 2 is that the verb pairs with the highest syntactic similarity are often synonyms, e.g. the cluster of *assail*, *chide*, and *lambaste*. As a striking example, the 14 most syntactically similar verbs to *believe* (in order) are *think*, *guess*, *hope*, *feel*, *wonder*, *theorize*, *fear*, *reckon*, *contend*, *suppose*, *understand*, *know*, *doubt*, and *suggest* – all mental action verbs. This observation further supports the distributional hypothesis of word similarity and corresponding technologies for identifying synonyms by similarity of lexical-syntactic context (Lin, 1998).

Verb pairs (instances)		*Cosine*
bind (83)	bound (95)	0.950
plunge (94)	tumble (87)	0.888
dive (36)	plunge (94)	0.867
dive (36)	tumble (87)	0.866
jump (79)	tumble (87)	0.865
fall (84)	fell (102)	0.859
intersperse (99)	perch (81)	0.859
assail (100)	chide (98)	0.859
dip (81)	fell (102)	0.858
buffet (72)	embroil (100)	0.856
embroil (100)	lock (73)	0.856
embroil (100)	superimpose (100)	0.856
fell (102)	jump (79)	0.855
fell (102)	tumble (87)	0.855
embroil (100)	whipsaw (63)	0.850
pluck (100)	whisk (99)	0.849
acquit (100)	hospitalize (99)	0.849
disincline (70)	obligate (94)	0.848
jump (79)	plunge (94)	0.848
dive (36)	jump (79)	0.847
assail (100)	lambaste (100)	0.847
festoon (98)	strew (100)	0.846
mar (78)	whipsaw (63)	0.846
pluck (100)	whipsaw (63)	0.846
ensconce (101)	whipsaw (63)	0.845

Table 2. Top 25 most syntactically similar pairs of the 3257 verbs in PropBank. Each verb is listed with the number of inflection instances used to calculate the cosine measurement.

5 Aligning Arguments Across Rolesets

The second key aspect of our approach to generalizing annotations is to make mappings between the argument roles of the novel target verb and the roles used for a given roleset in the PropBank corpus. For example, if we'd like to apply the training data for a roleset of the verb *desire* in PropBank to a novel roleset for the verb *yearn*, we need to know that the *desirer* corresponds to the *yearner*, the *desired* to the *yearned-for*, etc. In this section, we describe an approach to argument alignment that involves the application of the semantic role labeling approach described in section 3 to a single training example for the target verb.

To simplify the process of aligning argument labels across rolesets, we make a number of assumptions. First, we only consider cases where two rolesets have exactly the same number of arguments. The version of the PropBank corpus that we used in this research contained 4250 rolesets, each with 6 or fewer roles (typically two or three). Accordingly, when attempting to apply PropBank data to a novel roleset with a given argument count (e.g. two), we only consider the subset of PropBank data that labels rolesets with exactly the same count.

Second, our approach requires at least one fully-annotated training example for the target roleset. A fully-annotated sentence is one that contains a labeled constituent in its parse tree for each role in the roleset. As an illustration, the example sentence in section 1 (for the roleset *buy.01*) would not be considered a fully-annotated training example, as only four of the five arguments of the PropBank *buy.01* roleset are present in the sentence (it is missing a *benefactor*, as in "Chuck bought *his mother* a car from Jerry for $1000").

In both of these simplifying requirements, we ignore role labels that may be assigned to a sentence but that are not defined as part of the roleset, specifically the *ARGM* labels used in PropBank to label standard proposition modifiers (e.g. location, time, manner).

Our approach begins with a list of verbs ordered by their calculated syntactic similarity to the target verb, as described in section 4 of this paper. We subsequently apply two steps that transform this list into an ordered set of rolesets that can be aligned with the roles used in one or more fully-annotated training examples of the target verb. In describing these two steps, we use *instigate* as an example target verb. Instigate already appears in the PropBank corpus as a two-argument roleset, but it has only a single training example:

> [$_{arg0}$ The Mahatma, or "great souled one,"] [$_{instigate.01}$ instigated] [$_{arg1}$ several campaigns of passive resistance against the British government in India].

The syntactic similarity of *instigate* to all PropBank verbs was calculated in the manner described in the previous section. This resulting list of 3,180 entries begins with the following fourteen verbs: *orchestrate*, *misrepresent*, *summarize*, *wreak*, *rub*, *chase*, *refuse*, *embezzle*, *harass*, *spew*, *thrash*, *unearth*, *snub*, and *erect*.

The first step is to replace each of the verbs in the ordered list with corresponding rolesets from PropBank that have the same number of roles as the target verb. As an example, our target roleset for the verb *instigate* has two arguments, so each verb in the ordered list is replaced with the set of corresponding rolesets that also have two arguments, or removed if no two-argument rolesets exist for the verb in the PropBank corpus. The ordered list of verbs for *instigate* is transformed into an ordered list of 2,115 rolesets with two arguments, beginning with the following five entries: *orchestrate.01*, *chase.01*, *unearth.01*, *snub.01*, and *erect.01*.

The second step is to identify the alignments between the arguments of the target roleset and each of the rolesets in the ordered list. Beginning with the first roleset on the list (e.g. *orchestrate.01*), we build a semantic role labeler (as described in section 3) using its available training annotations from the PropPank corpus. We then apply this labeler to the single, fully-annotated example sentence for the target verb, treating it as if it were a test example of the same roleset. We then check to see if any of the core (numbered) role labels *overlap* with the annotations that are provided. In cases where an annotated constituent of the target test sentence is assigned a label from the source roleset, then the roleset mappings are noted along with the entry in the ordered list. If no mappings are found, the roleset is removed from the ordered list.

For example, the roleset for *orchestrate.01* contains two arguments (*ARG0* and *ARG1*) that correspond to the "conductor, manager" and the "things

being coordinated or managed". This roleset is used for only three sentence annotations in the PropBank corpus. Using these annotations as training data, we build a semantic role labeler for this roleset and apply it to the annotated sentence for *instigate.01*, treating it as if it were a test sentence for the roleset *orchestrate.01*. The labeler assigns the *orchestrate.01* label *ARG1* to the same constituent labeled *ARG1* in the test sentence, but fails to assign a label to the other argument constituent in the test sentence. Therefore, a single mapping is recorded in the ordered list of rolesets, namely that *ARG1* of *orchestrate.01* can be mapped to *ARG1* of *instigate.01*.

After all of the rolesets are considered, we are left with a filtered list of rolesets with their argument mappings, ordered by their syntactic similarity to the target verb. For the roleset instigate.01, this list consists of 789 entries, beginning with the following 5 mappings.

1. *orchestrate.01*, 1:1
2. *chase.01*, 0:0, 1:1
3. *unearth.01*, 0:0, 1:1
4. *snub.01*, 1:1
5. *erect.01*, 0:0, 1:1

Given this list, arbitrary amounts of PropBank annotations can be used as surrogate training data for the *instigate.01* roleset, beginning at the top of the list. To utilize surrogate training data in our semantic role labeling approach (Section 3), we combine parse tree path information for a selected portion of surrogate training data into a single list sorted by frequency, and apply these files to test sentences as normal.

Although we use an existing PropBank roleset (*instigate.01*) as an example in this section, this approach will work for any novel roleset where one fully-annotated training example is available. For example, arbitrary amounts of surrogate PropBank data can be found for the novel verb *yearn* by 1) searching for sentences with the verb *yearn* in the GigaWord corpus, 2) calculating the syntactic similarity between *yearn* and all PropBank verbs as described in Section 4, 3) aligning the arguments in a single fully-annotated example of *yearn* with ProbBank rolesets with the same number of arguments using the method described in this section, and 4) selecting arbitrary amounts of PropBank annotations to use as surrogate training data, starting from the top of the resulting list.

6 Evaluation

We conducted a large-scale evaluation to determine the performance of our semantic role labeling algorithm when using variable amounts of surrogate training data, and compared these results to the performance that could be obtained using various amounts of real training data (as described in section 3). Our hypothesis was that learning-curves for surrogate-trained labelers would be somewhat less steep, but that the availability of large-amounts of surrogate training data would more than make up for the gap.

To test this hypothesis, we conducted an evaluation using the PropBank corpus as our testing data as well as our source for surrogate training data. As described in section 5, our approach requires the availability of at least one fully-annotated sentence for a given roleset. Only 28.5% of the PropBank annotations assign labels for each of the numbered arguments in their given roleset, and only 2,858 of the 4,250 rolesets used in PropBank annotations (66.5%) have at least one fully-annotated sentence. Of these, 2,807 rolesets were for verbs that appeared at least once in our analysis of the GigaWord corpus (Section 4). Accordingly, we evaluated our approach using the annotations for this set of 2,807 rolesets as test data. For each of these rolesets, various amounts of surrogate training data were gathered from all 4,250 rolesets represented in PropBank, leaving out the data for whichever roleset was being tested.

For each of the target 2,807 rolesets, we generated a list of semantic role mappings ordered by syntactic similarity, using the methods described in sections 4 and 5. In aligning arguments, only a single training example from the target roleset was used, namely the first annotation within the PropBank corpus where all of the rolesets arguments were assigned. Our approach failed to identify any argument mappings for 41 of the target rolesets, leaving them without any surrogate training data to utilize. Of the remaining 2,766 rolesets, the number of mapped rolesets for a given target ranged from 1,041 to 1 (mean = 608, stdev = 297).

For each of the 2,766 target rolesets with alignable roles, we gathered increasingly larger amounts of surrogate training data by descending the ordered list of mappings translating the PropBank data for each entry according to its argument mappings. Then each of these incrementally larger sets

of training data was then used to build a semantic role labeler as described in section 3. The performance of each of the resulting labelers was then evaluated by applying it to all of the test data available for target roleset in PropBank, using the same scoring methods described in section 3. The performance scores for each labeler were recorded along with the total number of surrogate training examples used to build the labeler.

Figure 3 presents the performance result of our semantic role labeling approach using various amounts of surrogate training data. Along with precision, recall, and F-score data, Figure 3 also graphs the percentage of PropBank rolesets for which a given amount of training data had been identified using our approach, of the 2,858 rolesets with at least one fully-annotated training example. For instance, with 120 surrogate annotations our system achieves an F-score above 0.5, and we identified this much surrogate training data for 96% of PropBank rolesets with at least one fully-annotated sentence. This represents 64% of all PropBank rolesets that are used for annotation. Beyond 120 surrogate training examples, F-scores remain around 0.6 before slowly declining after around 700 examples.

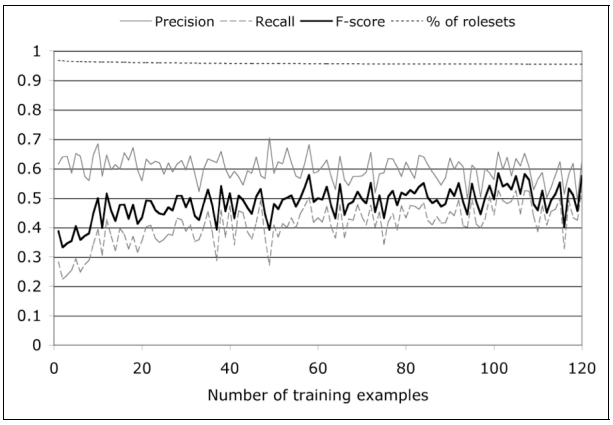

Figure 3. Performance of our semantic role labeling approach on PropBank rolesets using various amounts of surrogate training data

Several interesting comparisons can be made between the results presented in Figure 3 and those in Figure 2, where actual PropBank training data is used instead of surrogate training data. First, the precision obtained with surrogate training data is roughly 10% lower than with real data. Second, the recall performance of surrogate data performs similar to real data at first, but is consistently 10% lower than with real data after the first 50 training examples. Accordingly, F-scores for surrogate training data are 10% lower overall.

Even though the performance obtained using surrogate training data is less than with actual data, there is abundant amounts of it available for most PropBank rolesets. Comparing the "% of rolesets" plots in Figures 2 and 3, the real value of surrogate training data is apparent. Figure 2 suggests that over 20 real training examples are needed to achieve F-scores that are consistently above 0.5, but that less than 20% of PropBank rolesets have this much data available. In contrast, 64% of all PropBank rolesets can achieve this F-score performance with the use of surrogate training data. This percentage increases to 96% if every PropBank roleset is given at least one fully annotated sentence, where all of its numbered arguments are assigned to constituents.

In addition to supplementing the real training data available for existing PropBank rolesets, these results predict the labeling performance that can be obtained by applying this technique to a novel roleset with one fully-annotated training example, e.g. for the verb *yearn*. Using the first 120 surrogate training examples and our simple semantic role labeling approach, we would expect F-scores that are above 0.5, and that using the first 700 would yield F-scores around 0.6.

7 Discussion

The overall performance of our semantic role labeling approach is not competitive with leading contemporary systems, which typically employ support vector machine learning algorithms with syntactic features (Pradhan et al., 2005) or syntactic tree kernels (Moschitti et al., 2006). However, our work highlights a number of characteristics of the semantic role labeling task that will be helpful in improving performance in future systems. Parse tree paths features can be used to achieve high precision in semantic role labeling, but much of this precision may be specific to individual verbs. By generalizing parse tree path features only across syntactically similar verbs, we have shown that the drop in precision can be limited to roughly 10%.

The approach that we describe in this paper is not dependent on the use of PropBank rolesets; any large corpus of semantic role annotations could be

generalized in this manner. In particular, our approach would be applicable to corpora with frame-specific role labels, e.g. FrameNet (Baker et al., 1998). Likewise, our approach to generalizing parse tree path feature across syntactically similar verbs may improve the performance of automated semantic role labeling systems based on FrameNet data. Our work suggests that feature generalization based on verb-similarity may compliment approaches to generalization based on role-similarity (Gildea and Jurafsky, 2002; Baldewein et al., 2004).

There are a number of improvements that could be made to the approach described in this paper. Enhancements to the simple semantic role labeling algorithm would improve the alignment of arguments across rolesets, which would help align rolesets with greater syntactic similarity, as well as improve the performance obtained using the surrogate training data in assigning semantic roles.

This research raises many questions about the relationship between syntactic context and verb semantics. An important area for future research will be to explore the correlation between our distance metric for syntactic similarity and various quantitative measures of semantic similarity (Pedersen, et al., 2004). Particularly interesting would be to explore whether different senses of a given verb exhibited markedly different profiles of syntactic context. A strong syntactic/semantic correlation would suggest that further gains in the use of surrogate annotation data could be gained if syntactic similarity was computed between rolesets rather than their verbs. However, this would first require accurate word-sense disambiguation both for the test sentences as well as for the parsed corpora used to calculate parse tree path frequencies. Alternatively, parse tree path profiles associated with rolesets may be useful for word sense disambiguation, where the probability of a sense is computed as the likelihood that an ambiguous verb's parse tree paths are sampled from the distributions associated with each verb sense. These topics will be the focus of our future work in this area.

Abstract

Convolution tree kernel has shown promising results in semantic role classification. However, it only carries out hard matching, which may lead to over-fitting and less accurate similarity measure. To remove the constraint, this paper proposes a grammar-driven convolution tree kernel for semantic role classification by introducing more linguistic knowledge into the standard tree kernel. The proposed grammar-driven tree kernel displays two advantages over the previous one: 1) grammar-driven approximate substructure matching and 2) grammar-driven approximate tree node matching. The two improvements enable the grammar-driven tree kernel explore more linguistically motivated structure features than the previous one. Experiments on the CoNLL-2005 SRL shared task show that the grammar-driven tree kernel significantly outperforms the previous non-grammar-driven one in SRL. Moreover, we present a composite kernel to integrate feature-based and tree kernel-based methods. Experimental results show that the composite kernel outperforms the previously best-reported methods.

1 Introduction

Given a sentence, the task of Semantic Role Labeling (SRL) consists of analyzing the logical forms expressed by some target verbs or nouns and some constituents of the sentence. In particular, for each predicate (target verb or noun) all the constituents in the sentence which fill semantic arguments (roles) of the predicate have to be recognized. Typical semantic roles include *Agent, Patient, Instrument,* etc. and also adjuncts such as *Locative, Temporal, Manner,* and *Cause,* etc. Generally, semantic role identification and classification are regarded as two key steps in semantic role labeling. Semantic role identification involves classifying each syntactic element in a sentence into either a semantic argument or a non-argument while semantic role classification involves classifying each semantic argument identified into a specific semantic role. This paper focuses on semantic role classification task with the assumption that the semantic arguments have been identified correctly.

Both feature-based and kernel-based learning methods have been studied for semantic role classification (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005). In feature-based methods, a flat feature vector is used to represent a predicate-argument structure while, in kernel-based methods, a kernel function is used to measure directly the similarity between two predicate-argument structures. As we know, kernel methods are more effective in capturing structured features. Moschitti (2004) and Che et al. (2006) used a convolution tree kernel (Collins and Duffy, 2001) for semantic role classification. The convolution tree kernel takes sub-tree as its feature and counts the number of common sub-trees as the similarity between two predicate-arguments. This kernel has shown very

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 200–207,
Prague, Czech Republic, June 2007.

promising results in SRL. However, as a general learning algorithm, the tree kernel only carries out hard matching between any two sub-trees without considering any linguistic knowledge in kernel design. This makes the kernel fail to handle similar phrase structures (e.g., "buy a car" *vs*. "buy a *red* car") and near-synonymic grammar tags (e.g., the POS variations between "*high*/JJ degree/NN" [1] and "*higher*/JJR degree/NN") [2]. To some degree, it may lead to over-fitting and compromise performance.

This paper reports our preliminary study in addressing the above issue by introducing more linguistic knowledge into the convolution tree kernel. To our knowledge, this is the first attempt in this research direction. In detail, we propose a grammar-driven convolution tree kernel for semantic role classification that can carry out more linguistically motivated substructure matching. Experimental results show that the proposed method significantly outperforms the standard convolution tree kernel on the data set of the CoNLL-2005 SRL shared task.

The remainder of the paper is organized as follows: Section 2 reviews the previous work and Section 3 discusses our grammar-driven convolution tree kernel. Section 4 shows the experimental results. We conclude our work in Section 5.

2 Previous Work

Feature-based Methods for SRL: most features used in prior SRL research are generally extended from Gildea and Jurafsky (2002), who used a linear interpolation method and extracted basic flat features from a parse tree to identify and classify the constituents in the FrameNet (Baker et al., 1998). Here, the basic features include Phrase Type, Parse Tree Path, and Position. Most of the following work focused on feature engineering (Xue and Palmer, 2004; Jiang et al., 2005) and machine learning models (Nielsen and Pradhan, 2004; Pradhan et al., 2005a). Some other work paid much attention to the robust SRL (Pradhan et al., 2005b) and post inference (Punyakanok et al., 2004). These feature-based methods are considered as the state of the art methods for SRL. However, as we know, the standard flat features are less effective in modeling the syntactic structured information. For example, in SRL, the Parse Tree Path feature is sensitive to small changes of the syntactic structures. Thus, a predicate argument pair will have two different Path features even if their paths differ only for one node. This may result in data sparseness and model generalization problems.

Kernel-based Methods for SRL: as an alternative, kernel methods are more effective in modeling structured objects. This is because a kernel can measure the similarity between two structured objects using the original representation of the objects instead of explicitly enumerating their features. Many kernels have been proposed and applied to the NLP study. In particular, Haussler (1999) proposed the well-known convolution kernels for a discrete structure. In the context of it, more and more kernels for restricted syntaxes or specific domains (Collins and Duffy, 2001; Lodhi et al., 2002; Zelenko et al., 2003; Zhang et al., 2006) are proposed and explored in the NLP domain.

Of special interest here, Moschitti (2004) proposed Predicate Argument Feature (PAF) kernel for SRL under the framework of convolution tree kernel. He selected portions of syntactic parse trees as predicate-argument feature spaces, which include salient substructures of predicate-arguments, to define convolution kernels for the task of semantic role classification. Under the same framework, Che et al. (2006) proposed a hybrid convolution tree kernel, which consists of two individual convolution kernels: a Path kernel and a Constituent Structure kernel. Che et al. (2006) showed that their method outperformed PAF on the CoNLL-2005 SRL dataset.

The above two kernels are special instances of convolution tree kernel for SRL. As discussed in Section 1, convolution tree kernel only carries out hard matching, so it fails to handle similar phrase structures and near-synonymic grammar tags. This paper presents a grammar-driven convolution tree kernel to solve the two problems

3 Grammar-driven Convolution Tree Kernel

3.1 Convolution Tree Kernel

In convolution tree kernel (Collins and Duffy, 2001), a parse tree T is represented by a vector of integer counts of each sub-tree type (regardless of its ancestors): $\phi(T) = (\ldots, \#subtree_i(T), \ldots)$, where

[1] Please refer to http://www.cis.upenn.edu/~treebank/ for the detailed definitions of the grammar tags used in the paper.

[2] Some rewrite rules in English grammar are generalizations of others: for example, "NP→ DET JJ NN" is a specialized version of "NP→ DET NN". The same applies to POS. The standard convolution tree kernel is unable to capture the two cases.

$subtree_i(T)$ is the occurrence number of the i^{th} sub-tree type ($subtree_i$) in T. Since the number of different sub-trees is exponential with the parse tree size, it is computationally infeasible to directly use the feature vector $\phi(T)$. To solve this computational issue, Collins and Duffy (2001) proposed the following parse tree kernel to calculate the dot product between the above high dimensional vectors implicitly.

$$K(T_1,T_2) = <\phi(T_1),\phi(T_2)> = \sum_i \left(\left(\sum_{n_1\in N_1} I_{subtree_i}(n_1)\right)\cdot\left(\sum_{n_2\in N_2} I_{subtree_i}(n_2)\right)\right) = \sum_{n_1\in N_1}\sum_{n_2\in N_2}\Delta(n_1,n_2)$$

where N_1 and N_2 are the sets of nodes in trees T_1 and T_2, respectively, and $I_{subtree_i}(n)$ is a function that is 1 iff the $subtree_i$ occurs with root at node n and zero otherwise, and $\Delta(n_1,n_2)$ is the number of the common *subtrees* rooted at n_1 and n_2, i.e.,

$$\Delta(n_1,n_2) = \sum_i I_{subtree_i}(n_1)\cdot I_{subtree_i}(n_2)$$

$\Delta(n_1,n_2)$ can be further computed efficiently by the following recursive rules:

Rule 1: if the productions (CFG rules) at n_1 and n_2 are different, $\Delta(n_1,n_2)=0$;

Rule 2: else if both n_1 and n_2 are pre-terminals (POS tags), $\Delta(n_1,n_2)=1\times\lambda$;

Rule 3: else,

$$\Delta(n_1,n_2) = \lambda\prod_{j=1}^{nc(n_1)}(1+\Delta(ch(n_1,j),ch(n_2,j))),$$

where $nc(n_1)$ is the child number of n_1, $ch(n,j)$ is the j^{th} child of node n and λ ($0<\lambda<1$) is the decay factor in order to make the kernel value less variable with respect to the *subtree* sizes. In addition, the recursive **Rule 3** holds because given two nodes with the same children, one can construct common sub-trees using these children and common sub-trees of further offspring. The time complexity for computing this kernel is $O(|N_1|\cdot|N_2|)$.

3.2 Grammar-driven Convolution Tree Kernel

This Subsection introduces the two improvements and defines our grammar-driven tree kernel.

Improvement 1: Grammar-driven approximate matching between substructures. The conventional tree kernel requires exact matching between two contiguous phrase structures. This constraint may be too strict. For example, the two phrase structures "NP→DT JJ NN" (NP→*a red car*) and "NP→DT NN" (NP->*a car*) are not identical, thus they contribute nothing to the conventional kernel although they should share the same semantic role given a predicate. In this paper, we propose a grammar-driven approximate matching mechanism to capture the similarity between such kinds of quasi-structures for SRL.

First, we construct reduced rule set by defining optional nodes, for example, "NP->DT [JJ] NP" or "VP-> VB [ADVP] PP", where [*] denotes optional nodes. For convenience, we call "NP-> DT JJ NP" the original rule and "NP->DT [JJ] NP" the reduced rule. Here, we define two grammar-driven criteria to select optional nodes:

1) The reduced rules must be grammatical. It means that the reduced rule should be a valid rule in the original rule set. For example, "NP->DT [JJ] NP" is valid only when "NP->DT NP" is a valid rule in the original rule set while "NP->DT [JJ NP]" may not be valid since "NP->DT" is not a valid rule in the original rule set.

2) A valid reduced rule must keep the head child of its corresponding original rule and has at least two children. This can make the reduced rules retain the underlying semantic meaning of their corresponding original rules.

Given the reduced rule set, we can then formulate the approximate substructure matching mechanism as follows:

$$M(r_1,r_2) = \sum_{i,j}(I_T(T_{r1}^i,T_{r2}^j)\times\lambda_1^{a_i+b_j}) \qquad (1)$$

where r_1 is a production rule, representing a sub-tree of depth one[3], and T_{r1}^i is the i^{th} variation of the sub-tree r_1 by removing one ore more optional nodes[4], and likewise for r_2 and T_{r2}^j. $I_T(\bullet,\bullet)$ is a function that is 1 iff the two sub-trees are identical and zero otherwise. λ_1 ($0\le\lambda_1\le1$) is a small penalty to penal-

[3] Eq.(1) is defined over sub-structure of depth one. The approximate matching between structures of depth more than one can be achieved easily through the matching of sub-structures of depth one in the recursively-defined convolution kernel. We will discuss this issue when defining our kernel.

[4] To make sure that the new kernel is a proper kernel, we have to consider all the possible variations of the original sub-trees. Training program converges only when using a proper kernel.

ize optional nodes and the two parameters a_i and b_j stand for the numbers of occurrence of removed optional nodes in subtrees T_{r1}^i and T_{r2}^j, respectively. $M(r_1, r_2)$ returns the similarity (ie., the kernel value) between the two sub-trees r_1 and r_2 by summing up the similarities between all possible variations of the sub-trees r_1 and r_2.

Under the new approximate matching mechanism, two structures are matchable (but with a small penalty λ_1) if the two structures are identical after removing one or more optional nodes. In this case, the above example phrase structures "NP->*a red car*" and "NP->*a car*" are matchable with a penalty λ_1 in our new kernel. It means that one co-occurrence of the two structures contributes λ_1 to our proposed kernel while it contributes zero to the traditional one. Therefore, by this improvement, our method would be able to explore more linguistically appropriate features than the previous one (which is formulated as $I_T(r_1, r_2)$).

Improvement 2: Grammar-driven tree nodes approximate matching. The conventional tree kernel needs an exact matching between two (terminal/non-terminal) nodes. But, some similar POSs may represent similar roles, such as NN (*dog*) and NNS (*dogs*). In order to capture this phenomenon, we allow approximate matching between node features. The following illustrates some equivalent node feature sets:

- JJ, JJR, JJS
- VB, VBD, VBG, VBN, VBP, VBZ
- ……

where POSs in the same line can match each other with a small penalty $0 \le \lambda_2 \le 1$. We call this case node feature *mutation*. This improvement further generalizes the conventional tree kernel to get better coverage. The approximate node matching can be formulated as:

$$M(f_1, f_2) = \sum_{i,j} (I_f(f_1^i, f_2^j) \times \lambda_2^{a_i + b_j}) \qquad (2)$$

where f_1 is a node feature, f_1^i is the i^{th} mutation of f_1 and a_i is 0 iff f_1^i and f_1 are identical and 1 otherwise, and likewise for f_2. $I_f(\bullet, \bullet)$ is a function that is 1 iff the two features are identical and zero otherwise. Eq. (2) sums over all combinations of feature mutations as the node feature similarity. The same as Eq. (1), the reason for taking all the possibilities into account in Eq. (2) is to make sure that the new kernel is a proper kernel.

The above two improvements are grammar-driven, i.e., the two improvements retain the underlying linguistic grammar constraints and keep semantic meanings of original rules.

The Grammar-driven Kernel Definition: Given the two improvements discussed above, we can define the new kernel by beginning with the feature vector representation of a parse tree *T* as follows:

$$\phi'(T) = (\#\, subtree_1(T), \ldots, \#\, subtree_n(T))$$

where $\#\, subtree_i(T)$ is the occurrence number of the i^{th} sub-tree type ($subtree_i$) in *T*. Please note that, different from the previous tree kernel, here we loosen the condition for the occurrence of a subtree by allowing both original and reduced rules (**Improvement 1**) and node feature mutations (**Improvement 2**). In other words, we modify the criteria by which a subtree is said to occur. For example, one occurrence of the rule "NP->DT JJ NP" shall contribute 1 times to the feature "NP->DT JJ NP" and λ_1 times to the feature "NP->DT NP" in the new kernel while it only contributes 1 times to the feature "NP->DT JJ NP" in the previous one. Now we can define the new grammar-driven kernel $K_G(T_1, T_2)$ as follows:

$$\begin{aligned} K_G(T_1, T_2) &= \langle \phi'(T_1), \phi'(T_2) \rangle \\ &= \sum_i \left(\left(\sum_{n_1 \in N_1} I'_{subtree_i}(n_1) \right) \cdot \left(\sum_{n_2 \in N_2} I'_{subtree_i}(n_2) \right) \right) \\ &= \sum_{n_1 \in N_1} \sum_{n_2 \in N_2} \Delta'(n_1, n_2) \end{aligned} \qquad (3)$$

where N_1 and N_2 are the sets of nodes in trees T_1 and T_2, respectively. $I'_{subtree_i}(n)$ is a function that is $\lambda_1^a \cdot \lambda_2^b$ iff the $subtree_i$ occurs with root at node *n* and zero otherwise, where a and b are the numbers of removed optional nodes and mutated node features, respectively. $\Delta'(n_1, n_2)$ is the number of the common *subtrees* rooted at n_1 and n_2, i.e. ,

$$\Delta'(n_1, n_2) = \sum_i I'_{subtree_i}(n_1) \cdot I'_{subtree_i}(n_2) \qquad (4)$$

Please note that the value of $\Delta'(n_1, n_2)$ is no longer an integer as that in the conventional one since optional nodes and node feature mutations are considered in the new kernel. $\Delta'(n_1, n_2)$ can be further computed by the following recursive rules:

Rule A: if n_1 and n_2 are pre-terminals, then:

$$\Delta'(n_1, n_2) = \lambda \times M(f_1, f_2) \quad (5)$$

where f_1 and f_2 are features of nodes n_1 and n_2 respectively, and $M(f_1, f_2)$ is defined at Eq. (2).

Rule B: else if both n_1 and n_2 are the same non-terminals, then generate all variations of the subtrees of *depth one* rooted by n_1 and n_2 (denoted by T_{n1} and T_{n2} respectively) by removing different optional nodes, then:

$$\Delta'(n_1, n_2) = \lambda \times \sum_{i,j} (I_T(T_{n1}^i, T_{n2}^j) \times \lambda_1^{a_i + b_j} \times \prod_{k=1}^{nc(n_1,i)} (1 + \Delta'(ch(n_1, i, k), ch(n_2, j, k))) \quad (6)$$

where

- T_{n1}^i and T_{n2}^j stand for the i^{th} and j^{th} variations in sub-tree set T_{n1} and T_{n2}, respectively.
- $I_T(\bullet, \bullet)$ is a function that is 1 iff the two sub-trees are identical and zero otherwise.
- a_i and b_j stand for the number of removed optional nodes in subtrees T_{n1}^i and T_{n2}^j, respectively.
- $nc(n_1, i)$ returns the child number of n_1 in its i^{th} subtree variation T_{n1}^i.
- $ch(n_1, i, k)$ is the k^{th} child of node n_1 in its i^{th} variation subtree T_{n1}^i, and likewise for $ch(n_2, j, k)$.
- Finally, the same as the previous tree kernel, λ ($0 < \lambda < 1$) is the decay factor (see the discussion in Subsection 3.1).

Rule C: else $\Delta'(n_1, n_2) = 0$

Rule A accounts for **Improvement** 2 while **Rule B** accounts for **Improvement** 1. In **Rule B**, Eq. (6) is able to carry out multi-layer sub-tree approximate matching due to the introduction of the recursive part while Eq. (1) is only effective for sub-trees of depth one. Moreover, we note that Eq. (4) is a convolution kernel according to the definition and the proof given in Haussler (1999), and Eqs (5) and (6) reformulate Eq. (4) so that it can be computed efficiently, in this way, our kernel defined by Eq (3) is also a valid convolution kernel. Finally, let us study the computational issue of the new convolution tree kernel. Clearly, computing Eq. (6) requires exponential time in its worst case. However, in practice, it may only need $O(|N_1| \cdot |N_2|)$. This is because there are only 9.9% rules (647 out of the total 6,534 rules in the parse trees) have optional nodes and most of them have only one optional node. In fact, the actual running time is even much less and is close to linear in the size of the trees since $\Delta'(n_1, n_2) = 0$ holds for many node pairs (Collins and Duffy, 2001). In theory, we can also design an efficient algorithm to compute Eq. (6) using a dynamic programming algorithm (Moschitti, 2006). We just leave it for our future work.

3.3 Comparison with previous work

In above discussion, we show that the conventional convolution tree kernel is a special case of the grammar-driven tree kernel. From kernel function viewpoint, our kernel can carry out not only exact matching (as previous one described by **Rules 2** and **3** in Subsection 3.1) but also approximate matching (Eqs. (5) and (6) in Subsection 3.2). From feature exploration viewpoint, although they explore the same sub-structure feature space (defined recursively by the phrase parse rules), their feature values are different since our kernel captures the structure features in a more linguistically appropriate way by considering more linguistic knowledge in our kernel design.

Moschitti (2006) proposes a partial tree (PT) kernel which can carry out partial matching between sub-trees. The PT kernel generates a much larger feature space than both the conventional and the grammar-driven kernels. In this point, one can say that the grammar-driven tree kernel is a specialization of the PT kernel. However, the important difference between them is that the PT kernel is not grammar-driven, thus many non-linguistically motivated structures are matched in the PT kernel. This may potentially compromise the performance since some of the over-generated features may possibly be noisy due to the lack of linguistic interpretation and constraint.

Kashima and Koyanagi (2003) proposed a convolution kernel over labeled order trees by generalizing the standard convolution tree kernel. The labeled order tree kernel is much more flexible than the PT kernel and can explore much larger sub-tree features than the PT kernel. However, the same as the PT kernel, the labeled order tree kernel is not grammar-driven. Thus, it may face the same issues

(such as over-generated features) as the PT kernel when used in NLP applications.

Shen el al. (2003) proposed a lexicalized tree kernel to utilize LTAG-based features in parse reranking. Their methods need to obtain a LTAG derivation tree for each parse tree before kernel calculation. In contrast, we use the notion of optional arguments to define our grammar-driven tree kernel and use the empirical set of CFG rules to determine which arguments are optional.

4 Experiments

4.1 Experimental Setting

Data: We use the CoNLL-2005 SRL shared task data (Carreras and Màrquez, 2005) as our experimental corpus. The data consists of sections of the Wall Street Journal part of the Penn TreeBank (Marcus et al., 1993), with information on predicate-argument structures extracted from the PropBank corpus (Palmer et al., 2005). As defined by the shared task, we use sections 02-21 for training, section 24 for development and section 23 for test. There are 35 roles in the data including 7 Core (A0–A5, AA), 14 Adjunct (AM-) and 14 Reference (R-) arguments. Table 1 lists counts of sentences and arguments in the three data sets.

	Training	Development	Test
Sentences	39,832	1,346	2,416
Arguments	239,858	8,346	14,077

Table 1: Counts on the data set

We assume that the semantic role identification has been done correctly. In this way, we can focus on the classification task and evaluate it more accurately. We evaluate the performance with Accuracy. SVM (Vapnik, 1998) is selected as our classifier and the *one vs. others* strategy is adopted and the one with the largest margin is selected as the final answer. In our implementation, we use the binary SVMLight (Joachims, 1998) and modify the Tree Kernel Tools (Moschitti, 2004) to a grammar-driven one.

Kernel Setup: We use the Constituent, Predicate, and Predicate-Constituent related features, which are reported to get the best-reported performance (Pradhan et al., 2005a), as the baseline features. We use Che et al. (2006)'s hybrid convolution tree kernel (the best-reported method for kernel-based SRL) as our baseline kernel. It is defined as $K_{hybrid} = \theta K_{path} + (1-\theta)K_{cs}$ $(0 \le \theta \le 1)$ (for the detailed definitions of K_{path} and K_{cs}, please refer to Che et al. (2006)). Here, we use our grammar-driven tree kernel to compute K_{path} and K_{cs}, and we call it grammar-driven hybrid tree kernel while Che et al. (2006)'s is non-grammar-driven hybrid convolution tree kernel.

We use a greedy strategy to fine-tune parameters. Evaluation on the development set shows that our kernel yields the best performance when λ (decay factor of tree kernel), λ_1 and λ_2 (two penalty factors for the grammar-driven kernel), θ (hybrid kernel parameter) and c (a SVM training parameter to balance training error and margin) are set to 0.4, 0.6, 0.3, 0.6 and 2.4, respectively. For other parameters, we use default setting. In the CoNLL 2005 benchmark data, we get 647 rules with optional nodes out of the total 6,534 grammar rules and define three equivalent node feature sets as below:

- JJ, JJR, JJS
- RB, RBR, RBS
- NN, NNS, NNP, NNPS, NAC, NX

Here, the verb feature set "VB, VBD, VBG, VBN, VBP, VBZ" is removed since the voice information is very indicative to the arguments of ARG0 (Agent, operator) and ARG1 (Thing operated).

Methods	Accuracy (%)
Baseline: Non-grammar-driven	85.21
+Approximate Node Matching	86.27
+Approximate Substructure Matching	87.12
Ours: Grammar-driven Substructure and Node Matching	87.96
Feature-based method with polynomial kernel (d = 2)	89.92

Table 2: Performance comparison

4.2 Experimental Results

Table 2 compares the performances of different methods on the test set. First, we can see that the new grammar-driven hybrid convolution tree kernel significantly outperforms (χ^2 test with p=0.05) the

non-grammar one with an absolute improvement of 2.75 (87.96-85.21) percentage, representing a relative error rate reduction of 18.6% (2.75/(100-85.21)) . It suggests that 1) the linguistically motivated structure features are very useful for semantic role classification and 2) the grammar-driven kernel is much more effective in capturing such kinds of features due to the consideration of linguistic knowledge. Moreover, Table 2 shows that 1) both the grammar-driven approximate node matching and the grammar-driven approximate substructure matching are very useful in modeling syntactic tree structures for SRL since they contribute relative error rate reduction of 7.2% ((86.27-85.21)/(100-85.21)) and 12.9% ((87.12-85.21)/(100-85.21)), respectively; 2) the grammar-driven approximate substructure matching is more effective than the grammar-driven approximate node matching. However, we find that the performance of the grammar-driven kernel is still a bit lower than the feature-based method. This is not surprising since tree kernel methods only focus on modeling tree structure information. In this paper, it captures the syntactic parse tree structure features only while the features used in the feature-based methods cover more knowledge sources.

In order to make full use of the syntactic structure information and the other useful diverse flat features, we present a composite kernel to combine the grammar-driven hybrid kernel and feature-based method with polynomial kernel:

$$K_{comp} = \gamma K_{hybrid} + (1-\gamma) K_{poly} \qquad (0 \le \gamma \le 1)$$

Evaluation on the development set shows that the composite kernel yields the best performance when γ is set to 0.3. Using the same setting, the system achieves the performance of 91.02% in Accuracy in the same test set. It shows statistically significant improvement (χ^2 test with p= 0.10) over using the standard features with the polynomial kernel ($\gamma = 0$, Accuracy = 89.92%) and using the grammar-driven hybrid convolution tree kernel ($\gamma = 1$, Accuracy = 87.96%). The main reason is that the tree kernel can capture effectively more structure features while the standard flat features can cover some other useful features, such as Voice, SubCat, which are hard to be covered by the tree kernel. The experimental results suggest that these two kinds of methods are complementary to each other.

In order to further compare with other methods, we also do experiments on the dataset of English PropBank I (LDC2004T14). The training, development and test sets follow the conventional split of Sections 02-21, 00 and 23. Table 3 compares our method with other previously best-reported methods with the same setting as discussed previously. It shows that our method outperforms the previous best-reported one with a relative error rate reduction of 10.8% (0.97/(100-91)). This further verifies the effectiveness of the grammar-driven kernel method for semantic role classification.

Method	Accuracy (%)
Ours (Composite Kernel)	**91.97**
Moschitti (2006): PAF kernel only	87.7
Jiang et al. (2005): feature based	90.50
Pradhan et al. (2005a): feature based	91.0

Table 3: Performance comparison between our method and previous work

Method	Training Time	
	4 Sections	19 Sections
Ours: grammar-driven tree kernel	~8.1 hours	~7.9 days
Moschitti (2006): non-grammar-driven tree kernel	~7.9 hours	~7.1 days

Table 4: Training time comparison

Table 4 reports the training times of the two kernels. We can see that 1) the two kinds of convolution tree kernels have similar computing time. Although computing the grammar-driven one requires exponential time in its worst case, however, in practice, it may only need $O(|N_1| \cdot |N_2|)$ or linear and 2) it is very time-consuming to train a SVM classifier in a large dataset.

5 Conclusion and Future Work

In this paper, we propose a novel grammar-driven convolution tree kernel for semantic role classification. More linguistic knowledge is considered in the new kernel design. The experimental results verify that the grammar-driven kernel is more effective in capturing syntactic structure features than the previous convolution tree kernel because it allows grammar-driven approximate matching of substructures and node features. We also discuss the criteria to determine the optional nodes in a

CFG rule in defining our grammar-driven convolution tree kernel.

The extension of our work is to improve the performance of the entire semantic role labeling system using the grammar-driven tree kernel, including all four stages: pruning, semantic role identification, classification and post inference. In addition, a more interesting research topic is to study how to integrate linguistic knowledge and tree kernel methods to do feature selection for tree kernel-based NLP applications (Suzuki et al., 2004). In detail, a linguistics and statistics-based theory that can suggest the effectiveness of different substructure features and whether they should be generated or not by the tree kernels would be worked out.

Abstract

This paper presents a novel application of Alternating Structure Optimization (ASO) to the task of Semantic Role Labeling (SRL) of noun predicates in NomBank. ASO is a recently proposed linear multi-task learning algorithm, which extracts the common structures of multiple tasks to improve accuracy, via the use of auxiliary problems. In this paper, we explore a number of different auxiliary problems, and we are able to significantly improve the accuracy of the NomBank SRL task using this approach. To our knowledge, our proposed approach achieves the highest accuracy published to date on the English NomBank SRL task.

1 Introduction

The task of Semantic Role Labeling (SRL) is to identify predicate-argument relationships in natural language texts in a domain-independent fashion. In recent years, the availability of large human-labeled corpora such as PropBank (Palmer et al., 2005) and FrameNet (Baker et al., 1998) has made possible a statistical approach of identifying and classifying the arguments of verbs in natural language texts. A large number of SRL systems have been evaluated and compared on the standard data set in the CoNLL shared tasks (Carreras and Marquez, 2004; Carreras and Marquez, 2005), and many systems have performed reasonably well. Compared to the previous CoNLL shared tasks (noun phrase bracketing, chunking, clause identification, and named entity recognition), SRL represents a significant step towards processing the semantic content of natural language texts.

Although verbs are probably the most obvious predicates in a sentence, many nouns are also capable of having complex argument structures, often with much more flexibility than its verb counterpart. For example, compare *affect* and *effect*:

> [$_{subj}$ Auto prices] [$_{arg-ext}$ greatly] [$_{pred}$ affect] [$_{obj}$ the PPI].
>
> [$_{subj}$ Auto prices] have a [$_{arg-ext}$ big] [$_{pred}$ effect] [$_{obj}$ on the PPI].
>
> The [$_{pred}$ effect] [$_{subj}$ of auto prices] [$_{obj}$ on the PPI] is [$_{arg-ext}$ big].
>
> [$_{subj}$ The auto prices'] [$_{pred}$ effect] [$_{obj}$ on the PPI] is [$_{arg-ext}$ big].

The arguments of noun predicates can often be more easily omitted compared to the verb predicates:

> The [$_{pred}$ effect] [$_{subj}$ of auto prices] is [$_{arg-ext}$ big].
>
> The [$_{pred}$ effect] [$_{obj}$ on the PPI] is [$_{arg-ext}$ big].
>
> The [$_{pred}$ effect] is [$_{arg-ext}$ big].

With the recent release of NomBank (Meyers et al., 2004), it becomes possible to apply machine learning techniques to the task. So far we are aware of only one English NomBank-based SRL system (Jiang and Ng, 2006), which uses the maximum entropy classifier, although similar efforts are reported on the Chinese NomBank by (Xue, 2006)

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 208–215,
Prague, Czech Republic, June 2007.

and on FrameNet by (Pradhan et al., 2004) using a small set of hand-selected nominalizations. Noun predicates also appear in FrameNet semantic role labeling (Gildea and Jurafsky, 2002), and many FrameNet SRL systems are evaluated in Senseval-3 (Litkowski, 2004).

Semantic role labeling of NomBank is a multi-class classification problem by nature. Using the *one-vs-all* arrangement, that is, one binary classifier for each possible outcome, the SRL task can be treated as multiple binary classification problems. In the latter view, we are presented with the opportunity to exploit the *common structures* of these related problems. This is known as *multi-task learning* in the machine learning literature (Caruana, 1997; Ben-David and Schuller, 2003; Evgeniou and Pontil, 2004; Micchelli and Pontil, 2005; Maurer, 2006).

In this paper, we apply *Alternating Structure Optimization* (ASO) (Ando and Zhang, 2005a) to the semantic role labeling task on NomBank. ASO is a recently proposed linear multi-task learning algorithm based on empirical risk minimization. The method requires the use of multiple auxiliary problems, and its effectiveness may vary depending on the specific auxiliary problems used. ASO has been shown to be effective on the following natural language processing tasks: text categorization, named entity recognition, part-of-speech tagging, and word sense disambiguation (Ando and Zhang, 2005a; Ando and Zhang, 2005b; Ando, 2006).

This paper makes two significant contributions. First, we present a novel application of ASO to the SRL task on NomBank. We explore the effect of different auxiliary problems, and show that learning predictive structures with ASO results in significantly improved SRL accuracy. Second, we achieve accuracy higher than that reported in (Jiang and Ng, 2006) and advance the state of the art in SRL research.

The rest of this paper is organized as follows. We give an overview of NomBank and ASO in Sections 2 and 3 respectively. The baseline linear classifier is described in detail in Section 4, followed by the description of the ASO classifier in Section 5, where we focus on exploring different auxiliary problems. We provide discussions in Section 6, present related work in Section 7, and conclude in Section 8.

2 NomBank

NomBank annotates the set of arguments of noun predicates, just as PropBank annotates the arguments of verb predicates. As many noun predicates are nominalizations (e.g., *replacement* vs. *replace*), the same *frames* are shared with PropBank as much as possible, thus achieving some consistency with the latter regarding the accepted arguments and the meanings of each label.

Unlike in PropBank, arguments in NomBank can overlap with each other and with the predicate. For example:

> [$_{location}$ U.S.] [$_{pred,subj,obj}$ steelmakers] have supplied the steel.

Here the predicate *make* has subject *steelmakers* and object *steel*, analogous to *Steelmakers make steel.* The difference is that here *make* and *steel* are both part of the word *steelmaker*.

Each argument in NomBank is given one or more labels, out of the following 20: ARG0, ARG1, ARG2, ARG3, ARG4, ARG5, ARG8, ARG9, ARGM-ADV, ARGM-CAU, ARGM-DIR, ARGM-DIS, ARGM-EXT, ARGM-LOC, ARGM-MNR, ARGM-MOD, ARGM-NEG, ARGM-PNC, ARGM-PRD, and ARGM-TMP. Thus, the above sentence is annotated in NomBank as:

> [$_{\text{ARGM-LOC}}$ U.S.] [$_{\text{PRED,ARG0,ARG1}}$ steelmakers] have supplied the steel.

3 Alternating structure optimization

This section gives a brief overview of ASO as implemented in this work. For a more complete description, see (Ando and Zhang, 2005a).

3.1 Multi-task linear classifier

Given a set of training samples consisting of n feature vectors and their corresponding binary labels, $\{\mathbf{X}_i, Y_i\}$ for $i \in \{1, \ldots, n\}$ where each $\mathbf{X}_i$ is a p-dimensional vector, a binary linear classifier attempts to approximate the unknown relation by $Y_i = \mathbf{u}^{\mathrm{T}}\mathbf{X}_i$. The outcome is considered +1 if $\mathbf{u}^{\mathrm{T}}\mathbf{X}$ is positive, or –1 otherwise. A well-established way to find the *weight vector* $\mathbf{u}$ is *empirical risk minimization* with *least square regularization*:

$$\hat{\mathbf{u}} = \arg\min_{\mathbf{u}} \frac{1}{n} \sum_{i=1}^{n} L\big(\mathbf{u}^{\mathrm{T}}\mathbf{X}_i, Y_i\big) + \lambda \|\mathbf{u}\|^2 \quad (1)$$

Function $L(p, y)$ is known as the *loss function*. It encodes the penalty for a given discrepancy between the predicted label and the true label. In this work, we use a modification of Huber's robust loss function, similar to that used in (Ando and Zhang, 2005a):

$$L(p,y) = \begin{cases} -4py & \text{if } py < -1 \\ (1-py)^2 & \text{if } -1 \le py < 1 \\ 0 & \text{if } py \ge 1 \end{cases} \quad (2)$$

We fix the regularization parameter λ to 10^{-4}, similar to that used in (Ando and Zhang, 2005a). The expression $\|\mathbf{u}\|^2$ is defined as $\sum_{i=1}^{p} \mathbf{u}_p^2$.

When m binary classification problems are to be solved together, a $h \times p$ matrix Θ may be used to capture the *common structures* of the m weight vectors $\mathbf{u}_l$ for $l \in \{1, \ldots, m\}$ $(h \le m)$. We mandate that the rows of Θ be orthonormal, i.e., $\Theta\Theta^{\mathrm{T}} = I_{h \times h}$. The h rows of Θ represent the h most significant components shared by all the $\mathbf{u}$'s. This relationship is modeled by

$$\mathbf{u}_l = \mathbf{w}_l + \Theta^{\mathrm{T}} \mathbf{v}_l \quad (3)$$

The parameters $[\{\mathbf{w}_l, \mathbf{v}_l\}, \Theta]$ may then be found by *joint empirical risk minimization* over all the m problems, i.e., their values should minimize the combined empirical risk:

$$\sum_{l=1}^{m} \left(\frac{1}{n} \sum_{i=1}^{n} L\Big((\mathbf{w}_l + \Theta^{\mathrm{T}} \mathbf{v}_l)^{\mathrm{T}} \mathbf{X}_i^l, Y_i^l \Big) + \lambda \|\mathbf{w}_l\|^2 \right) \quad (4)$$

3.2 The ASO algorithm

An important observation in (Ando and Zhang, 2005a) is that the binary classification problems used to derive Θ are not necessarily those problems we are aiming to solve. In fact, new problems can be invented for the sole purpose of obtaining a better Θ. Thus, we distinguish between two types of problems in ASO: *auxiliary problems*, which are used to obtain Θ, and *target problems*, which are the problems we are aiming to solve[1].

For instance, in the argument identification task, the only target problem is to identify arguments vs. non-arguments, whereas in the argument classification task, there are 20 binary target problems, one to identify each of the 20 labels (ARG0, ARG1, ...).

The target problems can also be used as an auxiliary problem. In addition, we can *invent* new auxiliary problems, e.g., in the argument identification stage, we can predict whether there are three words between the constituent and the predicate using the features of argument identification.

Assuming there are k target problems and m auxiliary problems, it is shown in (Ando and Zhang, 2005a) that by performing one round of minimization, an approximate solution of Θ can be obtained from (4) by the following algorithm:

1. For each of the m *auxiliary problems*, learn $\mathbf{u}_l$ as described by (1).

2. Find $U = [\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_m]$, a $p \times m$ matrix. This is a simplified version of the definition in (Ando and Zhang, 2005a), made possible because the same λ is used for all auxiliary problems.

3. Perform Singular Value Decomposition (SVD) on U: $U = V_1 D V_2^{\mathrm{T}}$, where V_1 is a $p \times m$ matrix. The first h columns of V_1 are stored as rows of Θ.

4. Given Θ, we learn $\mathbf{w}$ and $\mathbf{v}$ for each of the k *target problems* by minimizing the empirical risk of the associated training samples:

$$\frac{1}{n} \sum_{i=1}^{n} L\Big((\mathbf{w} + \Theta^{\mathrm{T}} \mathbf{v})^{\mathrm{T}} \mathbf{X}_i, Y_i \Big) + \lambda \|\mathbf{w}\|^2 \quad (5)$$

5. The weight vector of each target problem can be found by:

$$\mathbf{u} = \mathbf{w} + \Theta^{\mathrm{T}} \mathbf{v} \quad (6)$$

By choosing a convex loss function, e.g., (2), steps 1 and 4 above can be formulated as convex optimization problems and are efficiently solvable.

The procedure above can be considered as a Principal Component Analysis in the predictor space. Step (3) above extracts the most significant components shared by the predictors of the auxiliary problems and hopefully, by the predictors of the target

[1] Note that this definition deviates slightly from the one in (Ando and Zhang, 2005a). We find the definition here more convenient for our subsequent discussion.

problems as well. The hint of potential significant components helps (5) to outperform the simple linear predictor (1).

4 Baseline classifier

The SRL task is typically separated into two stages: argument identification and argument classification. During the identification stage, each constituent in a sentence's parse tree is labeled as either argument or non-argument. During the classification stage, each argument is given one of the 20 possible labels (ARG0, ARG1, ...). The linear classifier described by (1) is used as the baseline in both stages. For comparison, the F1 scores of a maximum entropy classifier are also reported here.

4.1 Argument identification

Eighteen *baseline features* and six *additional features* are proposed in (Jiang and Ng, 2006) for NomBank argument identification. As the improvement of the F1 score due to the additional features is not statistically significant, we use the set of eighteen baseline features for simplicity. These features are reproduced in Table 1 for easy reference.

Unlike in (Jiang and Ng, 2006), we do not prune arguments dominated by other arguments or those that overlap with the predicate in the training data. Accordingly, we do not maximize the probability of the entire labeled parse tree as in (Toutanova et al., 2005). After the features of every constituent are extracted, each constituent is simply classified independently as either argument or non-argument.

The linear classifier described above is trained on sections 2 to 21 and tested on section 23. A maximum entropy classifier is trained and tested in the same manner. The F1 scores are presented in the first row of Table 3, in columns *linear* and *maxent* respectively. The *J&N* column presents the result reported in (Jiang and Ng, 2006) using both baseline and additional features. The last column *aso* presents the best result from this work, to be explained in Section 5.

4.2 Argument classification

In NomBank, some constituents have more than one label. For simplicity, we always assign exactly one label to each identified argument in this step. For the 0.16% arguments with multiple labels in the training data, we pick the first and discard the rest. (Note that the same is *not* done on the test data.)

1	pred	the stemmed predicate
2	subcat	grammar rule that expands the predicate P's parent
3	ptype	syntactic category (phrase type) of the constituent C
4	hw	syntactic head word of C
5	path	syntactic path from C to P
6	position	whether C is to the left/right of or overlaps with P
7	firstword	first word spanned by C
8	lastword	last word spanned by C
9	lsis.ptype	phrase type of left sister
10	rsis.hw	right sister's head word
11	rsis.hw.pos	POS of right sister's head word
12	parent.ptype	phrase type of parent
13	parent.hw	parent's head word
14	partialpath	path from C to the lowest common ancestor with P
15	ptype & length of path	
16	pred & hw	
17	pred & path	
18	pred & position	

Table 1: Features used in argument identification

A diverse set of 28 features is used in (Jiang and Ng, 2006) for argument classification. In this work, the number of features is pruned to 11, so that we can work with reasonably many auxiliary problems in later experiments with ASO.

To find a smaller set of effective features, we start with all the features considered in (Jiang and Ng, 2006), in (Xue and Palmer, 2004), and various combinations of them, for a total of 52 features. These features are then pruned by the following algorithm:

1. For each feature in the current feature set, do step (2).
2. Remove the selected feature from the feature set. Obtain the F1 score of the remaining features when applied to the argument classification task, on development data section 24 with gold identification.
3. Select the highest of all the scores obtained in

1	position	to the left/right of or overlaps with the predicate
2	ptype	syntactic category (phrase type) of the constituent C
3	firstword	first word spanned by C
4	lastword	last word spanned by C
5	rsis.ptype	phrase type of right sister
6	nomtype	NOM-TYPE of predicate supplied by NOMLEX dictionary
7	predicate & ptype	
8	predicate & lastword	
9	morphed predicate stem & head word	
10	morphed predicate stem & position	
11	nomtype & position	

Table 2: Features used in argument classification

step (2). The corresponding feature is removed from the current feature set if its F1 score is the same as or higher than the F1 score of retaining all features.

4. Repeat steps (1)-(3) until the F1 score starts to drop.

The 11 features so obtained are presented in Table 2. Using these features, a linear classifier and a maximum entropy classifier are trained on sections 2 to 21, and tested on section 23. The F1 scores are presented in the second row of Table 3, in columns *linear* and *maxent* respectively. The *J&N* column presents the result reported in (Jiang and Ng, 2006).

4.3 Further experiments and discussion

In the combined task, we run the identification task with gold parse trees, and then the classification task with the output of the identification task. This way the combined effect of errors from both stages on the final classification output can be assessed. The scores of this complete SRL system are presented in the third row of Table 3.

To test the performance of the combined task on automatic parse trees, we employ two different configurations. First, we train the various classifiers on sections 2 to 21 using gold argument labels and *automatic parse trees* produced by Charniak's reranking parser (Charniak and Johnson, 2005), and test them on section 23 with automatic parse trees. This is the same configuration as reported in (Pradhan et al., 2005; Jiang and Ng, 2006). The scores are presented in the fourth row *auto parse (t&t)* in Table 3.

Next, we train the various classifiers on sections 2 to 21 using gold argument labels and *gold parse trees*. To minimize the discrepancy between gold and automatic parse trees, we remove all the nodes in the gold trees whose POS are *-NONE-*, as they do not span any word and are thus never generated by the automatic parser. The resulting classifiers are then tested on section 23 using automatic parse trees. The scores are presented in the last row *auto parse (test)* of Table 3. We note that *auto parse (test)* consistently outperforms *auto parse (t&t)*.

We believe that *auto parse (test)* is a more realistic setting in which to test the performance of SRL on automatic parse trees. When presented with some previously unseen test data, we are forced to rely on its automatic parse trees. However, for the best results we should take advantage of gold parse trees whenever possible, including those of the *labeled* training data.

	J&N	maxent	linear	aso
identification	82.50	83.58	81.34	85.32
classification	87.80	88.35	87.86	89.17
combined	72.73	75.35	72.63	77.04
auto parse (t&t)	69.14	69.61	67.38	72.11
auto parse (test)	-	71.19	69.05	72.83

Table 3: F1 scores of various classifiers on NomBank SRL

Our maximum entropy classifier consistently outperforms (Jiang and Ng, 2006), which also uses a maximum entropy classifier. The primary difference is that we use a later version of NomBank (September 2006 release vs. September 2005 release). In addition, we use somewhat different features and treat overlapping arguments differently.

5 Applying ASO to SRL

Our ASO classifier uses the same features as the baseline linear classifier. The defining characteristic, and also the major challenge in successfully applying the ASO algorithm is to find related auxiliary problems that can reveal common structures shared

with the target problem. To organize our search for good auxiliary problems for SRL, we separate them into two categories, *unobservable auxiliary problems* and *observable auxiliary problems*.

5.1 Unobservable auxiliary problems

Unobservable auxiliary problems are problems whose true outcome cannot be observed from a raw text corpus but must come from another source, e.g., human labeling. For instance, predicting the argument class (i.e., ARG0, ARG1, ...) of a constituent is an unobservable auxiliary problem (which is also the only usable unobservable auxiliary problem here), because the true outcomes (i.e., the argument classes) are only available from human labels annotated in NomBank.

For argument identification, we invent the following 20 binary unobservable auxiliary problems to take advantage of information previously unused at this stage:

> To predict the outcome of argument classification (i.e., ARG0, ARG1, ...) using the features of argument identification (*pred*, *subcat*, ...).

Thus for argument identification, we have 20 auxiliary problems (one auxiliary problem for predicting each of the argument classes ARG0, ARG1, ...) and one target problem (predicting whether a constituent is an argument) for the ASO algorithm described in Section 3.2.

In the argument classification task, the 20 binary target problems are also the unobservable auxiliary problems (one auxiliary problem for predicting each of the argument classes ARG0, ARG1, ...). Thus, we use the same 20 problems as both auxiliary problems and target problems.

We train an ASO classifier on sections 2 to 21 and test it on section 23. With the 20 unobservable auxiliary problems, we obtain the F1 scores reported in the last column of Table 3. In all the experiments, we keep $h = 20$, i.e., all the 20 columns of V_1 are kept.

Comparing the F1 score of ASO against that of the linear classifier in every task (i.e., identification, classification, combined, both auto parse configurations), the improvement achieved by ASO is statistically significant ($p < 0.05$) based on the χ^2 test. Comparing the F1 score of ASO against that of the maximum entropy classifier, the improvement in all but one task (argument classification) is statistically significant ($p < 0.05$). For argument classification, the improvement is not statistically significant ($p = 0.08$).

5.2 Observable auxiliary problems

Observable auxiliary problems are problems whose true outcome can be observed from a raw text corpus without additional externally provided labels. An example is to predict whether *hw=trader* from a constituent's other features, since the head word of a constituent can be obtained from the raw text alone. By definition, an observable auxiliary problem can always be formulated as predicting a feature of the training data. Depending on whether the baseline linear classifier already uses the feature to be predicted, we face two possibilities:

Predicting a used feature In auxiliary problems of this type, we must take care to remove the feature itself from the training data. For example, we must not use the feature *path* or *pred&path* to predict *path* itself.

Predicting an unused feature These auxiliary problems provide information that the classifier was previously unable to incorporate. The desirable characteristics of such a feature are:

1. The feature, although unused, should have been considered for the target problem so it is probably related to the target problem.

2. The feature should not be highly correlated with a used feature, e.g., since the *lastword* feature is used in argument identification, we will not consider predicting *lastword.pos* as an auxiliary problem.

Each chosen feature can create thousands of binary auxiliary problems. E.g., by choosing to predict *hw*, we can create auxiliary problems predicting whether *hw=to*, whether *hw=trader*, etc. To have more positive training samples, we only predict the most frequent features. Thus we will probably predict whether *hw=to*, but not whether *hw=trader*, since *to* occurs more frequently than *trader* as a head word.

5.2.1 Argument identification

In argument identification using gold parse trees, we experiment with predicting three unused features as auxiliary problems: *distance* (distance between the predicate and the constituent), *parent.lsis.hw* (head word of the parent constituent's left sister) and *parent.rsis.hw* (head word of the parent constituent's right sister). We then experiment with predicting four used features: *hw*, *lastword*, *ptype* and *path*.

The ASO classifier is trained on sections 2 to 21, and tested on section 23. Due to the large data size, we are unable to use more than 20 binary auxiliary problems or to experiment with combinations of them. The F1 scores are presented in Table 4.

5.2.2 Argument classification

In argument classification using gold parse trees and gold identification, we experiment with predicting three unused features *path*, *partialpath*, and *chunkseq* (concatenation of the phrase types of text chunks between the predicate and the constituent). We then experiment with predicting three used features *hw*, *lastword*, and *ptype*.

Combinations of these auxiliary problems are also tested. In *all combined*, we use the first 100 problems from each of the six groups of observable auxiliary problems. In *selected combined*, we use the first 100 problems from each of *path*, *chunkseq*, *lastword* and *ptype* problems.

The ASO classifier is trained on sections 2 to 21, and tested on section 23. The F1 scores are shown in Table 5.

feature to be predicted	F1
20 most frequent *distance*s	81.48
20 most frequent *parent.lsis.hw*s	81.51
20 most frequent *parent.rsis.hw*s	81.60
20 most frequent *hw*s	81.40
20 most frequent *lastword*s	81.33
20 most frequent *ptype*s	81.35
20 most frequent *path*s	81.47
linear baseline	81.34

Table 4: F1 scores of ASO with observable auxiliary problems on argument identification. All $h = 20$.

From Table 4 and 5, we observe that although the use of observable auxiliary problems consistently improves the performance of the classifier, the differences are small and not statistically significant. Further experiments combining unobservable and observable auxiliary problems fail to outperform ASO with unobservable auxiliary problems alone.

feature to be predicted	F1
300 most frequent *path*s	87.97
300 most frequent *partialpath*s	87.95
300 most frequent *chunkseq*s	88.09
300 most frequent *hw*s	87.93
300 most frequent *lastword*s	88.01
all 63 *ptype*s	88.05
all combined	87.95
selected combined	88.07
linear baseline	87.86

Table 5: F1 scores of ASO with observable auxiliary problems on argument classification. All $h = 100$.

In summary, our work shows that unobservable auxiliary problems significantly improve the performance of NomBank SRL. In contrast, observable auxiliary problems are not effective.

6 Discussions

Some of our experiments are limited by the extensive computing resources required for a fuller exploration. For instance, "predicting unused features" type of auxiliary problems might hold some hope for further improvement in argument identification, if a larger number of auxiliary problems can be used.

ASO has been demonstrated to be an effective semi-supervised learning algorithm (Ando and Zhang, 2005a; Ando and Zhang, 2005b; Ando, 2006). However, we have been unable to use unlabeled data to improve the accuracy. One possible reason is the cumulative noise from the many cascading steps involved in automatic SRL of unlabeled data: syntactic parse, predicate identification (where we identify nouns with at least one argument), argument identification, and finally argument classification, which reduces the effectiveness of adding unlabeled data using ASO.

7 Related work

Multi-output neural networks learn several tasks simultaneously. In addition to the target outputs,

(Caruana, 1997) discusses configurations where both used inputs and unused inputs (due to excessive noise) are utilized as additional outputs. In contrast, our work concerns linear predictors using empirical risk minimization.

A variety of auxiliary problems are tested in (Ando and Zhang, 2005a; Ando and Zhang, 2005b) in the semi-supervised settings, i.e., their auxiliary problems are generated from unlabeled data. This differs significantly from the supervised setting in our work, where only labeled data is used. While (Ando and Zhang, 2005b) uses "predicting used features" (previous/current/next word) as auxiliary problems with good results in named entity recognition, the use of similar observable auxiliary problems in our work gives no statistically significant improvements.

More recently, for the word sense disambiguation (WSD) task, (Ando, 2006) experimented with both supervised and semi-supervised auxiliary problems, although the auxiliary problems she used are different from ours.

8 Conclusion

In this paper, we have presented a novel application of Alternating Structure Optimization (ASO) to the Semantic Role Labeling (SRL) task on NomBank. The possible auxiliary problems are categorized and tested extensively. Our results outperform those reported in (Jiang and Ng, 2006). To the best of our knowledge, we achieve the highest SRL accuracy published to date on the English NomBank.

A Simple, Similarity-based Model for Selectional Preferences

Katrin Erk
University of Texas at Austin
katrin.erk@mail.utexas.edu

Abstract

We propose a new, simple model for the automatic induction of selectional preferences, using corpus-based semantic similarity metrics. Focusing on the task of semantic role labeling, we compute selectional preferences for semantic roles. In evaluations the similarity-based model shows lower error rates than both Resnik's WordNet-based model and the EM-based clustering model, but has coverage problems.

1 Introduction

Selectional preferences, which characterize typical arguments of predicates, are a very useful and versatile knowledge source. They have been used for example for syntactic disambiguation (Hindle and Rooth, 1993), word sense disambiguation (WSD) (McCarthy and Carroll, 2003) and semantic role labeling (SRL) (Gildea and Jurafsky, 2002).

The corpus-based induction of selectional preferences was first proposed by Resnik (1996). All later approaches have followed the same two-step procedure, first collecting argument headwords from a corpus, then generalizing to other, similar words. Some approaches have used WordNet for the generalization step (Resnik, 1996; Clark and Weir, 2001; Abe and Li, 1993), others EM-based clustering (Rooth et al., 1999).

In this paper we propose a new, simple model for selectional preference induction that uses corpus-based semantic similarity metrics, such as Cosine or Lin's (1998) mutual information-based metric, for the generalization step. This model does not require any manually created lexical resources. In addition, the corpus for computing the similarity metrics can be freely chosen, allowing greater variation in the domain of generalization than a fixed lexical resource.

We focus on one application of selectional preferences: semantic role labeling. The argument positions for which we compute selectional preferences will be semantic roles in the FrameNet (Baker et al., 1998) paradigm, and the predicates we consider will be semantic classes of words rather than individual words (which means that different preferences will be learned for different senses of a predicate word). In SRL, the two most pressing issues today are (1) the development of strong semantic features to complement the current mostly syntactically-based systems, and (2) the problem of the domain dependence (Carreras and Marquez, 2005). In the CoNLL-05 shared task, participating systems showed about 10 points F-score difference between in-domain and out-of-domain test data. Concerning (1), we focus on selectional preferences as the strongest candidate for informative semantic features. Concerning (2), the corpus-based similarity metrics that we use for selectional preference induction open up interesting possibilities of mixing domains.

We evaluate the similarity-based model against Resnik's WordNet-based model as well as the EM-based clustering approach. In the evaluation, the similarity-model shows lower error rates than both Resnik's WordNet-based model and the EM-based clustering model. However, the EM-based clustering model has higher coverage than both other paradigms.

Plan of the paper. After discussing previ-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 216–223,
Prague, Czech Republic, June 2007.

ous approaches to selectional preference induction in Section 2, we introduce the similarity-based model in Section 3. Section 4 describes the data used for the experiments reported in Section 5, and Section 6 concludes.

2 Related Work

Selectional restrictions and selectional preferences that predicates impose on their arguments have long been used in semantic theories, (see e.g. (Katz and Fodor, 1963; Wilks, 1975)). The induction of selectional preferences from corpus data was pioneered by Resnik (1996). All subsequent approaches have followed the same two-step procedure, first collecting argument headwords from a corpus, then generalizing over the seen headwords to similar words. Resnik uses the WordNet noun hierarchy for generalization. His information-theoretic approach models the *selectional preference strength* of an argument position[1] r_p of a predicate p as

$$S(r_p) = \sum_c P(c|r_p) \log \frac{P(c|r_p)}{P(c)}$$

where the c are WordNet synsets. The preference that r_p has for a given synset c_0, the *selectional association* between the two, is then defined as the contribution of c_0 to r_p's selectional preference strength:

$$A(r_p, c_0) = \frac{P(c_0|r_p) \log \frac{P(c_0|r_p)}{P(c_0)}}{S(r_p)}$$

Further WordNet-based approaches to selectional preference induction include Clark and Weir (2001), and Abe and Li (1993). Brockmann and Lapata (2003) perform a comparison of WordNet-based models.

Rooth et al. (1999) generalize over seen headwords using EM-based clustering rather than WordNet. They model the probability of a word w occurring as the argument r_p of a predicate p as being independently conditioned on a set of classes C:

$$P(r_p, w) = \sum_{c \in C} P(c, r_p, w) = \sum_{c \in C} P(c) P(r_p|c) P(w|c)$$

The parameters $P(c)$, $P(r_p|c)$ and $P(w|c)$ are estimated using the EM algorithm.

While there have been no isolated comparisons of the two generalization paradigms that we are aware of, Gildea and Jurafsky's (2002) task-based evaluation has found clustering-based approaches to have better coverage than WordNet generalization, that is, for a given role there are more words for which they can state a preference.

3 Model

The approach we are proposing makes use of two corpora, a **primary corpus** and a **generalization corpus** (which may, but need not, be identical). The primary corpus is used to extract tuples (p, r_p, w) of a **predicate**, an **argument position** and a **seen headword**. The generalization corpus is used to compute a corpus-based semantic similarity metric.

Let $\text{Seen}(r_p)$ be the set of seen headwords for an argument r_p of a predicate p. Then we model the selectional preference S of r_p for a possible headword w_0 as a weighted sum of the similarities between w_0 and the seen headwords:

$$S_{r_p}(w_0) = \sum_{w \in \text{Seen}(r_p)} \text{sim}(w_0, w) \cdot \text{wt}_{r_p}(w)$$

$\text{sim}(w_0, w)$ is the similarity between the seen and the potential headword, and $\text{wt}_{r_p}(w)$ is the weight of seen headword w.

Similarity $\text{sim}(w_0, w)$ will be computed on the generalization corpus, again on the basis of extracted tuples (p, r_p, w). We will be using the similarity metrics shown in Table 1: Cosine, the Dice and Jaccard coefficients, and Hindle's (1990) and Lin's (1998) mutual information-based metrics. We write f for frequency, I for mutual information, and $R(w)$ for the set of arguments r_p for which w occurs as a headword.

In this paper we only study corpus-based metrics. The sim function can equally well be instantiated with a WordNet-based metric (for an overview see Budanitsky and Hirst (2006)), but we restrict our experiments to corpus-based metrics (a) in the interest of greatest possible

[1] We write r_p to indicate predicate-specific roles, like "the direct object of catch", rather than just "obj".

$$\mathrm{sim}_{\mathrm{cosine}}(w,w') = \frac{\sum_{r_p} f(w,r_p)\cdot f(w',r_p)}{\sqrt{\sum_{r_p} f(w,r_p)^2}\cdot\sqrt{\sum_{r_p} f(w',r_p)^2}} \qquad \mathrm{sim}_{\mathrm{Dice}}(w,w') = \frac{2\cdot|R(w)\cap R(w')|}{|R(w)|+|R(w')|}$$

$$\mathrm{sim}_{\mathrm{Lin}}(w,w') = \frac{\sum_{r_p\in R(w)\cap R(w')} I(w,r,p)I(w',r,p)}{\sum_{r_p\in R(w)} I(w,r,p)\sum_{r_p\in R(w)} I(w',r,p)} \qquad \mathrm{sim}_{\mathrm{Jaccard}}(w,w') = \frac{|R(w)\cap R(w')|}{|R(w)\cup R(w')|}$$

$$\mathrm{sim}_{\mathrm{Hindle}}(w,w') = \sum_{r_p} \mathrm{sim}_{\mathrm{Hindle}}(w,w',r_p) \qquad \text{where}$$

$$\mathrm{sim}_{\mathrm{Hindle}}(w,w',r_p) = \begin{cases} \min(I(w,r_p),I(w',r_p)) & \text{if } I(w,r_p)>0 \text{ and } I(w',r_p)>0 \\ \mathrm{abs}(\max(I(w,r_p),I(w',r_p))) & \text{if } I(w,r_p)<0 \text{ and } I(w',r_p)<0 \\ 0 & \text{else} \end{cases}$$

Table 1: Similarity measures used

resource-independence and (b) in order to be able to shape the similarity metric by the choice of generalization corpus.

For the headword weights $\mathrm{wt}_{r_p}(w)$, the simplest possibility is to assume a uniform weight distribution, i.e. $\mathrm{wt}_{r_p}(w) = 1$. In addition, we test a frequency-based weight, i.e. $\mathrm{wt}_{r_p}(w) = f(w,r_p)$, and inverse document frequency, which weighs a word according to its discriminativity: $\mathrm{wt}_{r_p}(w) = \log \frac{\text{num. words}}{\text{num. words to whose context w belongs}}$.

This similarity-based model of selectional preferences is a straightforward implementation of the idea of generalization from seen headwords to other, similar words. Like the clustering-based model, it is not tied to the availability of WordNet or any other manually created resource. The model uses two corpora, a primary corpus for the extraction of seen headwords and a generalization corpus for the computation of semantic similarity metrics. This gives the model flexibility to influence the similarity metric through the choice of text domain of the generalization corpus.

Instantiation used in this paper. Our aim is to compute selectional preferences for semantic roles. So we choose a particular instantiation of the similarity-based model that makes use of the fact that the two-corpora approach allows us to use different notions of "predicate" and "argument" in the primary and generalization corpus. Our primary corpus will consist of manually semantically annotated data, and we will use semantic verb classes as predicates and semantic roles as arguments. Examples of extracted (p, r_p, w) tuples are (Morality_evaluation, Evaluee, gamblers) and (Placing, Goal, briefcase). Semantic similarity, on the other hand, will be computed on automatically syntactically parsed corpus, where the predicates are words and the arguments are syntactic dependents. Examples of extracted (p, r_p, w) tuples from the generalization corpus include (catch, obj, frogs) and (intervene, in, deal).[2]

This instantiation of the similarity-based model allows us to compute word sense specific selectional preferences, generalizing over manually semantically annotated data using automatically syntactically annotated data.

4 Data

We use FrameNet (Baker et al., 1998), a semantic lexicon for English that groups words in semantic classes called *frames* and lists semantic roles for each frame. The FrameNet 1.3 annotated data comprises 139,439 sentences from the British National Corpus (BNC). For our experiments, we chose 100 frame-specific semantic roles at random, 20 each from five frequency bands: 50-100 annotated occurrences of the role, 100-200 occurrences, 200-500, 500-1000, and more than 1000 occurrences. The annotated data for these 100 roles comprised 59,608 sentences, our primary corpus. To determine headwords of the semantic roles, the corpus was parsed using the Collins (1997) parser.

Our generalization corpus is the BNC. It was parsed using Minipar (Lin, 1993), which is considerably faster than the Collins parser but failed to parse about a third of all sentences.

[2]For details about the syntactic and semantic analyses used, see Section 4.

Accordingly, the arguments r extracted from the generalization corpus are Minipar dependencies, except that paths through preposition nodes were collapsed, using the preposition as the dependency relation. We obtained parses for 5,941,811 sentences of the generalization corpus.

The EM-based clustering model was computed with all of the FrameNet 1.3 data (139,439 sentences) as input. Resnik's model was trained on the primary corpus (59,608 sentences).

5 Experiments

In this section we describe experiments comparing the similarity-based model for selectional preferences to Resnik's WordNet-based model and to an EM-based clustering model[3]. For the similarity-based model we test the five similarity metrics and three weighting schemes listed in section 3.

Experimental design

Like Rooth et al. (1999) we evaluate selectional preference induction approaches in a pseudo-disambiguation task. In a test set of pairs (r_p, w), each headword w is paired with a confounder w' chosen randomly from the BNC according to its frequency[4]. Noun headwords are paired with noun confounders in order not to disadvantage Resnik's model, which only works with nouns. The headword/confounder pairs are only computed once and reused in all cross-validation runs. The task is to choose the more likely role headword from the pair (w, w').

In the main part of the experiment, we count a pair as *covered* if both w and w' are assigned some level of preference by a model (*"full coverage"*). We contrast this with another condition, where we count a pair as covered if at least one of the two words w, w' is assigned a level of preference by a model (*"half coverage"*). If only one is assigned a preference, that word is counted as chosen.

To test the performance difference between models for significance, we use Dietterich's 5x2cv (Dietterich, 1998). The test involves five 2-fold cross-validation runs. Let $d_{i,j}$ ($i \in \{1,2\}, j \in \{1,\ldots,5\}$) be the difference in error rates between the two models when using split i of cross-validation run j as training data. Let $s_j^2 = (d_{1,j} - \bar{d}_j)^2 + (d_{2,j} - \bar{d}_j)^2$ be the variance for cross-validation run j, with $\bar{d}_j = \frac{d_{1,j}+d_{2,j}}{2}$. Then the 5x2cv $\tilde{t}$ statistic is defined as

$$\tilde{t} = \frac{d_{1,1}}{\sqrt{\frac{1}{5}\sum_{j=1}^{5} s_j^2}}$$

Under the null hypothesis, the $\tilde{t}$ statistic has approximately a t distribution with 5 degrees of freedom.[5]

	Error Rate	Coverage
Cosine	0.2667	0.3284
Dice	0.1951	0.3506
Hindle	0.2059	0.3530
Jaccard	**0.1858**	0.3506
Lin	**0.1635**	0.2214
EM 30/20	0.3115	0.5460
EM 40/20	0.3470	**0.9846**
Resnik	0.3953	0.3084

Table 2: Error rate and coverage (micro-average), similarity-based models with uniform weights.

Results and discussion

Error rates. Table 2 shows error rates and coverage for the different selectional preference induction methods. The first five models are similarity-based, computed with uniform weights. The name in the first column is the name of the similarity metric used. Next come EM-based clustering models, using 30 (40) clusters and 20 re-estimation steps[6], and the last row lists the results for Resnik's WordNet-based method. Results are micro-averaged.

The table shows very low error rates for the similarity-based models, up to 15 points lower than the EM-based models. The error rates

[3]We are grateful to Carsten Brockmann and Detlef Prescher for the use of their software.

[4]We exclude potential confounders that occur less than 30 or more than 3,000 times.

[5]Since the 5x2cv test fails when the error rates vary wildly, we excluded cases where error rates differ by 0.8 or more across the 10 runs, using the threshold recommended by Dietterich.

[6]The EM-based clustering software determines good values for these two parameters through pseudo-disambiguation tests on the training data.

Table 4: Error rates for similarity-based models, by semantic role frequency band. Micro-averages, uniform weights

of Resnik's model are considerably higher than both the EM-based and the similarity-based models, which is unexpected. While EM-based models have been shown to work better in SRL tasks (Gildea and Jurafsky, 2002), this has been attributed to the difference in coverage.

In addition to the *full coverage* condition, we also computed error rate and coverage for the *half coverage* case. In this condition, the error rates of the EM-based models are unchanged, while the error rates for all similarity-based models as well as Resnik's model rise to values between 0.4 and 0.6. So the EM-based model tends to have preferences only for the "right" words. Why this is so is not clear. It may be a genuine property, or an artifact of the FrameNet data, which only contains chosen, illustrative sentences for each frame. It is possible that these sentences have fewer occurrences of highly frequent but semantically less informative role headwords like "it" or "that" exactly because of their illustrative purpose.

Table 3 inspects differences between error rates using Dietterich's 5x2cv, basically confirming Table 2. Each cell shows the wins minus losses for the method listed in the row when compared against the method in the column. The number of cases that did not reach significance is given in brackets.

Coverage. The coverage rates of the similarity-based models, while comparable to Resnik's model, are considerably lower than for EM-based clustering, which achieves good coverage with 30 and almost perfect coverage with 40 clusters (Table 2). While peculiarities of the FrameNet data may have influenced the results in the EM-based model's favor (see the discussion of the *half coverage* condition above), the low coverage of the similarity-based models is still surprising. After all, the generalization corpus of the similarity-based models is far larger than the corpus used for clustering. Given the learning curve in Figure 1 it is unlikely that the reason for the lower coverage is data sparseness. However, EM-based clustering is a soft clustering method, which relates every predicate and every headword to every cluster, if only with a very low probabil-

ity. In similarity-based models, on the other hand, two words that have never been seen in the same argument slot in the generalization corpus will have zero similarity. That is, a similarity-based model can assign a level of preference for an argument r_p and word w_0 only if $R(w_0) \cap R(\text{Seen}(r_p))$ is nonempty. Since the flexibility of similarity-based models extends to the vector space for computing similarities, one obvious remedy to the coverage problem would be the use of a less sparse vector space. Given the low error rates of similarity-based models, it may even be advisable to use two vector spaces, backing off to the denser one for words not covered by the sparse but highly accurate space used in this paper.

Parameters of similarity-based models. Besides the similarity metric itself, which we discuss below, parameters of the similarity-based models include the number of seen headwords, the weighting scheme, and the number of similar words for each headword.

Table 4 breaks down error rates by semantic role frequency band for two of the similarity-based models, micro-averaging over roles of the same frequency band and over cross-validation runs. As the table shows, there was some variation across frequency bands, but not as much as between models.

The question of the number of seen headwords necessary to compute selectional preferences is further explored in Figure 1. The figure charts the number of seen headwords against error rate for a Jaccard similarity-based model (uniform weights). As can be seen, error rates reach a plateau at about 25 seen headwords for Jaccard. For other similarity metrics the result is similar.

The weighting schemes wt_{r_p} had surprisingly little influence on results. For Jaccard similarity, the model had an error rate of 0.1858 for uniform weights, 0.1874 for frequency weighting, and 0.1806 for discriminativity. For other similarity metrics the results were similar.

A cutoff was used in the similarity-based model: For each seen headword, only the 500 most similar words (according to a given similarity measure) were included in the computation; for all others, a similarity of 0 was assumed. Experiments testing a range of values for this parameter show that error rates stay stable for parameter values ≥ 200.

	Cos	Dic	Hin	Jac	Lin
(a) Freq. sim.	1889	3167	2959	3167	860
(b) Freq. wins	65%	73%	79%	72%	58%
(c) Num. sim.	81	60	67	60	66
(d) Intersec.	7.3	2.3	7.2	2.1	0.5

Table 5: Comparing sim. metrics: (a) avg. freq. of similar words; (b) % of times the more frequent word won; (c) number of distinct similar words per seen headword; (d) avg. size of intersection between roles

So similarity-based models seem not overly sensitive to the weighting scheme used, the number of seen headwords, or the number of similar words per seen headword. The difference between similarity metrics, however, is striking.

Differences between similarity metrics. As Table 2 shows, Lin and Jaccard worked best (though Lin has very low coverage), Dice and Hindle not as good, and Cosine showed the worst performance. To determine possible reasons for the difference, Table 5 explores properties of the five similarity measures.

Given a set $S = \text{Seen}(r_p)$ of seen headwords for some role r_p, each similarity metric produces a set $\text{like}(S)$ of words that have nonzero similarity to S, that is, to at least one word in S. Line (a) shows the average frequency of words in $\text{like}(S)$. The results confirm that the Lin and Cosine metrics tend to propose less frequent words as similar.

Line (b) pursues the question of the frequency bias further, showing the percentage of headword/confounder pairs for which the more frequent of the two words "won" in the pseudo-disambiguation task (using uniform weights). This it is an indirect estimate of the frequency bias of a similarity metric. Note that the headword actually was more frequent than the confounder in only 36% of all pairs.

These first two tests do not yield any explanation for the low performance of Cosine, as the results they show do not separate Cosine from

Jaccard	Cosine
Ride_vehicle:Vehicle truck 0.05 boat 0.05 coach 0.04 van 0.04 ship 0.04 lorry 0.04 creature 0.04 flight 0.04 guy 0.04 carriage 0.04 helicopter 0.04 lad 0.04	**Ride_vehicle:Vehicle** it 1.18 there 0.88 they 0.43 that 0.34 i 0.23 ship 0.19 second one 0.19 machine 0.19 e 0.19 other one 0.19 response 0.19 second 0.19

Table 6: Highest-ranked induced headwords (seen headwords omitted) for two semantic classes of the verb "take": similarity-based models, Jaccard and Cosine, uniform weights.

all other metrics. Lines (c) and (d), however, do just that. Line (c) looks at the size of like(S). Since we are using a cutoff of 500 similar words computed per word in S, the size of like(S) can only vary if the same word is suggested as similar for several seen headwords in S. This way, the size of like(S) functions as an indicator of the degree of uniformity or similarity that a similarity metric "perceives" among the members of S. To facilitate comparison across frequency bands, line (c) normalizes by the size of S, showing $\frac{|\text{like}(S)|}{|S|}$ micro-averaged over all roles. Here we see that Cosine seems to "perceive" considerably less similarity among the seen headwords than any of the other metrics.

Line (d) looks at the sets $s_{25}(r)$ of the 25 most preferred potential headwords of roles r, showing the average size of the intersection $s_{25}(r) \cap s_{25}(r')$ between two roles (preferences computed with uniform weights). It indicates another possible reason for Cosine's problem: Cosine seems to keep proposing the same words as similar for different roles. We will see this tendency also in the sample results we discuss next.

Sample results. Table 6 shows samples of headwords induced by the similarity-based model for two FrameNet senses of the verb "take": Ride_vehicle ("take the bus") and Ingest_substance ("take drugs"), a semantic class that is exclusively about ingesting controlled substances. The semantic role Vehicle of the Ride_vehicle frame and the role Substance of Ingest_substance are both typically realized as the direct object of "take". The table only shows new induced headwords; seen headwords were omitted from the list.

The particular implementation of the similarity-based model we have chosen, using frames and roles as predicates and arguments in the primary corpus, should enable the model to compute preferences specific to word senses. The sample in Table 6 shows that this is indeed the case: The preferences differ considerably for the two senses (frames) of "take", at least for the Jaccard metric, which shows a clear preference for vehicles for the Vehicle role. The Substance role of Ingest_substance is harder to characterize, with very diverse seen headwords such as "crack", "lines", "fluid", "speed". While the highest-ranked induced words for Jaccard do include three food items, there is no word, with the possible exception of "ice cream", that could be construed as a controlled substance. The induced headwords for the Cosine metric are considerably less pertinent for both roles and show the above-mentioned tendency to repeat some high-frequency words.

The inspection of "take" anecdotally confirms that different selectional preferences are learned for different senses. This point (which comes down to the usability of selectional preferences for WSD) should be verified in an empirical evaluation, possibly in another pseudo-disambiguation task, choosing as confounders seen headwords for *other* senses of a predicate word.

6 Conclusion

We have introduced the similarity-based model for inducing selectional preferences. Computing selectional preference as a weighted sum of similarities to seen headwords, it is a straight-

forward implementation of the idea of generalization from seen headwords to other, similar words. The similarity-based model is particularly simple and easy to compute, and seems not very sensitive to parameters. Like the EM-based clustering model, it is not dependent on lexical resources. It is, however, more flexible in that it induces similarities from a separate generalization corpus, which allows us to control the similarities we compute by the choice of text domain for the generalization corpus. In this paper we have used the model to compute sense-specific selectional preferences for semantic roles.

In a pseudo-disambiguation task the similarity-based model showed error rates down to 0.16, far lower than both EM-based clustering and Resnik's WordNet model. However its coverage is considerably lower than that of EM-based clustering, comparable to Resnik's model. The most probable reason for this is the sparsity of the underlying vector space. The choice of similarity metric is critical in similarity-based models, with Jaccard and Lin achieving the best performance, and Cosine surprisingly bringing up the rear.

Next steps will be to test the similarity-based model "in vivo", in an SRL task; to test the model in a WSD task; to evaluate the model on a primary corpus that is not semantically analyzed, for greater comparability to previous approaches; to explore other vector spaces to address the coverage issue; and to experiment on domain transfer, using an appropriate generalization corpus to induce selectional preferences for a domain different from that of the primary corpus. This is especially relevant in view of the domain-dependence problem that SRL faces.

Abstract

We study the issue of porting a known NLP method to a language with little existing NLP resources, specifically Hebrew SVM-based chunking. We introduce two SVM-based methods – Model Tampering and Anchored Learning. These allow fine grained analysis of the learned SVM models, which provides guidance to identify errors in the training corpus, distinguish the role and interaction of lexical features and eventually construct a model with ∼10% error reduction. The resulting chunker is shown to be robust in the presence of noise in the training corpus, relies on less lexical features than was previously understood and achieves an F-measure performance of 92.2 on automatically PoS-tagged text. The SVM analysis methods also provide general insight on SVM-based chunking.

1 Introduction

While high-quality NLP corpora and tools are available in English, such resources are difficult to obtain in most other languages. Three challenges must be met when adapting results established in English to another language: (1) acquiring high quality annotated data; (2) adapting the English task definition to the nature of a different language, and (3) adapting the algorithm to the new language. This paper presents a case study in the adaptation of a well known task to a language with few NLP resources available. Specifically, we deal with SVM based Hebrew NP chunking. In (Goldberg et al., 2006), we established that the task is not trivially transferable to Hebrew, but reported that SVM based chunking (Kudo and Matsumoto, 2000) performs well. We extend that work and study the problem from 3 angles: (1) how to deal with a corpus that is smaller and with a higher level of noise than is available in English; we propose techniques that help identify 'suspicious' data points in the corpus, and identify how robust the model is in the presence of noise; (2) we compare the task definition in English and in Hebrew through quantitative evaluation of the differences between the two languages by analyzing the relative importance of features in the learned SVM models; and (3) we analyze the structure of learned SVM models to better understand the characteristics of the chunking problem in Hebrew.

While most work on chunking with machine learning techniques tend to treat the classification engine as a black-box, we try to investigate the resulting classification model in order to understand its inner working, strengths and weaknesses. We introduce two SVM-based methods – Model Tampering and Anchored Learning – and demonstrate how a fine-grained analysis of SVM models provides insights on all three accounts. The understanding of the relative contribution of each feature in the model helps us construct a better model, which achieves ∼10% error reduction in Hebrew chunking, as well as identify corpus errors. The methods also provide general insight on SVM-based chunking.

2 Previous Work

NP chunking is the task of marking the boundaries of simple noun-phrases in text. It is a well studied problem in English, and was the focus of CoNLL2000's Shared Task (Sang and Buchholz,

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 224–231,
Prague, Czech Republic, June 2007.

2000). Early attempts at NP Chunking were rule learning systems, such as the Error Driven Pruning method of Pierce and Cardie (1998). Following Ramshaw and Marcus (1995), the current dominant approach is formulating chunking as a classification task, in which each word is classified as the (B)eginning, (I)nside or (O)outside of a chunk. Features for this classification usually involve local context features. Kudo and Matsumoto (2000) used SVM as a classification engine and achieved an F-Score of 93.79 on the shared task NPs. Since SVM is a binary classifier, to use it for the 3-class classification of the chunking task, 3 different classifiers {B/I, B/O, I/O} were trained and their majority vote was taken.

NP chunks in the shared task data are BaseNPs, which are non-recursive NPs, a definition first proposed by Ramshaw and Marcus (1995). This definition yields good NP chunks for English. In (Goldberg et al., 2006) we argued that it is not applicable to Hebrew, mainly because of the prevalence of the Hebrew's construct state ($smixut$). $Smixut$ is similar to a noun-compound construct, but one that can join a noun (with a special morphological marking) with a full NP. It appears in about 40% of Hebrew NPs. We proposed an alternative definition (termed SimpleNP) for Hebrew NP chunks. A SimpleNP cannot contain embedded relatives, prepositions, VPs and NP-conjunctions (except when they are licensed by $smixut$). It can contain $smixut$, possessives (even when they are attached by the 'של/of' preposition) and partitives (and, therefore, allows for a limited amount of recursion). We applied this definition to the Hebrew Tree Bank (Sima'an et al., 2001), and constructed a moderate size corpus (about 5,000 sentences) for Hebrew SimpleNP chunking. SimpleNPs are different than English BaseNPs, and indeed some methods that work well for English performed poorly on Hebrew data. However, we found that chunking with SVM provides good result for Hebrew SimpleNPs. We analyzed that this success comes from SVM's ability to use lexical features, as well as two Hebrew morphological features, namely "number" and "construct-state".

One of the main issues when dealing with Hebrew chunking is that the available tree bank is rather small, and since it is quite new, and has not been used intensively, it contains a certain amount of inconsistencies and tagging errors. In addition, the identification of SimpleNPs from the tree bank also introduces some errors. Finally, we want to investigate chunking in a scenario where PoS tags are assigned automatically and chunks are then computed. The Hebrew PoS tagger we use introduces about 8% errors (compared with about 4% in English). We are, therefore, interested in identifying errors in the chunking corpus, and investigating how the chunker operates in the presence of noise in the PoS tag sequence.

3 Model Tampering

3.1 Notation and Technical Review

This section presents notation as well as a technical review of SVM chunking details relevant to the current study. Further details can be found in Kudo and Matsumoto (2000; 2003).

SVM (Vapnik, 1995) is a supervised binary classifier. The input to the learner is a set of l training samples $(x_1, y_1), \ldots, (x_l, y_l)$, $x \in R^n$, $y \in \{+1, -1\}$. x_i is an n dimensional feature vector representing the ith sample, and y_i is the label for that sample. The result of the learning process is the set SV of Support Vectors, the associated weights α_i, and a constant b. The Support Vectors are a subset of the training vectors, and together with the weights and b they define a hyperplane that optimally separates the training samples. The basic SVM formulation is of a linear classifier, but by introducing a kernel function K that non-linearly transforms the data from R^n into a higher dimensional space, SVM can be used to perform non-linear classification. SVM's decision function is: $y(x) = sgn\left(\sum_{j \in SV} y_j \alpha_j K(x_j, x) + b\right)$ where x is an n dimensional feature vector to be classified. In the linear case, K is a dot product operation and the sum $w = \sum y_j \alpha_j x_j$ is an n dimensional weight vector assigning weight for each of the n features. The other kernel function we consider in this paper is a polynomial kernel of degree 2: $K(x_i, x_j) = (x_i \cdot x_j + 1)^2$. When using binary valued features, this kernel function essentially implies that the classifier considers not only the explicitly specified features, but also all available pairs of features. In order to cope with inseparable data, the learning process of SVM allows for some misclassification, the amount of which is determined by a

parameter C, which can be thought of as a penalty for each misclassified training sample.

In SVM based chunking, each word and its context is considered a learning sample. We refer to the word being classified as w_0, and to its part-of-speech (PoS) tag, morphology, and B/I/O tag as p_0, m_0 and t_0 respectively. The information considered for classification is $w_{-cw} \ldots w_{cw}$, $p_{-cp} \ldots p_{cp}$, $m_{-cm} \ldots m_{cm}$ and $t_{-ct} \ldots t_{-1}$. The feature vector F is an indexed list of all the features present in the corpus. A feature f_i of the form $w_{+1} = dog$ means that the word following the one being classified is 'dog'. Every learning sample is represented by an $n = |F|$ dimensional binary vector x. $x_i = 1$ iff the feature f_i is active in the given sample, and 0 otherwise. This encoding leads to extremely high dimensional vectors, due to the lexical features $w_{-cw} \ldots w_{cw}$.

3.2 Introducing Model Tampering

An important observation about SVM classifiers is that features which are not active in any of the Support Vectors have no effect on the classifier decision. We introduce Model Tampering, a procedure in which we change the Support Vectors in a model by forcing some values in the vectors to 0.

The result of this procedure is a new Model in which the deleted features never take part in the classification.

Model tampering is different than feature selection: on the one hand, it is a method that helps us identify irrelevant features in a model after training; on the other hand, and this is the key insight, removing features **after** training is not the same as removing them before training. The presence of the low-relevance features during training has an impact on the generalization performed by the learner as shown below.

3.3 The Role of Lexical Features

In Goldberg *et al.* (2006), we have established that using lexical features increases the chunking F-measure from 78 to over 92 on the Hebrew Treebank. We refine this observation by using Model Tampering, in order to assess the importance of lexical features in NP Chunking. We are interested in identifying which specific lexical items and contexts impact the chunking decision, and quantifying their effect. Our method is to train a chunking model on a given training corpus, tamper with the resulting model in various ways and measure the performance[1] of the tampered models on a test corpus.

3.4 Experimental Setting

We conducted experiments both for English and Hebrew chunking. For the Hebrew experiments, we use the corpora of (Goldberg et al., 2006). The first one is derived from the original Treebank by projecting the full syntactic tree, constructed manually, onto a set of NP chunks according to the SimpleNP rules. We refer to the resulting corpus as HEB_{Gold} since PoS tags are fully reliable. The HEB_{Err} version of the corpus is obtained by projecting the chunk boundaries on the sequence of PoS and morphology tags obtained by the automatic PoS tagger of Adler & Elhadad (2006). This corpus includes an error rate of about 8% on PoS tags. The first 500 sentences are used for testing, and the rest for training. The corpus contains 27K NP chunks. For the English experiments, we use the now-standard training and test sets that were introduced in (Marcus and Ramshaw, 1995)[2]. Training was done using Kudo's YAMCHA toolkit[3]. Both Hebrew and English models were trained using a polynomial kernel of degree 2, with $C = 1$. For English, the features used were: $w_{-2} \ldots w_2$, $p_{-2} \ldots p_2$, $t_{-2} \ldots t_{-1}$. The same features were used for Hebrew, with the addition of $m_{-2} \ldots m_2$. These are the same settings as in (Kudo and Matsumoto, 2000; Goldberg et al., 2006).

3.5 Tamperings

We experimented with the following tamperings:

TopN – We define *model feature count* to be the number of Support Vectors in which a feature is active in a given classifier. This tampering leaves in the model only the top N lexical features in each classifier, according to their count.

NoPOS – all the lexical features corresponding to a given part-of-speech are removed from the model. For example, in a NoJJ tampering, all the features of the form $w_i = X$ are removed from all the support vectors in which $p_i = JJ$ is active.

Loc≠i – all the lexical features with index i are removed from the model *e.g.*, in a Loc≠+2 tamper-

[1] The performance metric we use is the standard Precision/Recall/F measures, as computed by the conlleval program: http://www.cnts.ua.ac.be/conll2000/chunking/conlleval.txt

[2] ftp://ftp.cis.upenn.edu/pub/chunker

[3] http://chasen.org/∼taku/software/yamcha/

ing, features of the form $w_{+2} = X$ are removed).

Loc=i – all the lexical features with an index other than i are removed from the model.

3.6 Results and Discussion

Highlights of the results are presented in Tables (1-3). The numbers reported are F measures.

TopN	HEB$_{Gold}$	HEB$_{Err}$	ENG
ALL	93.58	92.48	93.79
N=0	78.32	76.27	90.10
N=10	90.21	88.68	90.24
N=50	91.78	90.85	91.22
N=100	92.25	91.62	91.72
N=500	93.60	92.23	93.12
N=1000	93.56	92.41	93.30

Table 1: Results of TopN Tampering.

The results of the TopN tamperings show that for both languages, most of the lexical features are irrelevant for the classification – the numbers achieved by using all the lexical features (about 30,000 in Hebrew and 75,000 in English) are very close to those obtained using only a few lexical features. This finding is very encouraging, and suggests that SVM based chunking is robust to corpus variations.

Another conclusion is that lexical features help balance the fact that PoS tags can be noisy: we know both HEB_{Err} and ENG include PoS tagging errors (about 8% in Hebrew and 4% in English). While in the case of "perfect" PoS tagging (HEB_{Gold}), a very small amount of lexical features is sufficient to reach the best F-result (500 out of 30,264), in the presence of PoS errors, more than the top 1000 lexical features are needed to reach the result obtained with all lexical features.

More striking is the fact that in Hebrew, the top 10 lexical features are responsible for an improvement of 12.4 in F-score. The words covered by these 10 features are the following: `Start of Sentence marker` and `comma`, `quote`, '`of/`של', '`and/`ו', '`the/`ה' and '`in/`ב'.

This finding suggests that the Hebrew PoS tagset might not be informative enough for the chunking task, especially where punctuation [4] and prepositions are concerned. The results in Table 2 give further support for this claim.

[4]Unlike the WSJ PoS tagset in which most punctuations get unique tags, our tagset treat punctuation marks as one group.

NoPOS	HEB$_G$	HEB$_E$	NoPOS	HEB$_G$	HEB$_E$
Prep	**85.25**	**84.40**	Pronoun	92.97	92.14
Punct	**88.90**	**87.66**	Conjunction	92.31	91.67
Adverb	92.02	90.72	Determiner	92.55	91.39

Table 2: Results of Hebrew NoPOS Tampering. Other scores are $\geq$ 93.3(HEB$_G$), $\geq$ 92.2(HEB$_E$).

When removing lexical features of a specific PoS, the most dramatic loss of F-score is reached for Prepositions and Punctuation marks, followed by Adverbs, and Conjunctions. Strikingly, lexical information for most open-class PoS (including Proper Names and Nouns) has very little impact on Hebrew chunking performance.

From this observation, one could conclude that enriching a model based only on PoS with lexical features for only a few closed-class PoS (prepositions and punctuation) could provide appropriate results even with a simpler learning method, one that cannot deal with a large number of features. We tested this hypothesis by training the Error-Driven Pruning (EDP) method of (Cardie and Pierce, 1998) with an extended set of features. EDP with PoS features only produced an F-result of 76.3 on HEB_{Gold}. By adding lexical features only for prepositions {של כ ה ב מ}, one conjunction {ו} and punctuation, the F-score on HEB_{Gold} indeed jumps to 85.4. However, when applied on HEB_{Err}, EDP falls down again to 59.4. This striking disparity, by comparison, lets us appreciate the resilience of the SVM model to PoS tagging errors, and its generalization capability even with a reduced number of lexical features.

Another implication of this data is that commas and quotation marks play a major role in determining NP boundaries in Hebrew. In Goldberg *et al.* (2006), we noted the Hebrew Treebank is not consistent in its treatment of punctuation, and thus we evaluated the chunker only after performing normalization of chunk boundaries for punctuations. We now hypothesize that, since commas and quotation marks play such an important role in the classification, performing such normalization *before* the training stage might be beneficial. Indeed results on the normalized corpus show improvement of about 1.0 in F score on both HEB_{Err} and HEB_{Gold}. A 10-fold cross validation experiment on punctuation normalized HEB_{Err} resulted in an F-Score of 92.2, improving the results reported by (Goldberg et al.,

2006) on the same setting (91.4).

Loc=I	HEB$_E$	ENG	Loc≠I	HEB$_E$	ENG
-2	78.26	89.79	-2	91.62	93.87
-1	76.96	90.90	-1	91.86	93.03
0	90.33	92.37	0	79.44	91.16
1	76.90	90.47	1	92.33	93.30
2	76.55	90.06	2	92.18	93.65

Table 3: Results of Loc Tamperings.

We now turn to analyzing the importance of context positions (Table 3). For both languages, the most important lexical feature (by far) is at position 0, that is, the word currently being classified. For English, it is followed by positions 1 and -1, and then positions 2 and -2. For Hebrew, back context seems to have more effect than front context. In Hebrew, all the positions positively contribute to the decision, while in English removing $w_{2/-2}$ slightly improves the results (note also that including only feature $w_{2/-2}$ performs worse than with no lexical information in English).

3.7 The Real Role of Lexical Features

Model tampering (i.e., removing features after the learning stage) is not the same as learning without these features. This claim is verified empirically: training on the English corpus without the lexical features at position –2 yields worse results than with them (93.73 vs. 93.79) – while removing the w_{-2} features via tampering on a model trained with w_{-2} yields better results (93.87). Similarly, for all corpora, training using only the top 1,000 features (as defined in the Top1000 tampering) results in loss of about 2 in F-Score (ENG 92.02, HEB_{Err} 90.30, HEB_{Gold} 91.67), while tampering Top1000 yields a result very close to the best obtained (93.56, 92.41 or 93.3F).

This observation leads us to an interesting conclusion about the real role of lexical features in SVM based chunking: **rare events (features) are used to memorize hard examples**. Intuitively, by giving a heavy weight to rare events, the classifier learns specific rules such as "*if the word at position -2 is X and the PoS at position 2 is Y, then the current word is* **I***nside a noun-phrase*". Most of these rules are accidental – there is no real relation between the particular word-pos combination and the class of the current word, it just happens to be this way in the training samples. Marking the rare occurrences helps the learner achieve better generalization on the other, more common cases, which are similar to the outlier on most features, except the "irrelevant ones". As the events are rare, such rules usually have no effect on chunking accuracy: they simply never occur in the test data. This observation refines the common conception that SVM chunking does not suffer from irrelevant features: in chunking, SVM indeed generalizes well for the common cases but also over-fits the model on outliers.

Model tampering helps us design a model in two ways: (1) it is a way to "open the black box" obtained when training an SVM and to analyze the respective importance of features. In our case, this analysis allowed us to identify the importance of punctuation and prepositions and improve the model by defining more focused features (improving overall result by ∼1.0 F-point). (2) The analysis also led us to the conclusion that "feature selection" is complex in the case of SVM – irrelevant features help prevent over-generalization by forcing over-fitting on outliers.

We have also confirmed that the model learned remains robust in the presence of noise in the PoS tags and relies on only few lexical features. This verification is critical in the context of languages with few computational resources, as we expect the size of corpora and the quality of taggers to keep lagging behind that achieved in English.

4 Anchored Learning

We pursue the observation of how SVM deals with outliers by developing the *Anchored Learning* method. The idea behind Anchored Learning is to add a unique feature a_i (an *anchor*) to each training sample (we add as many new features to the model as there are training samples). These new features make our data linearly separable. The SVM learner can then use these anchors (which will never occur on the test data) to memorize the hard cases, decreasing this burden from "real" features.

We present two uses for Anchored Learning. The first is the identification of hard cases and corpus errors, and the second is a preliminary feature selection approach for SVM to improve chunking accuracy.

4.1 Mining for Errors and Hard Cases

Following the intuition that SVM gives more weight to anchor features of hard-to-classify cases, we can

actively look for such cases by training an SVM chunker on anchored data (as the anchored data is guaranteed to be linearly separable, we can set a very high value to the C parameter, preventing any misclassification), and then investigating either the anchors whose weights[5] are above some threshold t or the top N heaviest anchors, and their corresponding corpus locations. **These locations are those that the learner considers hard to classify**. They can be either corpus errors, or genuinely hard cases.

This method is similar to the corpus error detection method presented by Nakagawa and Matsumoto (2002). They constructed an SVM model for PoS tagging, and considered Support Vectors with high α values to be indicative of suspicious corpus locations. These locations can be either outliers, or correctly labeled locations similar to an outlier. They then looked for similar corpus locations with a different label, to point out right-wrong pairs with high precision.

Using anchors improves their method in three aspects: (1) without anchors, similar examples are often indistinguishable to the SVM learner, and in case they have conflicting labels both examples will be given high weights. That is, both the regular case and the hard case will be considered as hard examples. Moreover, similar corpus errors might result in only one support vector that cover all the group of similar errors. Anchors mitigate these effects, resulting in better precision and recall. (2) The more errors there are in the corpus, the less linearly separable it is. Un-anchored learning on erroneous corpus can take unreasonable amount of time. (3) Anchors allow learning while removing some of the important features but still allow the process to converge in reasonable time. This lets us analyze which cases become hard to learn if we don't use certain features, or in other words: what problematic cases are solved by specific features.

The hard cases analysis achieved by anchored learning is different from the usual error analysis carried out on observed classification errors. The traditional methods give us intuitions about where the classifier **fails to generalize**, while the method we present here gives us intuition about what the classifier **considers hard to learn**, based on the training examples alone.

[5]As each anchor appear in only one support vector, we can treat the vector's α value as the anchor weight

The intuition that "hard to learn" examples are suspect corpus errors is not new, and appears also in Abney *et al.* (1999) , who consider the "heaviest" samples in the final distribution of the AdaBoost algorithm to be the hardest to classify and thus likely corpus errors. While AdaBoost models are easy to interpret, this is not the case with SVM. Anchored learning allows us to extract the hard to learn cases from an SVM model. Interestingly, while both AdaBoost and SVM are 'large margin' based classifiers, there is less than 50% overlap in the hard cases for the two methods (in terms of mistakes on the test data, there were 234 mistakes shared by AdaBoost and SVM, 69 errors unique to SVM and 126 errors unique to AdaBoost)[6]. Analyzing the difference in what the two classifiers consider hard is interesting, and we will address it in future work. In the current work, we note that for finding corpus errors the two methods are complementary.

Experiment 1 – Locating Hard Cases

A linear SVM model (M_{full}) was trained on the training subset of the anchored, punctuation-normalized, HEB_{Gold} corpus, with the same features as in the previous experiments, and a C value of 9,999. Corpus locations corresponding to anchors with weights >1 were inspected. There were about 120 such locations out of 4,500 sentences used in the training set. Decreasing the threshold t would result in more cases. We analyzed these locations into 3 categories: corpus errors, cases that challenge the SimpleNP definition, and cases where the chunking decision is genuinely difficult to make in the absence of global syntactic context or world knowledge.

Corpus Errors: The analysis revealed the following corpus errors: we identified 29 hard cases related to conjunction and apposition (is the comma, colon or slash inside an NP or separating two distinct NPs). 14 of these hard cases were indeed mistakes in the corpus. This was anticipated, as we distinguished appositions and conjunctive commas using heuristics, since the Treebank marking of conjunctions is somewhat inconsistent.

In order to build the Chunk NP corpus, the syntactic trees of the Treebank were processed to derive chunks according to the SimpleNP definition. The hard cases analysis identified 18 instances where this

[6]These numbers are for pairwise Linear SVM and AdaBoost classifiers trained on the same features.

transformation results in erroneous chunks. For example, null elements result in improper chunks, such as chunks containing only adverbs or only adjectives.

We also found 3 invalid sentences, 6 inconsistencies in the tagging of interrogatives with respect to chunk boundaries, as well as 34 other specific mistakes. Overall, more than half of the locations identified by the anchors were corpus errors. Looking for cases similar to the errors identified by anchors, we found 99 more locations, 77 of which were errors.

Refining the SimpleNP Definition: The hard cases analysis identified examples that challenge the SimpleNP definition proposed in Goldberg *et al.* (2006). The most notable cases are:

The 'et' marker : '*et*' is a syntactic marker of definite direct objects in Hebrew. It was regarded as a part of SimpleNPs in their definition. In some cases, this forces the resulting SimpleNP to be too inclusive:

[את הממשלה, הכנסת בית המשפט והתקשורת]

['et' (the government, the parliament and the media)]

Because in the Treebank the conjunction depends on '*et*' as a single constituent, it is fully embedded in the chunk. Such a conjunction should not be considered simple.

The של *preposition ('of')* marks generalized possession and was considered unambiguous and included in SimpleNPs. We found cases where 'של' causes PP attachment ambiguity:

[נשיא בית הדין] ל [משמעת] של [המשטרה]

[president-cons house-cons the-law] for [discipline] of [the police] / The Police Disciplinary Court President

Because 2 prepositions are involved in this NP, 'של' (*of*) and 'ל' (*for*), the 'של' part cannot be attached unambiguously to its head ('*court*'). It is unclear whether the 'ל' preposition should be given special treatment to allow it to enter simple NPs in certain contexts, or whether the inconsistent handling of the 'של' that results from the 'ל' inter-position is preferable.

Complex determiners and quantifiers: In many cases, complex determiners in Hebrew are multi-word expressions that include nouns. The inclusion of such determiners inside the SimpleNPs is not consistent.

Genuinely hard cases were also identified. These include prepositions, conjunctions and multi-word idioms (most of them are adjectives and prepositions which are made up of nouns and determiners, *e.g.*, as the word *unanimously* is expressed in Hebrew as the multi-word expression 'one mouth'). Also, some *adverbials* and *adjectives* are impossible to distinguish using only local context.

The anchors analysis helped us improve the chunking method on two accounts: (1) it identified corpus errors with high precision; (2) it made us focus on hard cases that challenge the linguistic definition of chunks we have adopted. Following these findings, we intend to refine the Hebrew SimpleNP definition, and create a new version of the Hebrew chunking corpus.

Experiment 2 – determining the role of contextual lexical features

The intent of this experiment is to understand the role of the contextual lexical features (w_i, $i \neq 0$). This is done by training 2 additional anchored linear SVM models, $M_{no-cont}$ and M_{near}. These are the same as M_{full} except for the lexical features used during training. $M_{no-cont}$ uses only w_0, while M_{near} uses w_0,w_{-1},w_{+1}.

Anchors are again used to locate the hard examples for each classifier, and the differences are examined. The examples that are hard for M_{near} but not for M_{full} are those solved by w_{-2},w_{+2}. Similarly, the examples that are hard for $M_{no-cont}$ but not for M_{near} are those solved by w_{-1},w_{+1}. Table 4 indicates the number of hard cases identified by the anchor method for each model. One way to interpret these figures, is that the introduction of features $w_{-1,+1}$ solves 5 times more hard cases than $w_{-2,+2}$.

Model	**Number of hard cases ($t = 1$)**	**Hard cases for classifier B-I**
M_{full}	120	2
M_{near}	320 (+ 200)	12
$M_{no-cont}$	1360 (+ 1040)	164

Table 4: Number of hard cases per model type.

Qualitative analysis of the hard cases solved by the contextual lexical features shows that they contribute mostly to the identification of chunk boundaries in cases of conjunction, apposition, attachment of adverbs and adjectives, and some multi-word expressions.

The number of hard cases specific to the B-I classifier indicates how the features contribute to the decision of splitting or continuing back-to-back NPs. Back-to-back NPs amount to 6% of the NPs in HEB_{Gold} and 8% of the NPs in ENG. However,

while in English most of these cases are easily resolved, Hebrew phenomena such as null-equatives and free word order make them harder. To quantify the difference: 79% of the first words of the second NP in English belong to one of the closed classes POS, DT, WDT, PRP, WP – categories which mostly cannot appear in the middle of base NPs. In contrast, in Hebrew, 59% are Nouns, Numbers or Proper Names. Moreover, in English the ratio of unique first words to number of adjacent NPs is 0.068, while in Hebrew it is 0.47. That is, in Hebrew, almost every second such NP starts with a different word.

These figures explain why surrounding lexical information is needed by the learner in order to classify such cases. They also suggest that this learning is mostly superficial, that is, the learner just memorizes some examples, but these will not generalize well on test data. Indeed, the most common class of errors reported in Goldberg *et al.* , 2006 are of the split/merge type. These are followed by conjunction related errors, which suffer from the same problem. Morphological features of *smixut* and agreement can help to some extent, but this is still a limited solution. It seems that deciding the [NP][NP] case is beyond the capabilities of chunking with local context features alone, and more global features should be sought.

4.2 Facilitating Better Learning

This section presents preliminary results using Anchored Learning for better NP chunking. We present a setting (English Base NP chunking) in which selected features coupled together with anchored learning show an improvement over previous results.

Section 3.6 hinted that SVM based chunking might be hurt by using too many lexical features. Specifically, the features w_{-2},w_{+2} were shown to cause the chunker to overfit in English chunking. Learning without these features, however, yields lower results. This can be overcome by introducing anchors as a substitute. Anchors play the same role as rare features when learning, while lowering the chance of misleading the classifier on test data.

The results of the experiment using 5-fold cross validation on ENG indicate that the F-score improves on average from 93.95 to 94.10 when using anchors instead of $w_{\pm 2}$ (+0.15), while just ignoring the $w_{\pm 2}$ features drops the F-score by 0.10. The improvement is minor but consistent. Its implication is that anchors can substitute for "irrelevant" lexical features for better learning results. In future work, we will experiment with better informed sets of lexical features mixed with anchors.

5 Conclusion

We have introduced two novel methods to understand the inner structure of SVM-learned models. We have applied these techniques to Hebrew NP chunking, and demonstrated that the learned model is robust in the presence of noise in the PoS tags, and relies on only a few lexical features. We have identified corpus errors, better understood the nature of the task in Hebrew – and compared it quantitatively to the task in English.

The methods provide general insight in the way SVM classification works for chunking.

Abstract

We present a web mining method for discovering and enhancing relationships in which a specified concept (word class) participates. We discover a whole range of relationships focused on the given concept, rather than generic known relationships as in most previous work. Our method is based on clustering patterns that contain concept words and other words related to them. We evaluate the method on three different rich concepts and find that in each case the method generates a broad variety of relationships with good precision.

1 Introduction

The huge amount of information available on the web has led to a flurry of research on methods for automatic creation of structured information from large unstructured text corpora. The challenge is to create as much information as possible while providing as little input as possible.

A lot of this research is based on the initial insight (Hearst, 1992) that certain lexical patterns ('X is a country') can be exploited to automatically generate hyponyms of a specified word. Subsequent work (to be discussed in detail below) extended this initial idea along two dimensions.

One objective was to require as small a user-provided initial seed as possible. Thus, it was observed that given one or more such lexical patterns, a corpus could be used to generate examples of hyponyms that could then, in turn, be exploited to generate more lexical patterns. The larger and more reliable sets of patterns thus generated resulted in larger and more precise sets of hyponyms and vice versa. The initial step of the resulting alternating bootstrap process – the user-provided input – could just as well consist of examples of hyponyms as of lexical patterns.

A second objective was to extend the information that could be learned from the process beyond hyponyms of a given word. Thus, the approach was extended to finding lexical patterns that could produce synonyms and other standard lexical relations. These relations comprise all those words that stand in some known binary relation with a specified word.

In this paper, we introduce a novel extension of this problem: given a particular concept (initially represented by two seed words), discover relations in which it participates, without specifying their types in advance. We will generate a concept class and a variety of natural binary relations involving that class.

An advantage of our method is that it is particularly suitable for web mining, even given the restrictions on query amounts that exist in some of today's leading search engines.

The outline of the paper is as follows. In the next section we will define more precisely the problem we intend to solve. In section 3, we will consider related work. In section 4 we will provide an overview of our solution and in section 5 we will consider the details of the method. In section 6 we will illustrate and evaluate the results obtained by our method. Finally, in section 7 we will offer some conclusions and considerations for further work.

2 Problem Definition

In several studies (e.g., Widdows and Dorow, 2002; Pantel et al, 2004; Davidov and Rappoport, 2006) it has been shown that relatively unsupervised and language-independent methods could be used to generate many thousands of sets of words whose semantics is similar in some sense. Although examination of any such set invariably makes it clear why these words have been grouped together into a single concept, it is important to emphasize that the method itself provides no explicit concept definition; in some sense, the implied class is in the eye of the beholder. Nevertheless, both human judgment and comparison with standard lists indicate that the generated sets correspond to concepts with high precision.

We wish now to build on that result in the following way. Given a large corpus (such as the web) and two or more examples of some concept X, automatically generate examples of one or more relations $R \subset X \times Y$, where Y is some concept and R is some binary relationship between elements of X and elements of Y.

We can think of the relations we wish to generate as bipartite graphs. Unlike most earlier work, the bipartite graphs we wish to generate might be one-to-one (for example, countries and their capitals), many-to-one (for example, countries and the regions they are in) or many-to-many (for example, countries and the products they manufacture). For a given class X, we would like to generate not one but possibly many different such relations.

The only input we require, aside from a corpus, is a small set of examples of some class. However, since such sets can be generated in entirely unsupervised fashion, our challenge is effectively to generate relations directly from a corpus given no additional information of any kind. The key point is that we do not in any manner specify in advance what types of relations we wish to find.

3 Related Work

As far as we know, no previous work has directly addressed the discovery of generic binary relations in an unrestricted domain without (at least implicitly) pre-specifying relationship types. Most related work deals with discovery of hypernymy (Hearst, 1992; Pantel et al, 2004), synonymy (Roark and Charniak, 1998; Widdows and Dorow, 2002; Davidov and Rappoport, 2006) and meronymy (Berland and Charniak, 1999).

In addition to these basic types, several studies deal with the discovery and labeling of more specific relation sub-types, including inter-verb relations (Chklovski and Pantel, 2004) and noun-compound relationships (Moldovan et al, 2004).

Studying relationships between tagged named entities, (Hasegawa et al, 2004; Hassan et al, 2006) proposed unsupervised clustering methods that assign given (or semi-automatically extracted) sets of pairs into several clusters, where each cluster corresponds to one of a known relationship type. These studies, however, focused on the classification of pairs that were either given or extracted using some supervision, rather than on discovery and definition of which relationships are actually in the corpus.

Several papers report on methods for using the web to discover instances of binary relations. However, each of these assumes that the relations themselves are known in advance (implicitly or explicitly) so that the method can be provided with seed patterns (Agichtein and Gravano, 2000; Pantel et al, 2004), pattern-based rules (Etzioni et al, 2004), relation keywords (Sekine, 2006), or word pairs exemplifying relation instances (Pasca et al, 2006; Alfonseca et al, 2006; Rosenfeld and Feldman, 2006).

In some recent work (Strube and Ponzetto, 2006), it has been shown that related pairs can be generated without pre-specifying the nature of the relation sought. However, this work does not focus on differentiating among different relations, so that the generated relations might conflate a number of distinct ones.

It should be noted that some of these papers utilize language and domain-dependent preprocessing including syntactic parsing (Suchanek et al, 2006) and named entity tagging (Hasegawa et al, 2004), while others take advantage of handcrafted databases such as WordNet (Moldovan et al, 2004; Costello et al, 2006) and Wikipedia (Strube and Ponzetto, 2006).

Finally, (Turney, 2006) provided a pattern distance measure which allows a fully unsupervised measurement of relational similarity between two pairs of words; however, relationship types were not discovered explicitly.

4 Outline of the Method

We will use two concept words contained in a concept class C to generate a collection of distinct relations in which C participates. In this section we offer a brief overview of our method.

Step 1: Use a seed consisting of two (or more) example words to automatically obtain other examples that belong to the same class. Call these *concept words*. (For instance, if our example words were *France* and *Angola*, we would generate more country names.)

Step 2: For each concept word, collect instances of contexts in which the word appears together with one other content word. Call this other word a *target word* for that concept word. (For example, for *France* we might find 'Paris is the capital of France'. *Paris* would be a target word for *France*.)

Step 3: For each concept word, group the contexts in which it appears according to the target word that appears in the context. (Thus 'X is the capital of Y' would likely be grouped with 'Y's capital is X'.)

Step 4: Identify similar context groups that appear across many different concept words. Merge these into a single concept-word-independent cluster. (The group including the two contexts above would appear, with some variation, for other countries as well, and all these would be merged into a single cluster representing the relation *capital-of(X,Y)*.)

Step 5: For each cluster, output the relation consisting of all <concept word, target word> pairs that appear together in a context included in the cluster. (The cluster considered above would result in a set of pairs consisting of a country and its capital. Other clusters generated by the same seed might include countries and their languages, countries and the regions in which they are located, and so forth.)

5 Details of the Method

In this section we consider the details of each of the above-enumerated steps. It should be noted that each step can be performed using standard web searches; no special pre-processed corpus is required.

5.1 Generalizing the seed

The first step is to take the seed, which might consist of as few as two concept words, and generate many (ideally, all, when the concept is a closed set of words) members of the class to which they belong. We do this as follows, essentially implementing a simplified version of the method of Davidov and Rappoport (2006). For any pair of seed words S_i and S_j, search the corpus for word patterns of the form S_iHS_j, where H is a high-frequency word in the corpus (we used the 100 most frequent words in the corpus). Of these, we keep all those patterns, which we call *symmetric patterns*, for which S_jHS_i is also found in the corpus. Repeat this process to find symmetric patterns with any of the structures $HSHS$, $SHSH$ or $SHHS$. It was shown in (Davidov and Rappoport, 2006) that pairs of words that often appear together in such symmetric patterns tend to belong to the same class (that is, they share some notable aspect of their semantics). Other words in the class can thus be generated by searching a sub-corpus of documents including at least two concept words for those words X that appear in a sufficient number of instances of both the patterns S_iHX and XHS_i, where S_i is a word in the class. The same can be done for the other three pattern structures. The process can be bootstrapped as more words are added to the class.

Note that our method differs from that of Davidov and Rappoport (2006) in that here we provide an initial seed pair, representing our target concept, while there the goal is grouping of as many words as possible into concept classes. The focus of our paper is on relations involving a specific concept.

5.2 Collecting contexts

For each concept word S, we search the corpus for distinct contexts in which S appears. (For our purposes, a context is a window with exactly five words or punctuation marks before or after the concept word; we choose 10,000 of these, if available.) We call the aggregate text found in all these context windows the S-corpus.

From among these contexts, we choose all patterns of the form $H_1SH_2XH_3$ or $H_1XH_2SH_3$, where:

- X is a word that appears with frequency below f_1 in the S-corpus and that has sufficiently high pointwise mutual information with S. We use these two criteria to ensure that X is a content word and that it is related to S. The lower the threshold f_1, the less noise we allow in, though possibly at the expense of recall. We used $f_1 = 1,000$ occurrences per million words.

- H_2 is a string of words each of which occurs with frequency above f_2 in the S-corpus. We want H_2 to consist mainly of words common in the context of S in order to restrict patterns to those that are somewhat generic. Thus, in the context of countries we would like to retain words like *capital* while eliminating more specific words that are unlikely to express generic patterns. We used $f_2 = 100$ occurrences per million words (there is room here for automatic optimization, of course).

- H_1 and H_3 are either punctuation or words that occur with frequency above f_3 in the S-corpus. This is mainly to ensure that X and S aren't fragments of multi-word expressions. We used $f_3 = 100$ occurrences per million words.

- We call these patterns, *S-patterns* and we call X the *target* of the S-pattern. The idea is that S and X very likely stand in some fixed relation to each other where that relation is captured by the S-pattern.

5.3 Grouping S-patterns

If S is in fact related to X in some way, there might be a number of S-patterns that capture this relationship. For each X, we group all the S-patterns that have X as a target. (Note that two S-patterns with two different targets might be otherwise identical, so that essentially the same pattern might appear in two different groups.) We now merge groups with large (more than 2/3) overlap. We call the resulting groups, *S-groups.*

5.4 Identifying pattern clusters

If the S-patterns in a given S-group actually capture some relationship between S and the target, then one would expect that similar groups would appear for a multiplicity of concept words S. Suppose that we have S-groups for three different concept words S such that the pairwise overlap among the three groups is more than 2/3 (where for this purpose two patterns are deemed identical if they differ only at S and X). Then the set of patterns that appear in two or three of these S-groups is called a *cluster core.* We now group all patterns in other S-groups that have an overlap of more than 2/3 with the cluster core into a candidate pattern pool P. The set of all patterns in P that appear in at least two S-groups (among those that formed P) *pattern cluster.* A pattern cluster that has patterns instantiated by at least half of the concept words is said to represent a relation.

5.5 Refining relations

A relation consists of pairs (S, X) where S is a concept word and X is the target of some S-pattern in a given pattern cluster. Note that for a given S, there might be one or many values of X satisfying the relation. As a final refinement, for each given S, we rank all such X according to pointwise mutual information with S and retain only the highest 2/3. If most values of S have only a single corresponding X satisfying the relation and the rest have none, we try to automatically fill in the missing values by searching the corpus for relevant S-patterns for the missing values of S. (In our case the corpus is the web, so we perform additional clarifying queries.)

Finally, we delete all relations in which all concept words are related to most target words and all relations in which the concept words and the target words are identical. Such relations can certainly be of interest (see Section 7), but are not our focus in this paper.

5.6 Notes on required Web resources

In our implementation we use the Google search engine. Google restricts individual users to 1,000 queries per day and 1,000 pages per query. In each stage we conducted queries iteratively, each time downloading all 1,000 documents for the query.

In the first stage our goal was to discover symmetric relationships from the web and consequently discover additional concept words. For queries in this stage of our algorithm we invoked two requirements.

First, the query should contain at least two concept words. This proved very effective in reduc-

ing ambiguity. Thus of 1,000 documents for the query *bass*, 760 deal with music, while if we add to the query a second word from the intended concept (e.g., *barracuda*), then none of the 1,000 documents deal with music and the vast majority deal with fish, as intended.

Second, we avoid doing overlapping queries. To do this we used Google's ability to exclude from search results those pages containing a given term (in our case, one of the concept words).

We performed up to 300 different queries for individual concepts in the first stage of our algorithm.

In the second stage, we used web queries to assemble S-corpora. On average, about 1/3 of the concept words initially lacked sufficient data and we performed up to twenty additional queries for each rare concept word to fill its corpus.

In the last stage, when clusters are constructed, we used web queries for filling missing pairs of one-to-one or several-to-several relationships. The total number of filling queries for a specific concept was below 1,000, and we needed only the first results of these queries. Empirically, it took between 0.5 to 6 day limits (i.e., 500–6,000 queries) to extract relationships for a concept, depending on its size (the number of documents used for each query was at most 100). Obviously this strategy can be improved by focused crawling from primary Google hits, which can drastically reduce the required number of queries.

6 Evaluation

In this section we wish to consider the variety of relations that can be generated by our method from a given seed and to measure the quality of these relations in terms of their precision and recall.

With regard to precision, two claims are being made. One is that the generated relations correspond to identifiable relations. The other claim is that to the extent that a generated relation can be reasonably identified, the generated pairs do indeed belong to the identified relation. (There is a small degree of circularity in this characterization but this is probably the best we can hope for.)

As a practical matter, it is extremely difficult to measure precision and recall for relations that have not been pre-determined in any way. For each generated relation, authoritative resources must be marshaled as a gold standard. For purposes of evaluation, we ran our algorithm on three representative domains – countries, fish species and star constellations – and tracked down gold standard resources (encyclopedias, academic texts, informative websites, etc) for the bulk of the relations generated in each domain.

This choice of domains allowed us to explore different aspects of algorithmic behavior. Country and constellation domains are both well defined and closed domains. However they are substantially different.

Country names is a relatively large domain which has very low lexical ambiguity, and a large number of potentially useful relations. The main challenge in this domain was to capture it well.

Constellation names, in contrast, are a relatively small but highly ambiguous domain. They are used in proper names, mythology, names of entertainment facilities etc. Our evaluation examined how well the algorithm can deal with such ambiguity.

The fish domain contains a very high number of members. Unlike countries, it is a semi-open non-homogenous domain with a very large number of subclasses and groups. Also, unlike countries, it does not contain many proper nouns, which are empirically generally easier to identify in patterns. So the main challenge in this domain is to extract unblurred relationships and not to diverge from the domain during the concept acquisition phase.

We do not show here all-to-all relationships such as fish parts (common to all or almost all fish), because we focus on relationships that separate between members of the concept class, which are harder to acquire and evaluate.

6.1 Countries

Our seed consisted of two country names. The intended result for the first stage of the algorithm was a list of countries. There are 193 countries in the world (www.countrywatch.com) some of which have multiple names so that the total number of commonly used country names is 243. Of these, 223 names (comprising 180 countries) are character strings with no white space. Since we consider only single word names, these 223 are the names we hope to capture in this stage.

Using the seed words *France* and *Angola*, we obtained 202 country names (comprising 167 distinct countries) as well as 32 other names (consisting mostly of names of other geopolitical entities). Using the list of 223 single word countries as our gold standard, this gives precision of 0.90 and recall of 0.86. (Ten other seed pairs gave results ranging in precision: 0.86-0.93 and recall: 0.79-0.90.)

The second part of the algorithm generated a set of 31 binary relations. Of these, 25 were clearly identifiable relations many of which are shown in Table 1. Note that for three of these there are standard exhaustive lists against which we could measure both precision and recall; for the others shown, sources were available for measuring precision but no exhaustive list was available from which to measure recall, so we measured coverage (the number of countries for which at least one target concept is found as related).

Another eleven meaningful relations were generated for which we did not compute precision numbers. These include *celebrity-from, animal-of, lake-in, borders-on* and *enemy-of.* (The set of relations generated by other seed pairs differed only slightly from those shown here for *France* and *Angola*.)

6.2 Fish species

In our second experiment, our seed consisted of two fish species, *barracuda* and *bluefish.* There are 770 species listed in WordNet of which 447 names are character strings with no white space. The first stage of the algorithm returned 305 of the species listed in Wordnet, another 37 species not listed in Wordnet, as well as 48 other names (consisting mostly of other sea creatures). The second part of the algorithm generated a set of 15 binary relations all of which are meaningful. Those for which we could find some gold standard are listed in Table 2.

Other relations generated include *served-with, bait-for, food-type, spot-type,* and *gill-type.*

6.3 Constellations

Our seed consisted of two constellation names, *Orion* and *Cassiopeia.* There are 88 standard constellations (www.astro.wisc.edu) some of which have multiple names so that the total number of commonly used constellations is 98. Of these, 87 names (77 constellations) are strings with no white space.

Relationship *Sample pattern* (Sample pair)	Prec.	Rec/Cov
capital-of *in (x), capital of (y),* (Luanda, Angola)	0.92	R=0.79
language-spoken-in *to (x) or other (y) speaking* (Spain, Spanish)	0.92	R=0.60
in-region *throughout (x), from (y) to* (America, Canada)	0.73	R=0.71
city-in *west (x) – forecast for (y).* (England, London)	0.82	C=0.95
river-in *central (x), on the (y) river* (China, Haine)	0.92	C=0.68
mountain-range-in *the (x) mountains in (y) ,* (Chella, Angola)	0.77	C=0.69
sub-region-of *the (y) region of (x),* (Veneto, Italy)	0.81	C=0.81
industry-of *the (x) industry in (y) ,* (Oil, Russia)	0.70	C=0.90
island-in *, (x) island , (y) ,* (Bathurst, Canada)	0.98	C=0.55
president-of *president (x) of (y) has* (Bush, USA)	0.86	C=0.51
political-position-in *former (x) of (y) face* (President, Ecuador)	0.81	C=0.75
political-party-of *the (x) party of (y) ,* (Labour, England)	0.91	C=0.53
festival-of *the (x) festival, (y) ,* (Tanabata, Japan)	0.90	C=0.78
religious-denomination-of *the (x) church in (y) ,* (Christian, Rome)	0.80	C=0.62

Table 1: Results on seed { *France, Angola* }.

Relationship *Sample pattern* (Sample pair)	Prec.	Cov
region-found-in *best (x) fishing in (y) .* (Walleye, Canada)	0.83	0.80
sea-found-in *of (x) catches in the (y) sea* (Shark, Adriatic)	0.82	0.64
lake-found-in *lake (y) is famous for (x) ,* (Marion, Catfish)	0.79	0.51
habitat-of *, (x) and other (y) fish* (Menhaden, Saltwater)	0.78	0.92
also-called *. (y) , also called (x) ,* (Lemonfish, Ling)	0.91	0.58
eats *the (x) eats the (y) and* (Perch, Minnow)	0.90	0.85
color-of *the (x) was (y) color* (Shark, Gray)	0.95	0.85
used-for-food *catch (x) – best for (y) or* (Bluefish, Sashimi)	0.80	0.53
in-family *the (x) family , includes (y) ,* (Salmonid, Trout)	0.95	0.60

Table 2: Results on seed { *barracud, bluefish* }.

The first stage of the algorithm returned 81 constellation names (77 distinct constellations) as well as 38 other names (consisting mostly of names of individual stars). Using the list of 87 single word constellation names as our gold standard, this gives precision of 0.68 and recall of 0.93.

The second part of the algorithm generated a set of ten binary relations. Of these, one concerned travel and entertainment (constellations are quite popular as names of hotels and lounges) and another three were not interesting. Apparently, the requirement that half the constellations appear in a relation limited the number of viable relations since many constellations are quite obscure. The six interesting relations are shown in Table 3 along with precision and coverage.

7 Discussion

In this paper we have addressed a novel type of problem: given a specific concept, discover in fully unsupervised fashion, a range of relations in which it participates. This can be extremely useful for studying and researching a particular concept or field of study.

As others have shown as well, two concept words can be sufficient to generate almost the entire class to which the words belong when the class is well-defined. With the method presented in this paper, using no further user-provided information, we can, for a given concept, automatically generate a diverse collection of binary relations on this concept. These relations need not be pre-specified in any way. Results on the three domains we considered indicate that, taken as an aggregate, the relations that are generated for a given domain paint a rather clear picture of the range of information pertinent to that domain.

Moreover, all this was done using standard search engine methods on the web. No language-dependent tools were used (not even stemming); in fact, we reproduced many of our results using Google in Russian.

The method depends on a number of numerical parameters that control the subtle tradeoff between quantity and quality of generated relations. There is certainly much room for tuning of these parameters.

The concept and target words used in this paper are single words. Extending this to multiple-word expressions would substantially contribute to the applicability of our results.

In this research we effectively disregard many relationships of an all-to-all nature. However, such relationships can often be very useful for ontology construction, since in many cases they introduce strong connections between two different concepts. Thus, for fish we discovered that one of the all-to-all relationships captures a precise set of fish body parts, and another captures swimming verbs. Such relations introduce strong and distinct connections between the concept of fish and the concepts of fish-body-parts and swimming. Such connections may be extremely useful for ontology construction.

Relationship *Sample pattern* (Sample pair)	Prec.	Cov
nearby-constellation *constellation (x), near (y),* (Auriga, Taurus)	0.87	0.70
star-in *star (x) in (y) is* (Antares , Scorpius)	0.82	0.76
shape-of *, (x) is depicted as (y).* (Lacerta, Lizard)	0.90	0.55
abbreviated-as *. (x) abbr (y),* (Hidra, Hya)	0.93	0.90

Adding Noun Phrase Structure to the Penn Treebank

David Vadas and **James R. Curran**
School of Information Technologies
University of Sydney
NSW 2006, Australia
{dvadas1, james}@it.usyd.edu.au

Abstract

The Penn Treebank does not annotate within base noun phrases (NPs), committing only to flat structures that ignore the complexity of English NPs. This means that tools trained on Treebank data cannot learn the correct internal structure of NPs.

This paper details the process of adding gold-standard bracketing within each noun phrase in the Penn Treebank. We then examine the consistency and reliability of our annotations. Finally, we use this resource to determine NP structure using several statistical approaches, thus demonstrating the utility of the corpus. This adds detail to the Penn Treebank that is necessary for many NLP applications.

1 Introduction

The Penn Treebank (Marcus et al., 1993) is perhaps the most influential resource in Natural Language Processing (NLP). It is used as a standard training and evaluation corpus in many syntactic analysis tasks, ranging from part of speech (POS) tagging and chunking, to full parsing.

Unfortunately, the Penn Treebank does not annotate the internal structure of base noun phrases, instead leaving them flat. This significantly simplified and sped up the manual annotation process.

Therefore, any system trained on Penn Treebank data will be unable to model the syntactic and semantic structure inside base-NPs.

The following NP is an example of the flat structure of base-NPs within the Penn Treebank:

```
(NP (NNP Air) (NNP Force) (NN contract))
```

Air Force is a specific entity and should form a separate constituent underneath the NP, as in our new annotation scheme:

```
(NP
  (NML (NNP Air) (NNP Force))
  (NN contract))
```

We use NML to specify that *Air Force* together is a nominal modifier of *contract*. Adding this annotation better represents the true syntactic and semantic structure, which will improve the performance of downstream NLP systems.

Our main contribution is a gold-standard labelled bracketing for every ambiguous noun phrase in the Penn Treebank. We describe the annotation guidelines and process, including the use of named entity data to improve annotation quality. We check the correctness of the corpus by measuring inter-annotator agreement, by reannotating the first section, and by comparing against the sub-NP structure in DepBank (King et al., 2003).

We also give an analysis of our extended Treebank, quantifying how much structure we have added, and how it is distributed across NPs. Finally, we test the utility of the extended Treebank for training statistical models on two tasks: NP bracketing (Lauer, 1995; Nakov and Hearst, 2005) and full parsing (Collins, 1999).

This new resource will allow any system or annotated corpus developed from the Penn Treebank, to represent noun phrase structure more accurately.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 240–247,
Prague, Czech Republic, June 2007.

2 Motivation

Many approaches to identifying base noun phrases have been explored as part of chunking (Ramshaw and Marcus, 1995), but determining sub-NP structure is rarely addressed. We could use multi-word expressions (MWEs) to identify some structure. For example, knowing *stock market* is a MWE may help bracket *stock market prices* correctly, and Named Entities (NEs) can be used the same way. However, this only resolves NPs dominating MWEs or NEs.

Understanding base-NP structure is important, since otherwise parsers will propose nonsensical noun phrases like *Force contract* by default and pass them onto downstream components. For example, Question Answering (QA) systems need to supply an NP as the answer to a factoid question, often using a parser to identify candidate NPs to return to the user. If the parser never generates the correct sub-NP structure, then the system may return a nonsensical answer even though the correct dominating noun phrase has been found.

Base-NP structure is also important for annotated data derived from the Penn Treebank. For instance, CCGbank (Hockenmaier, 2003) was created by semi-automatically converting the Treebank phrase structure to Combinatory Categorial Grammar (CCG) (Steedman, 2000) derivations. Since CCG derivations are binary branching, they cannot directly represent the flat structure of the Penn Treebank base-NPs.

Without the correct bracketing in the Treebank, strictly right-branching trees were created for all base-NPs. This has an unwelcome effect when conjunctions occur within an NP (Figure 1). An additional grammar rule is needed just to get a parse, but it is still not correct (Hockenmaier, 2003, p. 64). The awkward conversion results in bracketing (a) which should be (b):

(a) *(consumer ((electronics) and (appliances (retailing chain))))*

(b) *((((consumer electronics) and appliances) retailing) chain)*

We have previously experimented with using NEs to improve parsing performance on CCGbank. Due to the mis-alignment of NEs and right-branching NPs, the increase in performance was negligible.

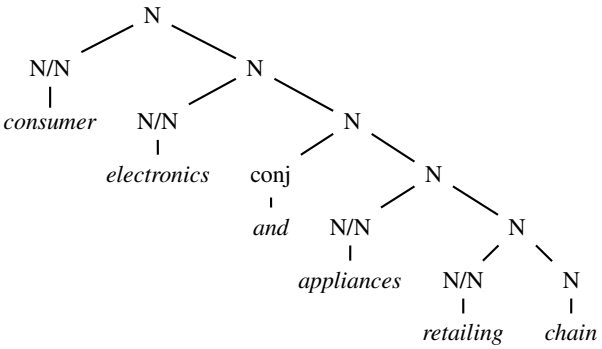

Figure 1: CCG derivation from Hockenmaier (2003)

3 Background

The NP bracketing task has often been posed in terms of choosing between the left or right branching structure of three word noun compounds:

(a) *(world (oil prices))* – Right-branching

(b) *((crude oil) prices)* – Left-branching

Most approaches to the problem use unsupervised methods, based on competing association strength between two of the words in the compound (Marcus, 1980, p. 253). There are two possible models to choose from: dependency or adjacency. The *dependency model* compares the association between words 1-2 to words 1-3, while the *adjacency model* compares words 1-2 to words 2-3.

Lauer (1995) has demonstrated superior performance of the dependency model using a test set of 244 (216 unique) noun compounds drawn from Grolier's encyclopedia. This data has been used to evaluate most research since. He uses Roget's thesaurus to smooth words into semantic classes, and then calculates association between classes based on their counts in a "training set" also drawn from Grolier's. He achieves 80.7% accuracy using POS tags to indentify bigrams in the training set.

Lapata and Keller (2004) derive estimates from web counts, and only compare at a lexical level, achieving 78.7% accuracy. Nakov and Hearst (2005) also use web counts, but incorporate additional counts from several variations on simple bigram queries, including queries for the pairs of words concatenated or joined by a hyphen. This results in an impressive 89.3% accuracy.

There have also been attempts to solve this task using supervised methods, even though the lack of gold-standard data makes this difficult. Girju et al.

(2005) draw a training set from raw WSJ text and use it to train a decision tree classifier achieving 73.1% accuracy. When they shuffled their data with Lauer's to create a new test and training split, their accuracy increased to 83.1% which may be a result of the ∼10% duplication in Lauer's test set.

We have created a new NP bracketing data set from our extended Treebank by extracting all rightmost three noun sequences from base-NPs. Our initial experiments are presented in Section 6.1.

4 Corpus Creation

According to Marcus et al. (1993), asking annotators to markup base-NP structure significantly reduced annotation speed, and for this reason base-NPs were left flat. The bracketing guidelines (Bies et al., 1995) also mention the considerable difficulty of identifying the correct scope for nominal modifiers. We found however, that while there are certainly difficult cases, the vast majority are quite simple and can be annotated reliably. Our annotation philosophy can be summarised as:

1. most cases are easy and fit a common pattern;
2. prefer the implicit right-branching structure for difficult decisions. Finance jargon was a common source of these;
3. mark very difficult to bracket NPs and discuss with other annotators later;

During this process we identified numerous cases that require a more sophisticated annotation scheme. There are genuine flat cases, primarily names like *John A. Smith*, that we would like to distinguish from implicitly right-branching NPs in the next version of the corpus. Although our scheme is still developing, we believe that the current annotation is already useful for statistical modelling, and we demonstrate this empirically in Section 6.

4.1 Annotation Process

Our annotation guidelines[1] are based on those developed for annotating full sub-NP structure in the biomedical domain (Kulick et al., 2004). The annotation guidelines for this biomedical corpus (an addendum to the Penn Treebank guidelines) introduce the use of NML nodes to mark internal NP structure.

In summary, our guidelines leave right-branching structures untouched, and insert labelled brackets around left-branching structures. The label of the newly created constituent is NML or JJP, depending on whether its head is a noun or an adjective. We also chose not to alter the existing Penn Treebank annotation, even though the annotators found many errors during the annotation process. We wanted to keep our extended Treebank as similar to the original as possible, so that they remain comparable.

We developed a bracketing tool, which identifies ambiguous NPs and presents them to the user for disambiguation. An ambiguous NP is any (possibly non-base) NP with three or more contiguous children that are either single words or another NP. Certain common patterns, such as three words beginning with a determiner, are unambiguous, and were filtered out. The annotator is also shown the entire sentence surrounding the ambiguous NP.

The bracketing tool often suggests a bracketing using rules based mostly on named entity tags, which are drawn from the BBN corpus (Weischedel and Brunstein, 2005). For example, since *Air Force* is given ORG tags, the tool suggests that they be bracketed together first. Other suggestions come from previous bracketings of the same words, which helps to keep the annotator consistent.

Two post processes were carried out to increase annotation consistency and correctness. 915 difficult NPs were marked by the annotator and were then discussed with two other experts. Secondly, certain phrases that occurred numerous times and were non-trivial to bracket, e.g. *London Interbank Offered Rate*, were identified. An extra pass was made through the corpus, ensuring that every instance of these phrases was bracketed consistently.

4.2 Annotation Time

Annotation initially took over 9 hours per section of the Treebank. However, with practice this was reduced to about 3 hours per section. Each section contains around 2500 ambiguous NPs, i.e. annotating took approximately 5 seconds per NP. Most NPs require no bracketing, or fit into a standard pattern which the annotator soon becomes accustomed to, hence the task can be performed quite quickly.

For the original bracketing of the Treebank, annotators performed at 375–475 words per hour after a

[1] The guidelines and corpus are available on our webpages.

	PREC.	RECALL	F-SCORE
Brackets	89.17	87.50	88.33
Dependencies	96.40	96.40	96.40
Brackets, revised	97.56	98.03	97.79
Dependencies, revised	99.27	99.27	99.27

Table 1: Agreement between annotators

few weeks, and increased to about 1000 words per hour after gaining more experience (Marcus et al., 1993). For our annotation process, counting each word in every NP shown, our speed was around 800 words per hour. This figure is not unexpected, as the task was not large enough to get more than a month's experience, and there is less structure to annotate.

5 Corpus Analysis

5.1 Inter-annotator Agreement

The annotation was performed by the first author. A second Computational Linguistics PhD student also annotated Section 23, allowing inter-annotator agreement, and the reliability of the annotations, to be measured. This also maximised the quality of the section used for parser testing.

We measured the proportion of matching brackets and dependencies between annotators, shown in Table 1, both before and after they discussed cases of disagreement and revised their annotations. The number of dependencies is fixed by the length of the NP, so the dependency precision and recall are the same. Counting matched brackets is a harsher evaluation, as there are many NPs that both annotators agree should have no additional bracketing, which are not taken into account by the metric.

The disagreements occurred for a small number of repeated instances, such as this case:

```
(NP                          (NP (NNP Goldman)
  (NML (NNP Goldman)           (, ,)
    (, ,)                      (NNP Sachs)
    (NNP Sachs) )              (CC &) (NNP Co) )
  (CC &) (NNP Co) )
```

The first annotator felt that `Goldman , Sachs` should form their own NML constituent, while the second annotator did not.

We can also look at exact matching on NPs, where the annotators originally agreed in 2667 of 2908 cases (91.71%), and after revision, in 2864 of 2907 cases (98.52%). These results demonstrate that high agreement rates are achievable for these annotations.

	MATCHED	TOTAL	%
By dependency	1409 (1315)	1479	95.27 (88.91)
By noun phrase	562 (489)	626	89.78 (78.12)
By dependency, only annotated NPs	578 (543)	627	92.19 (86.60)
By noun phrase, only annotated NPs	186 (162)	229	81.22 (70.74)

Table 2: Agreement with DepBank

5.2 DepBank Agreement

Another approach to measuring annotator reliability is to compare with an independently annotated corpus on the same text. We used the PARC700 Dependency Bank (King et al., 2003) which consists of 700 Section 23 sentences annotated with labelled dependencies. We use the Briscoe and Carroll (2006) version of DepBank, a 560 sentence subset used to evaluate the RASP parser.

Some translation is required to compare our brackets to DepBank dependencies. We map the brackets to dependencies by finding the head of the NP, using the Collins (1999) head finding rules, and then creating a dependency between each other child's head and this head. This does not work perfectly, and mismatches occur because of which dependencies DepBank marks explicitly, and how it chooses heads. The errors are investigated manually to determine their cause.

The results are shown in Table 2, with the number of agreements before manual checking shown in parentheses. Once again the dependency numbers are higher than those at the NP level. Similarly, when we only look at cases where we have inserted some annotations, we are looking at more difficult cases and the score is not as high.

The results of this analysis are quite positive. Over half of the disagreements that occur (in either measure) are caused by how company names are bracketed. While we have always separated the company name from post-modifiers such as *Corp* and *Inc*, DepBank does not in most cases. These results show that consistently and correctly bracketing noun phrase structure is possible, and that inter-annotator agreement is at an acceptable level.

5.3 Corpus Composition and Consistency

Looking at the entire Penn Treebank corpus, the annotation tool finds 60959 ambiguous NPs out of the 432639 NPs in the corpus (14.09%). 22851 of

LEVEL	COUNT	POS TAGS	EXAMPLE
NP	1073	JJ JJ NNS	big red cars
	1581	DT JJ NN NN	a high interest rate
	1693	JJ NN NNS	high interest rates
	3557	NNP NNP NNP	John A. Smith
NML	1468	NN NN	(interest rate) rises
	1538	JJ NN	(heavy truck) rentals
	1650	NNP NNP NNP	(A. B. C.) Corp
	8524	NNP NNP	(John Smith) Jr.
JJP	82	JJ JJ	(dark red) car
	114	RB JJ	(very high) rates
	122	JJ CC JJ	(big and red) apples
	160	" JJ "	(" smart ") cars

Table 3: Common POS tag sequences

these (37.49%) had brackets inserted by the annotator. This is as we expect, as the majority of NPs are right-branching. Of the brackets added, 22368 were NML nodes, while 863 were JJP.

To compare, we can count the number of existing NP and ADJP nodes found in the NPs that the bracketing tool presents. We find there are 32772 NP children, and 579 ADJP, which are quite similar numbers to the amount of nodes we have added. From this, we can say that our annotation process has introduced almost as much structural information into NPs as there was in the original Penn Treebank.

Table 3 shows the most common POS tag sequences for NP, NML and JJP nodes. An example is given showing typical words that match the POS tags. For NML and JJP, we also show the words bracketed, as they would appear under an NP node.

We checked the consistency of the annotations by identifying NPs with the same word sequence and checking whether they were always bracketed identically. After the first pass through, there were 360 word sequences with multiple bracketings, which occurred in 1923 NP instances. 489 of these instances differed from the majority case for that sequence, and were probably errors.

The annotator had marked certain difficult and commonly repeating NPs. From this we generated a list of phrases, and then made another pass through the corpus, synchronising all instances that contained one of these phrases. After this, only 150 instances differed from the majority case. Inspecting these remaining inconsistencies showed cases like:

```
(NP-TMP (NML (NNP Nov.) (CD 15))
  (, ,)
  (CD 1999))
```

where we were inconsistent in inserting the NML node because the Penn Treebank sometimes already has the structure annotated under an NP node. Since we do not make changes to existing brackets, we cannot fix these cases. Other inconsistencies are rare, but will be examined and corrected in a future release.

The annotator made a second pass over Section 00 to correct changes made after the beginning of the annotation process. Comparing the two passes can give us some idea of how the annotator changed as he grew more practiced at the task.

We find that the old and new versions are identical in 88.65% of NPs, with labelled precision, recall and F-score being 97.17%, 76.69% and 85.72% respectively. This tells us that there were many brackets originally missed that were added in the second pass. This is not surprising since the main problem with how Section 00 was annotated originally was that company names were not separated from their post-modifier (such as *Corp*). Besides this, it suggests that there is not a great deal of difference between an annotator just learning the task, and one who has had a great deal of experience with it.

5.4 Named Entity Suggestions

We have also evaluated how well the suggestion feature of the annotation tool performs. In particular, we want to determine how useful named entities are in determining the correct bracketing.

We ran the tool over the original corpus, following NE-based suggestions where possible. We find that when evaluated against our annotations, the F-score is 50.71%. We need to look closer at the precision and recall though, as they are quite different. The precision of 93.84% is quite high. However, there are many brackets where the entities do not help at all, and so the recall of this method was only 34.74%. This suggests that a NE feature may help to identify the correct bracketing in one third of cases.

6 Experiments

Having bracketed NPs in the Penn Treebank, we now describe our initial experiments on how this additional level of annotation can be exploited.

6.1 NP Bracketing Data

The obvious first task to consider is noun phrase bracketing itself. We implement a similar system to

CORPUS	# ITEMS	LEFT	RIGHT
Penn Treebank	5582	58.99%	41.01%
Lauer's	244	66.80%	33.20%

Table 4: Comparison of NP bracketing corpora

N-GRAM	MATCH
Unigrams	51.20%
Adjacency bigrams	6.35%
Dependency bigrams	3.85%
All bigrams	5.83%
Trigrams	1.40%

Table 5: Lexical overlap

Lauer (1995), described in Section 3, and report on results from our own data and Lauer's original set.

First, we extracted three word noun sequences from all the ambiguous NPs. If the last three children are nouns, then they became an example in our data set. If there is a NML node containing the first two nouns then it is left-branching, otherwise it is right-branching. Because we are only looking at the right-most part of the NP, we know that we are not extracting any nonsensical items. We also remove all items where the nouns are all part of a named entity to eliminate flat structure cases.

Statistics about the new data set and Lauer's data set are given in Table 4. As can be seen, the Penn Treebank based corpus is significantly larger, and has a more even mix of left and right-branching noun phrases. We also measured the amount of lexical overlap between the two corpora, shown in Table 5. This displays the percentage of n-grams in Lauer's corpus that are also in our corpus. We can clearly see that the two corpora are quite dissimilar, as even on unigrams barely half are shared.

6.2 NP Bracketing Results

With our new data set, we began running experiments similar to those carried out in the literature (Nakov and Hearst, 2005). We implemented both an adjacency and dependency model, and three different association measures: raw counts, bigram probability, and χ^2. We draw our counts from a corpus of n-gram counts calculated over 1 trillion words from the web (Brants and Franz, 2006).

The results from the experiments, on both our and Lauer's data set, are shown in Table 6. Our results

ASSOC. MEASURE	LAUER	PTB
Raw counts, adj.	75.41%	77.46%
Raw counts, dep.	77.05%	68.85%
Probability, adj.	71.31%	76.42%
Probability, dep.	**80.33%**	69.56%
χ^2, adj.	71.31%	**77.93%**
χ^2, dep.	74.59%	68.92%

Table 6: Bracketing task, unsupervised results

FEATURES	LAUER	10-FOLD CROSS
All features	80.74%	**89.91%** (1.04%)
Lexical	71.31%	**84.52%** (1.77%)
n-gram counts	75.41%	82.50% (1.49%)
Probability	72.54%	78.34% (2.11%)
χ^2	75.41%	80.10% (1.71%)
Adjacency model	72.95%	79.52% (1.32%)
Dependency model	**78.69%**	72.86% (1.48%)
Both models	76.23%	79.67% (1.42%)
-Lexical	79.92%	85.72% (0.77%)
-n-gram counts	80.74%	89.11% (1.39%)
-Probability	79.10%	**89.79%** (1.22%)
-χ^2	80.74%	**89.79%** (0.98%)
-Adjacency model	81.56%	89.63% (0.96%)
-Dependency model	81.15%	89.72% (0.86%)
-Both models	**81.97%**	89.63% (0.95%)

Table 7: Bracketing task, supervised results

on Lauer's corpus are similar to those reported previously, with the dependency model outperforming the adjacency model on all measures. The bigram probability scores highest out of all the measures, while the χ^2 score performed the worst.

The results on the new corpus are even more surprising, with the adjacency model outperforming the dependency model by a wide margin. The χ^2 measure gives the highest accuracy, but still only just outperforms the raw counts. Our analysis shows that the good performance of the adjacency model comes from the large number of named entities in the corpus. When we remove all items that have any word as an entity, the results change, and the dependency model is superior. We also suspect that another cause of the unusual results is the different proportions of left and right-branching NPs.

With a large annotated corpus, we can now run supervised NP bracketing experiments. We present two configurations in Table 7: training on our corpus and testing on Lauer's set; and performing 10-fold cross validation using our corpus alone.

The feature set we explore encodes the information we used in the unsupervised experiments. Ta-

	OVERALL			ONLY NML JJP			NOT NML JJP		
	PREC.	RECALL	F-SCORE	PREC.	RECALL	F-SCORE	PREC.	RECALL	F-SCORE
Original	88.93	88.90	88.92	–	–	–	88.93	88.90	88.92
NML and JJP bracketed	88.63	88.29	88.46	77.93	62.93	69.63	88.85	88.93	88.89
Relabelled brackets	88.17	87.88	88.02	91.93	51.38	65.91	87.86	88.65	88.25

Table 8: Parsing performance

ble 7 shows the performance with: all features, followed by the individual features, and finally, after removing individual features.

The feature set includes: lexical features for each n-gram in the noun compound; n-gram counts for unigrams, bigrams and trigrams; raw probability and χ^2 association scores for all three bigrams in the compound; and the adjacency and dependency results for all three association measures. We discretised the non-binary features using an implementation of Fayyad and Irani's (1993) algorithm, and classify using MegaM[2].

The results on Lauer's set demonstrate that the dependency model performs well by itself but not with the other features. In fact, a better result comes from using every feature *except* those from the dependency and adjacency models. It is also impressive how good the performance is, considering the large differences between our data set and Lauer's.

These differences also account for the disparate cross-validation figures. On this data, the lexical features perform the best, which is to be expected given the nature of the corpus. The best model in this case comes from using all the features.

6.3 Collins Parsing

We can also look at the impact of our new annotations upon full statistical parsing. We use Bikel's implementation (Bikel, 2004) of Collins' parser (Collins, 1999) in order to carry out these experiments, using the non-deficient Collins settings. The numbers we give are labelled bracket precision, recall and F-scores for all sentences. Bikel mentions that base-NPs are treated very differently in Collins' parser, and so it will be interesting to observe the results using our new annotations.

Firstly, we compare the parser's performance on the original Penn Treebank and the new NML and JJP bracketed version. Table 8 shows that the new brackets make parsing marginally more difficult overall (by about 0.5% in F-score).

The performance on only the new NML and JJP brackets is not very high. This shows the difficulty of correctly bracketing NPs. Conversely, the figures for all brackets except NML and JJP are only a tiny amount less in our extended corpus. This means that performance for other phrases is hardly changed by the new NP brackets.

We also ran an experiment where the new NML and JJP labels were relabelled as NP and ADJP. These are the labels that would be given if NPs were originally bracketed with the rest of the Penn Treebank. This meant the model would not have to discriminate between two different types of noun and adjective structure. The performance, as shown in Table 8, was even lower with this approach, suggesting that the distinction is larger than we anticipated. On the other hand, the precision on NML and JJP constituents was quite high, so the parser is able to identify at least some of the structure very well.

7 Conclusion

The work presented in this paper is a first step towards accurate representation of noun phrase structure in NLP corpora. There are several distinctions that our annotation currently ignores that we would like to identify correctly in the future. Firstly, NPs with genuine flat structure are currently treated as implicitly right branching. Secondly, there is still ambiguity in determining the head of a noun phrase. Although Collins' head finding rules work in most NPs, there are cases such as *IBM Australia* where the head is not the right-most noun. Similarly, apposition is very common in the Penn Treebank, in NPs such as *John Smith , IBM president*. We would like to be able to identify these multi-head constructs properly, rather than simply treating them as a single entity (or even worse, as two different entities).

Having the correct NP structure also means that we can now represent the true structure in CCGbank, one of the problems we described earlier. Transfer-

[2]Available at http://www.cs.utah.edu/ hal/megam/

ring our annotations should be fairly simple, requiring just a few changes to how NPs are treated in the current translation process.

The addition of consistent, gold-standard, noun phrase structure to a large corpus is a significant achievement. We have shown that the these annotations can be created in a feasible time frame with high inter-annotator agreement of 98.52% (measuring exact NP matches). The new brackets cause only a small drop in parsing performance, and no significant decrease on the existing structure. As NEs were useful for suggesting brackets automatically, we intend to incorporate NE information into statistical parsing models in the future.

Our annotated corpus can improve the performance of any system that relies on NPs from parsers trained on the Penn Treebank. A Collins' parser trained on our corpus is now able to identify sub-NP brackets, making it of use in other NLP systems. QA systems, for example, will be able to exploit internal NP structure. In the future, we will improve the parser's performance on NML and JJP brackets.

We have provided a significantly larger corpus for analysing NP structure than has ever been made available before. This is integrated within perhaps the most influential corpus in NLP. The large number of systems trained on Penn Treebank data can all benefit from the extended resource we have created.

Acknowledgements

We would like to thank Matthew Honnibal, our second annotator, who also helped design the guidelines; Toby Hawker, for implementing the discretiser; Mark Lauer for releasing his data; and the anonymous reviewers for their helpful feedback. This work has been supported by the Australian Research Council under Discovery Projects DP0453131 and DP0665973.

Abstract

A key question facing the parsing community is how to compare parsers which use different grammar formalisms and produce different output. Evaluating a parser on the same resource used to create it can lead to non-comparable accuracy scores and an over-optimistic view of parser performance. In this paper we evaluate a CCG parser on DepBank, and demonstrate the difficulties in converting the parser output into DepBank grammatical relations. In addition we present a method for measuring the effectiveness of the conversion, which provides an upper bound on parsing accuracy. The CCG parser obtains an F-score of 81.9% on labelled dependencies, against an upper bound of 84.8%. We compare the CCG parser against the RASP parser, outperforming RASP by over 5% overall and on the majority of dependency types.

1 Introduction

Parsers have been developed for a variety of grammar formalisms, for example HPSG (Toutanova et al., 2002; Malouf and van Noord, 2004), LFG (Kaplan et al., 2004; Cahill et al., 2004), TAG (Sarkar and Joshi, 2003), CCG (Hockenmaier and Steedman, 2002; Clark and Curran, 2004b), and variants of phrase-structure grammar (Briscoe et al., 2006), including the phrase-structure grammar implicit in the Penn Treebank (Collins, 2003; Charniak, 2000). Different parsers produce different output, for example phrase structure trees (Collins, 2003), dependency trees (Nivre and Scholz, 2004), grammatical relations (Briscoe et al., 2006), and formalism-specific dependencies (Clark and Curran, 2004b). This variety of formalisms and output creates a challenge for parser evaluation.

The majority of parser evaluations have used test sets drawn from the same resource used to develop the parser. This allows the many parsers based on the Penn Treebank, for example, to be meaningfully compared. However, there are two drawbacks to this approach. First, parser evaluations using different resources cannot be compared; for example, the Parseval scores obtained by Penn Treebank parsers cannot be compared with the dependency F-scores obtained by evaluating on the Parc Dependency Bank. Second, using the same resource for development and testing can lead to an over-optimistic view of parser performance.

In this paper we evaluate a CCG parser (Clark and Curran, 2004b) on the Briscoe and Carroll version of DepBank (Briscoe and Carroll, 2006). The CCG parser produces head-dependency relations, so evaluating the parser should simply be a matter of converting the CCG dependencies into those in DepBank. Such conversions have been performed for other parsers, including parsers producing phrase structure output (Kaplan et al., 2004; Preiss, 2003). However, we found that performing such a conversion is a time-consuming and non-trivial task.

The contributions of this paper are as follows. First, we demonstrate the considerable difficulties associated with formalism-independent parser evaluation, highlighting the problems in converting the

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 248–255,
Prague, Czech Republic, June 2007.

output of a parser from one representation to another. Second, we develop a method for measuring how effective the conversion process is, which also provides an upper bound for the performance of the parser, given the conversion process being used; this method can be adapted by other researchers to strengthen their own parser comparisons. And third, we provide the first evaluation of a wide-coverage CCG parser outside of CCGbank, obtaining impressive results on DepBank and outperforming the RASP parser (Briscoe et al., 2006) by over 5% overall and on the majority of dependency types.

2 Previous Work

The most common form of parser evaluation is to apply the Parseval metrics to phrase-structure parsers based on the Penn Treebank, and the highest reported scores are now over 90% (Bod, 2003; Charniak and Johnson, 2005). However, it is unclear whether these high scores accurately reflect the performance of parsers in applications. It has been argued that the Parseval metrics are too forgiving and that phrase structure is not the ideal representation for a gold standard (Carroll et al., 1998). Also, using the same resource for training and testing may result in the parser learning systematic errors which are present in both the training and testing material. An example of this is from CCGbank (Hockenmaier, 2003), where all modifiers in noun-noun compound constructions modify the final noun (because the Penn Treebank, from which CCGbank is derived, does not contain the necessary information to obtain the correct bracketing). Thus there are non-negligible, systematic errors in both the training and testing material, and the CCG parsers are being rewarded for following particular mistakes.

There are parser evaluation suites which have been designed to be formalism-independent and which have been carefully and manually corrected. Carroll et al. (1998) describe such a suite, consisting of sentences taken from the Susanne corpus, annotated with Grammatical Relations (GRs) which specify the syntactic relation between a head and dependent. Thus all that is required to use such a scheme, in theory, is that the parser being evaluated is able to identify heads. A similar resource — the Parc Dependency Bank (DepBank) (King et al., 2003) — has been created using sentences from the Penn Treebank. Briscoe and Carroll (2006) reannotated this resource using their GRs scheme, and used it to evaluate the RASP parser.

Kaplan et al. (2004) compare the Collins (2003) parser with the Parc LFG parser by mapping LFG F-structures and Penn Treebank parses into DepBank dependencies, claiming that the LFG parser is considerably more accurate with only a slight reduction in speed. Preiss (2003) compares the parsers of Collins (2003) and Charniak (2000), the GR finder of Buchholz et al. (1999), and the RASP parser, using the Carroll et al. (1998) gold-standard. The Penn Treebank trees of the Collins and Charniak parsers, and the GRs of the Buchholz parser, are mapped into the required GRs, with the result that the GR finder of Buchholz is the most accurate.

The major weakness of these evaluations is that there is no measure of the difficultly of the conversion process for each of the parsers. Kaplan et al. (2004) clearly invested considerable time and expertise in mapping the output of the Collins parser into the DepBank dependencies, but they also note that "This conversion was relatively straightforward for LFG structures . . . However, a certain amount of skill and intuition was required to provide a fair conversion of the Collins trees". Without some measure of the difficulty — and effectiveness — of the conversion, there remains a suspicion that the Collins parser is being unfairly penalised.

One way of providing such a measure is to convert the original gold standard on which the parser is based and evaluate that against the new gold standard (assuming the two resources are based on the same corpus). In the case of Kaplan et al. (2004), the testing procedure would include running their conversion process on Section 23 of the Penn Treebank and evaluating the output against DepBank. As well as providing some measure of the effectiveness of the conversion, this method would also provide an upper bound for the Collins parser, giving the score that a perfect Penn Treebank parser would obtain on DepBank (given the conversion process).

We perform such an evaluation for the CCG parser, with the surprising result that the upper bound on DepBank is only 84.8%, despite the considerable effort invested in developing the conversion process.

3 The CCG Parser

Clark and Curran (2004b) describes the CCG parser used for the evaluation. The grammar used by the parser is extracted from CCGbank, a CCG version of the Penn Treebank (Hockenmaier, 2003). The grammar consists of 425 lexical categories — expressing subcategorisation information — plus a small number of combinatory rules which combine the categories (Steedman, 2000). A supertagger first assigns lexical categories to the words in a sentence, which are then combined by the parser using the combinatory rules and the CKY algorithm. A log-linear model scores the alternative parses. We use the normal-form model, which assigns probabilities to single derivations based on the normal-form derivations in CCGbank. The features in the model are defined over local parts of the derivation and include word-word dependencies. A packed chart representation allows efficient decoding, with the Viterbi algorithm finding the most probable derivation.

The parser outputs predicate-argument dependencies defined in terms of CCG lexical categories. More formally, a CCG predicate-argument dependency is a 5-tuple: $\langle h_f, f, s, h_a, l \rangle$, where h_f is the lexical item of the lexical category expressing the dependency relation; f is the lexical category; s is the argument slot; h_a is the head word of the argument; and l encodes whether the dependency is long-range. For example, the dependency encoding *company* as the object of *bought* (as in *IBM bought the company*) is represented as follows:

$$\langle \textit{bought}, (S\backslash NP_1)/NP_2, 2, \textit{company}, - \rangle \quad (1)$$

The lexical category $(S\backslash NP_1)/NP_2$ is the category of a transitive verb, with the first argument slot corresponding to the subject, and the second argument slot corresponding to the direct object. The final field indicates the nature of any long-range dependency; in (1) the dependency is local.

The predicate-argument dependencies — including long-range dependencies — are encoded in the lexicon by adding head and dependency annotation to the lexical categories. For example, the expanded category for the control verb *persuade* is $(((S[dcl]_{persuade}\backslash NP_1)/(S[to]_2\backslash NP_X))/NP_{X,3})$. Numerical subscripts on the argument categories represent dependency relations; the head of the final declarative sentence is *persuade*; and the head of the infinitival complement's subject is identified with the head of the object, using the variable *X*, as in standard unification-based accounts of control.

Previous evaluations of CCG parsers have used the predicate-argument dependencies from CCGbank as a test set (Hockenmaier and Steedman, 2002; Clark and Curran, 2004b), with impressive results of over 84% F-score on labelled dependencies. In this paper we reinforce the earlier results with the first evaluation of a CCG parser outside of CCGbank.

4 Dependency Conversion to DepBank

For the gold standard we chose the version of DepBank reannotated by Briscoe and Carroll (2006), consisting of 700 sentences from Section 23 of the Penn Treebank. The B&C scheme is similar to the original DepBank scheme (King et al., 2003), but overall contains less grammatical detail; Briscoe and Carroll (2006) describes the differences. We chose this resource for the following reasons: it is publicly available, allowing other researchers to compare against our results; the GRs making up the annotation share some similarities with the predicate-argument dependencies output by the CCG parser; and we can directly compare our parser against a non-CCG parser, namely the RASP parser. We chose not to use the corpus based on the Susanne corpus (Carroll et al., 1998) because the GRs are less like the CCG dependencies; the corpus is not based on the Penn Treebank, making comparison more difficult because of tokenisation differences, for example; and the latest results for RASP are on DepBank.

The GRs are described in Briscoe and Carroll (2006) and Briscoe et al. (2006). Table 1 lists the GRs used in the evaluation. As an example, the sentence *The parent sold Imperial* produces three GRs: `(det parent The)`, `(ncsubj sold parent _)` and `(dobj sold Imperial)`. Note that some GRs — in this example `ncsubj` — have a *subtype slot*, giving extra information. The subtype slot for `ncsubj` is used to indicate passive subjects, with the null value "_" for active subjects and `obj` for passive subjects. Other subtype slots are discussed in Section 4.2.

The CCG dependencies were transformed into GRs in two stages. The first stage was to create a mapping between the CCG dependencies and the

GR	description
conj	coordinator
aux	auxiliary
det	determiner
ncmod	non-clausal modifier
xmod	unsaturated predicative modifier
cmod	saturated clausal modifier
pmod	PP modifier with a PP complement
ncsubj	non-clausal subject
xsubj	unsaturated predicative subject
csubj	saturated clausal subject
dobj	direct object
obj2	second object
iobj	indirect object
pcomp	PP which is a PP complement
xcomp	unsaturated VP complement
ccomp	saturated clausal complement
ta	textual adjunct delimited by punctuation

Table 1: GRs in B&C's annotation of DepBank

GRs. This involved mapping each argument slot in the 425 lexical categories in the CCG lexicon onto a GR. In the second stage, the GRs created from the parser output were post-processed to correct some of the obvious remaining differences between the CCG and GR representations.

In the process of performing the transformation we encountered a methodological problem: without looking at examples it was difficult to create the mapping and impossible to know whether the two representations were converging. Briscoe et al. (2006) split the 700 sentences in DepBank into a test and development set, but the latter only consists of 140 sentences which was not enough to reliably create the transformation. There are some development files in the RASP release which provide examples of the GRs, which were used when possible, but these only cover a subset of the CCG lexical categories.

Our solution to this problem was to convert the gold standard dependencies from CCGbank into GRs and use these to develop the transformation. So we did inspect the annotation in DepBank, and compared it to the transformed CCG dependencies, but only the *gold-standard* CCG dependencies. Thus the parser output was never used during this process. We also ensured that the dependency mapping and the post processing are general to the GRs scheme and not specific to the test set or parser.

4.1 Mapping the CCG dependencies to GRs

Table 2 gives some examples of the mapping; `%l` indicates the word associated with the lexical category

CCG lexical category	slot	GR
$(S[dcl]\backslash NP_1)/NP_2$	1	`(ncsubj %l %f _)`
$(S[dcl]\backslash NP_1)/NP_2$	2	`(dobj %l %f)`
$(S\backslash NP)/(S\backslash NP)_1$	1	`(ncmod _ %f %l)`
$(NP\backslash NP_1)/NP_2$	1	`(ncmod _ %f %l)`
$(NP\backslash NP_1)/NP_2$	2	`(dobj %l %f)`
$NP[nb]/N_1$	1	`(det %f %l)`
$(NP\backslash NP_1)/(S[pss]\backslash NP)_2$	1	`(xmod _ %f %l)`
$(NP\backslash NP_1)/(S[pss]\backslash NP)_2$	2	`(xcomp _ %l %f)`
$((S\backslash NP)\backslash(S\backslash NP)_1)/S[dcl]_2$	1	`(cmod _ %f %l)`
$((S\backslash NP)\backslash(S\backslash NP)_1)/S[dcl]_2$	2	`(ccomp _ %l %f)`
$((S[dcl]\backslash NP_1)/NP_2)/NP_3$	2	`(obj2 %l %f)`
$(S[dcl]\backslash NP_1)/(S[b]\backslash NP)_2$	2	`(aux %f %l)`

Table 2: Examples of the dependency mapping

and `%f` is the head of the constituent filling the argument slot. Note that the order of `%l` and `%f` varies according to whether the GR represents a complement or modifier, in line with the Briscoe and Carroll annotation. For many of the CCG dependencies, the mapping into GRs is straightforward. For example, the first two rows of Table 2 show the mapping for the transitive verb category $(S[dcl]\backslash NP_1)/NP_2$: argument slot 1 is a non-clausal subject and argument slot 2 is a direct object.

Creating the dependency transformation is more difficult than these examples suggest. The first problem is that the mapping from CCG dependencies to GRs is many-to-many. For example, the transitive verb category $(S[dcl]\backslash NP)/NP$ applies to the copula in sentences like *Imperial Corp. is the parent of Imperial Savings & Loan*. With the default annotation, the relation between *is* and *parent* would be `dobj`, whereas in DepBank the argument of the copula is analysed as an `xcomp`. Table 3 gives some examples of how we attempt to deal with this problem. The constraint in the first example means that, whenever the word associated with the transitive verb category is a form of *be*, the second argument is `xcomp`, otherwise the default case applies (in this case `dobj`). There are a number of categories with similar constraints, checking whether the word associated with the category is a form of *be*.

The second type of constraint, shown in the third line of the table, checks the lexical category of the word filling the argument slot. In this example, if the lexical category of the preposition is PP/NP, then the second argument of $(S[dcl]\backslash NP)/PP$ maps to `iobj`; thus in *The loss stems from several factors* the relation between the verb and preposition is `(iobj stems from)`. If the lexical category of

CCG lexical category	slot	GR	constraint	example
$(S[dcl]\backslash NP_1)/NP_2$	2	(xcomp _ %l %f)	word=be	The parent *is Imperial*
		(dobj %l %f)		The parent *sold Imperial*
$(S[dcl]\backslash NP_1)/PP_2$	2	(iobj %l %f)	cat=PP/NP	The loss *stems from* several factors
		(xcomp _ %l %f)	cat=$PP/(S[ng]\backslash NP)$	The future *depends on* building ties
$(S[dcl]\backslash NP_1)/(S[to]\backslash NP)_2$	2	(xcomp %f %l %k)	cat=$(S[to]\backslash NP)/(S[b]\backslash NP)$	*wants to wean* itself away from

Table 3: Examples of the many-to-many nature of the CCG dependency to GRs mapping, and a ternary GR

the preposition is $PP/(S[ng]\backslash NP)$, then the GR is xcomp; thus in *The future depends on building ties* the relation between the verb and preposition is (xcomp _ depends on). There are a number of CCG dependencies with similar constraints, many of them covering the iobj/xcomp distinction.

The second difficulty is that not all the GRs are binary relations, whereas the CCG dependencies are all binary. The primary example of this is to-infinitival constructions. For example, in the sentence *The company wants to wean itself away from expensive gimmicks*, the CCG parser produces two dependencies relating *wants*, *to* and *wean*, whereas there is only one GR: (xcomp to wants wean). The final row of Table 3 gives an example. We implement this constraint by introducing a %k variable into the GR template which denotes the argument of the category in the constraint column (which, as before, is the lexical category of the word filling the argument slot). In the example, the current category is $(S[dcl]\backslash NP_1)/(S[to]\backslash NP)_2$, which is associated with *wants*; this combines with $(S[to]\backslash NP)/(S[b]\backslash NP)$, associated with *to*; and the argument of $(S[to]\backslash NP)/(S[b]\backslash NP)$ is *wean*. The %k variable allows us to look beyond the arguments of the current category when creating the GRs.

A further difficulty is that the head passing conventions differ between DepBank and CCGbank. By *head passing* we mean the mechanism which determines the heads of constituents and the mechanism by which words become arguments of long-range dependencies. For example, in the sentence *The group said it would consider withholding royalty payments*, the DepBank and CCGbank annotations create a dependency between *said* and the following clause. However, in DepBank the relation is between *said* and *consider*, whereas in CCGbank the relation is between *said* and *would*. We fixed this problem by defining the head of *would consider* to be *consider* rather than *would*, by changing the annotation of all the relevant lexical categories in the CCG lexicon (mainly those creating aux relations).

There are more subject relations in CCGbank than DepBank. In the previous example, CCGbank has a subject relation between *it* and *consider*, and also *it* and *would*, whereas DepBank only has the relation between *it* and *consider*. In practice this means ignoring a number of the subject dependencies output by the CCG parser.

Another example where the dependencies differ is the treatment of relative pronouns. For example, in *Sen. Mitchell, who had proposed the streamlining*, the subject of *proposed* is *Mitchell* in CCGbank but *who* in DepBank. Again, we implemented this change by fixing the head annotation in the lexical categories which apply to relative pronouns.

4.2 Post processing of the GR output

To obtain some idea of whether the schemes were converging, we performed the following oracle experiment. We took the CCG derivations from CCGbank corresponding to the sentences in DepBank, and forced the parser to produce gold-standard derivations, outputting the newly created GRs. Treating the DepBank GRs as a gold-standard, and comparing these with the CCGbank GRs, gave precision and recall scores of only 76.23% and 79.56% respectively (using the RASP evaluation tool). Thus given the current mapping, the perfect CCGbank parser would achieve an F-score of only 77.86% when evaluated against DepBank.

On inspecting the output, it was clear that a number of general rules could be applied to bring the schemes closer together, which was implemented as a post-processing script. The first set of changes deals with coordination. One significant difference between DepBank and CCGbank is the treatment of coordinations as arguments. Consider the example *The president and chief executive officer said the loss stems from several factors.* For both DepBank and the transformed CCGbank there are two conj GRs arising

from the coordination: (conj and president) and (conj and officer). The difference arises in the subject of *said*: in DepBank the subject is *and*: (ncsubj said and _), whereas in CCGbank there are two subjects: (ncsubj said president _) and (ncsubj said officer _). We deal with this difference by replacing any pairs of GRs which differ only in their arguments, and where the arguments are coordinated items, with a single GR containing the coordination term as the argument.

Ampersands are a frequently occurring problem in WSJ text. For example, the CCGbank analysis of *Standard & Poor's index* assigns the lexical category N/N to both *Standard* and *&*, treating them as modifiers of *Poor*, whereas DepBank treats *&* as a coordinating term. We fixed this by creating conj GRs between any *&* and the two words either side; removing the modifier GR between the two words; and replacing any GRs in which the words either side of the *&* are arguments with a single GR in which *&* is the argument.

The ta relation, which identifies text adjuncts delimited by punctuation, is difficult to assign correctly to the parser output. The simple punctuation rules used by the parser do not contain enough information to distinguish between the various cases of ta. Thus the only rule we have implemented, which is somewhat specific to the newspaper genre, is to replace GRs of the form (cmod _ say arg) with (ta quote arg say), where say can be any of *say*, *said* or *says*. This rule applies to only a small subset of the ta cases but has high enough precision to be worthy of inclusion.

A common source of error is the distinction between iobj and ncmod, which is not surprising given the difficulty that human annotators have in distinguishing arguments and adjuncts. There are many cases where an argument in DepBank is an adjunct in CCGbank, and vice versa. The only change we have made is to turn all ncmod GRs with *of* as the modifier into iobj GRs (unless the ncmod is a partitive predeterminer). This was found to have high precision and applies to a large number of cases.

There are some dependencies in CCGbank which do not appear in DepBank. Examples include any dependencies in which a punctuation mark is one of the arguments; these were removed from the output.

We attempt to fill the subtype slot for some GRs. The subtype slot specifies additional information about the GR; examples include the value obj in a passive ncsubj, indicating that the subject is an underlying object; the value num in ncmod, indicating a numerical quantity; and prt in ncmod to indicate a verb particle. The passive case is identified as follows: any lexical category which starts $S[pss]\backslash NP$ indicates a passive verb, and we also mark any verbs POS tagged VBN and assigned the lexical category N/N as passive. Both these rules have high precision, but still leave many of the cases in DepBank unidentified. The numerical case is identified using two rules: the num subtype is added if any argument in a GR is assigned the lexical category $N/N[num]$, and if any of the arguments in an ncmod is POS tagged CD. prt is added to an ncmod if the modifiee has any of the verb POS tags and if the modifier has POS tag RP.

The final columns of Table 4 show the accuracy of the transformed gold-standard CCGbank dependencies when compared with DepBank; the simple post-processing rules have increased the F-score from 77.86% to 84.76%. This F-score is an *upper bound* on the performance of the CCG parser.

5 Results

The results in Table 4 were obtained by parsing the sentences from CCGbank corresponding to those in the 560-sentence test set used by Briscoe et al. (2006). We used the CCGbank sentences because these differ in some ways to the original Penn Treebank sentences (there are no quotation marks in CCGbank, for example) and the parser has been trained on CCGbank. Even here we experienced some unexpected difficulties, since some of the tokenisation is different between DepBank and CCGbank and there are some sentences in DepBank which have been significantly shortened compared to the original Penn Treebank sentences. We modified the CCGbank sentences — and the CCGbank analyses since these were used for the oracle experiments — to be as close to the DepBank sentences as possible. All the results were obtained using the RASP evaluation scripts, with the results for the RASP parser taken from Briscoe et al. (2006). The results for CCGbank were obtained using the oracle method described above.

Table 4: Accuracy on DepBank. F-score is the balanced harmonic mean of precision (P) and recall (R): $2PR/(P+R)$. # GRs is the number of GRs in DepBank.

The CCG parser results are based on automatically assigned POS tags, using the Curran and Clark (2003) tagger. The coverage of the parser on DepBank is 100%. For a GR in the parser output to be correct, it has to match the gold-standard GR exactly, including any subtype slots; however, it is possible for a GR to be incorrect at one level but correct at a *subsuming level*.[1] For example, if an ncmod GR is incorrectly labelled with xmod, but is otherwise correct, it will be correct for all levels which subsume both ncmod and xmod, for example mod. The micro-averaged scores are calculated by aggregating the counts for all the relations in the hierarchy, including the subsuming relations; the macro-averaged scores are the mean of the individual scores for each relation (Briscoe et al., 2006).

The results show that the performance of the CCG parser is higher than RASP overall, and also higher on the majority of GR types (especially the more frequent types). RASP uses an unlexicalised parsing model and has not been tuned to newspaper text. On the other hand it has had many years of development; thus it provides a strong baseline for this test set. The overall F-score for the CCG parser, 81.86%, is only 3 points below that for CCGbank, which provides an upper bound for the CCG parser (given the conversion process being used).

[1]The GRs are arranged in a hierarchy, with those in Table 1 at the leaves; a small number of more general GRs subsume these (Briscoe and Carroll, 2006).

6 Conclusion

A contribution of this paper has been to highlight the difficulties associated with cross-formalism parser comparison. Note that the difficulties are not unique to CCG, and many would apply to any cross-formalism comparison, especially with parsers using automatically extracted grammars. Parser evaluation has improved on the original Parseval measures (Carroll et al., 1998), but the challenge remains to develop a representation and evaluation suite which can be easily applied to a wide variety of parsers and formalisms. Despite the difficulties, we have given the first evaluation of a CCG parser outside of CCGbank, outperforming the RASP parser by over 5% overall and on the majority of dependency types.

Can the CCG parser be compared with parsers other than RASP? Briscoe and Carroll (2006) give a rough comparison of RASP with the Parc LFG parser on the different versions of DepBank, obtaining similar results overall, but they acknowledge that the results are not strictly comparable because of the different annotation schemes used. Comparison with Penn Treebank parsers would be difficult because, for many constructions, the Penn Treebank trees and

CCG derivations are different shapes, and reversing the mapping Hockenmaier used to create CCGbank would be very difficult. Hence we challenge other parser developers to map their own parse output into the version of DepBank used here.

One aspect of parser evaluation not covered in this paper is efficiency. The CCG parser took only 22.6 seconds to parse the 560 sentences in DepBank, with the accuracy given earlier. Using a cluster of 18 machines we have also parsed the entire Gigaword corpus in less than five days. Hence, we conclude that accurate, large-scale, linguistically-motivated NLP is now practical with CCG.

Frustratingly Easy Domain Adaptation

Hal Daumé III

Abstract

We describe an approach to domain adaptation that is appropriate exactly in the case when one has enough "target" data to do slightly better than just using only "source" data. Our approach is incredibly simple, easy to implement as a preprocessing step (10 lines of Perl!) and outperforms state-of-the-art approaches on a range of datasets. Moreover, it is trivially extended to a multi-domain adaptation problem, where one has data from a variety of different domains.

1 Introduction

The task of domain adaptation is to develop learning algorithms that can be easily ported from one domain to another—say, from newswire to biomedical documents. This problem is particularly interesting in NLP because we are often in the situation that we have a large collection of labeled data in one "source" domain (say, newswire) but truly desire a model that performs well in a second "target" domain. The approach we present in this paper is based on the idea of transforming the domain adaptation learning problem into a standard supervised learning problem to which any standard algorithm may be applied (eg., maxent, SVMs, etc.). Our transformation is incredibly simple: we augment the feature space of both the source and target data and use the result as input to a standard learning algorithm.

There are roughly two varieties of the domain adaptation problem that have been addressed in the literature: the fully supervised case and the semi-supervised case. The fully supervised case models the following scenario. We have access to a large, annotated corpus of data from a source domain. In addition, we spend a little money to annotate a small corpus in the target domain. We want to leverage both annotated datasets to obtain a model that performs well on the target domain. The semi-supervised case is similar, but instead of having a small annotated target corpus, we have a large but *unannotated* target corpus. In this paper, we focus exclusively on the fully supervised case.

One particularly nice property of our approach is that it is incredibly easy to implement: the Appendix provides a 10 line, 194 character Perl script for performing the complete transformation (available at `http://hal3.name/easyadapt.pl.gz`). In addition to this simplicity, our algorithm performs as well as (or, in some cases, better than) current state of the art techniques.

2 Problem Formalization and Prior Work

To facilitate discussion, we first introduce some notation. Denote by $\mathcal{X}$ the input space (typically either a real vector or a binary vector), and by $\mathcal{Y}$ the output space. We will write $\mathcal{D}^s$ to denote the distribution over source examples and $\mathcal{D}^t$ to denote the distribution over target examples. We assume access to a samples $D^s \sim \mathcal{D}^s$ of source examples from the source domain, and samples $D^t \sim \mathcal{D}^t$ of target examples from the target domain. We will assume that D^s is a collection of N examples and D^t is a collection of M examples (where, typically, $N \gg M$). Our goal is to learn a function $h : \mathcal{X} \to \mathcal{Y}$ with low expected loss with respect to the target domain.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 256–263,
Prague, Czech Republic, June 2007.

For the purposes of discussion, we will suppose that $\mathcal{X} = \mathbb{R}^F$ and that $\mathcal{Y} = \{-1, +1\}$. However, most of the techniques described in this section (as well as our own technique) are more general.

There are several "obvious" ways to attack the domain adaptation problem without developing new algorithms. Many of these are presented and evaluated by Daumé III and Marcu (2006).

The SRCONLY baseline ignores the target data and trains a single model, only on the source data.

The TGTONLY baseline trains a single model only on the target data.

The ALL baseline simply trains a standard learning algorithm on the union of the two datasets.

A potential problem with the ALL baseline is that if $N \gg M$, then D^s may "wash out" any affect D^t might have. We will discuss this problem in more detail later, but one potential solution is to re-weight examples from D^s. For instance, if $N = 10 \times M$, we may weight each example from the source domain by 0.1. The next baseline, WEIGHTED, is exactly this approach, with the weight chosen by cross-validation.

The PRED baseline is based on the idea of using the output of the source classifier as a feature in the target classifier. Specifically, we first train a SRCONLY model. Then we run the SRCONLY model on the target data (training, development and test). We use the predictions made by the SRCONLY model as additional features and train a second model on the target data, augmented with this new feature.

In the LININT baseline, we linearly interpolate the predictions of the SRCONLY and the TGTONLY models. The interpolation parameter is adjusted based on target development data.

These baselines are actually surprisingly difficult to beat. To date, there are two models that have successfully defeated them on a handful of datasets. The first model, which we shall refer to as the PRIOR model, was first introduced by Chelba and Acero (2004). The idea of this model is to use the SRCONLY model as a *prior* on the weights for a second model, trained on the target data. Chelba and Acero (2004) describe this approach within the context of a maximum entropy classifier, but the idea is more general. In particular, for many learning algorithms (maxent, SVMs, averaged perceptron, naive Bayes, etc.), one *regularizes* the weight vector toward zero. In other words, all of these algorithms contain a regularization term on the weights $\boldsymbol{w}$ of the form $\lambda ||\boldsymbol{w}||_2^2$. In the generalized PRIOR model, we simply replace this regularization term with $\lambda ||\boldsymbol{w} - \boldsymbol{w}^s||_2^2$, where $\boldsymbol{w}^s$ is the weight vector learned in the SRCONLY model.[1] In this way, the model trained on the target data "prefers" to have weights that are similar to the weights from the SRCONLY model, unless the data demands otherwise. Daumé III and Marcu (2006) provide empirical evidence on four datasets that the PRIOR model outperforms the baseline approaches.

More recently, Daumé III and Marcu (2006) presented an algorithm for domain adaptation for maximum entropy classifiers. The key idea of their approach is to learn *three* separate models. One model captures "source specific" information, one captures "target specific" information and one captures "general" information. The distinction between these three sorts of information is made on a *per-example* basis. In this way, each source example is considered either source specific or general, while each target example is considered either target specific or general. Daumé III and Marcu (2006) present an EM algorithm for training their model. This model consistently outperformed all the baseline approaches as well as the PRIOR model. Unfortunately, despite the empirical success of this algorithm, it is quite complex to implement and is roughly 10 to 15 times slower than training the PRIOR model.

3 Adaptation by Feature Augmentation

In this section, we describe our approach to the domain adaptation problem. Essentially, all we are going to do is take each feature in the original problem and make three versions of it: a general version, a source-specific version and a target-specific version. The augmented source data will contain only general and source-specific versions. The augmented target

[1] For the maximum entropy, SVM and naive Bayes learning algorithms, modifying the regularization term is simple because it appears explicitly. For the perceptron algorithm, one can obtain an equivalent regularization by performing standard perceptron updates, but using $(\boldsymbol{w} + \boldsymbol{w}^s)^\top \boldsymbol{x}$ for making predictions rather than simply $\boldsymbol{w}^\top \boldsymbol{x}$.

data contains general and target-specific versions.

To state this more formally, first recall the notation from Section 2: $\mathcal{X}$ and $\mathcal{Y}$ are the input and output spaces, respectively; D^s is the source domain data set and D^t is the target domain data set. Suppose for simplicity that $\mathcal{X} = \mathbb{R}^F$ for some $F > 0$. We will define our augmented input space by $\breve{\mathcal{X}} = \mathbb{R}^{3F}$. Then, define mappings $\Phi^s, \Phi^t : \mathcal{X} \to \breve{\mathcal{X}}$ for mapping the source and target data respectively. These are defined by Eq (1), where $\mathbf{0} = \langle 0, 0, \ldots, 0 \rangle \in \mathbb{R}^F$ is the zero vector.

$$\Phi^s(\boldsymbol{x}) = \langle \boldsymbol{x}, \boldsymbol{x}, \mathbf{0} \rangle, \quad \Phi^t(\boldsymbol{x}) = \langle \boldsymbol{x}, \mathbf{0}, \boldsymbol{x} \rangle \tag{1}$$

Before we proceed with a formal analysis of this transformation, let us consider why it might be expected to work. Suppose our task is part of speech tagging, our source domain is the Wall Street Journal and our target domain is a collection of reviews of computer hardware. Here, a word like "the" should be tagged as a determiner in both cases. However, a word like "monitor" is more likely to be a verb in the WSJ and more likely to be a noun in the hardware corpus. Consider a simple case where $\mathcal{X} = \mathbb{R}^2$, where x_1 indicates if the word is "the" and x_2 indicates if the word is "monitor." Then, in $\breve{\mathcal{X}}$, $\breve{x}_1$ and $\breve{x}_2$ will be "general" versions of the two indicator functions, $\breve{x}_3$ and $\breve{x}_4$ will be source-specific versions, and $\breve{x}_5$ and $\breve{x}_6$ will be target-specific versions.

Now, consider what a learning algorithm could do to capture the fact that the appropriate tag for "the" remains constant across the domains, and the tag for "monitor" changes. In this case, the model can set the "determiner" weight vector to something like $\langle 1, 0, 0, 0, 0, 0 \rangle$. This places high weight on the common version of "the" and indicates that "the" is most likely a determiner, regardless of the domain. On the other hand, the weight vector for "noun" might look something like $\langle 0, 0, 0, 0, 0, 1 \rangle$, indicating that the word "monitor" is a noun *only* in the target domain. Similar, the weight vector for "verb" might look like $\langle 0, 0, 0, 1, 0, 0 \rangle$, indicating the "monitor" is a verb *only* in the source domain.

Note that this expansion is actually redundant. We could equally well use $\Phi^s(\boldsymbol{x}) = \langle \boldsymbol{x}, \boldsymbol{x} \rangle$ and $\Phi^t(\boldsymbol{x}) = \langle \boldsymbol{x}, \mathbf{0} \rangle$. However, it turns out that it is easier to analyze the first case, so we will stick with that. Moreover, the first case has the nice property that it is straightforward to generalize it to the multi-domain adaptation problem: when there are more than two domains. In general, for K domains, the augmented feature space will consist of $K+1$ copies of the original feature space.

3.1 A Kernelized Version

It is straightforward to derive a kernelized version of the above approach. We do not exploit this property in our experiments—all are conducted with a simple linear kernel. However, by deriving the kernelized version, we gain some insight into the method. For this reason, we sketch the derivation here.

Suppose that the data points x are drawn from a reproducing kernel Hilbert space $\mathcal{X}$ with kernel $K : \mathcal{X} \times \mathcal{X} \to \mathcal{R}$, with K positive semi-definite. Then, K can be written as the dot product (in $\mathcal{X}$) of two (perhaps infinite-dimensional) vectors: $K(x, x') = \langle \Phi(x), \Phi(x') \rangle_{\mathcal{X}}$. Define Φ^s and Φ^t in terms of Φ, as:

$$\begin{aligned} \Phi^s(x) &= \langle \Phi(x), \Phi(x), \mathbf{0} \rangle \\ \Phi^t(x) &= \langle \Phi(x), \mathbf{0}, \Phi(x) \rangle \end{aligned} \tag{2}$$

Now, we can compute the kernel product between Φ^s and Φ^t in the expanded RKHS by making use of the original kernel K. We denote the expanded kernel by $\breve{K}(x, x')$. It is simplest to first describe $\breve{K}(x, x')$ when x and x' are from the same domain, then analyze the case when the domain differs. When the domain is the same, we get: $\breve{K}(x, x') = \langle \Phi(x), \Phi(x') \rangle_{\mathcal{X}} + \langle \Phi(x), \Phi(x') \rangle_{\mathcal{X}} = 2K(x, x')$. When they are from different domains, we get: $\breve{K}(x, x') = \langle \Phi(x), \Phi(x') \rangle_{\mathcal{X}} = K(x, x')$. Putting this together, we have:

$$\breve{K}(x, x') = \begin{cases} 2K(x, x') & \text{same domain} \\ K(x, x') & \text{diff. domain} \end{cases} \tag{3}$$

This is an intuitively pleasing result. What it says is that—considering the kernel as a measure of similarity—data points from the same domain are "by default" twice as similar as those from different domains. Loosely speaking, this means that data points from the target domain have twice as much influence as source points when making predictions about test target data.

3.2 Analysis

We first note an obvious property of the feature-augmentation approach. Namely, it does not make learning harder, in a minimum Bayes error sense. A more interesting statement would be that it makes learning *easier*, along the lines of the result of (Ben-David et al., 2006) — note, however, that their results are for the "semi-supervised" domain adaptation problem and so do not apply directly. As yet, we do not know a proper formalism in which to analyze the fully supervised case.

It turns out that the feature-augmentation method is remarkably similar to the PRIOR model[2]. Suppose we learn feature-augmented weights in a classifier regularized by an ℓ_2 norm (eg., SVMs, maximum entropy). We can denote by w_s the sum of the "source" and "general" components of the learned weight vector, and by w_t the sum of the "target" and "general" components, so that w_s and w_t are the predictive weights for each task. Then, the regularization condition on the entire weight vector is approximately $||w_g||^2 + ||w_s - w_g||^2 + ||w_t - w_g||^2$, with free parameter w_g which can be chosen to minimize this sum. This leads to a regularizer proportional to $||w_s - w_t||^2$, akin to the PRIOR model.

Given this similarity between the feature-augmentation method and the PRIOR model, one might wonder why we expect our approach to do better. Our belief is that this occurs because we optimize w_s and w_t *jointly*, not sequentially. First, this means that we do not need to cross-validate to estimate good hyperparameters for each task (though in our experiments, we do not use any hyperparameters). Second, and more importantly, this means that the single supervised learning algorithm that is run is allowed to regulate the trade-off between source/target and general weights. In the PRIOR model, we are forced to use the prior variance on in the target learning scenario to do this ourselves.

3.3 Multi-domain adaptation

Our formulation is agnostic to the number of "source" domains. In particular, it may be the case that the source data actually falls into a variety of more specific domains. This is simple to account for in our model. In the two-domain case, we expanded the feature space from $\mathbb{R}^F$ to $\mathbb{R}^{3F}$. For a K-domain problem, we simply expand the feature space to $\mathbb{R}^{(K+1)F}$ in the obvious way (the "$+1$" corresponds to the "general domain" while each of the other $1 \ldots K$ correspond to a single task).

[2]Thanks an anonymous reviewer for pointing this out!

4 Results

In this section we describe experimental results on a wide variety of domains. First we describe the tasks, then we present experimental results, and finally we look more closely at a few of the experiments.

4.1 Tasks

All tasks we consider are sequence labeling tasks (either named-entity recognition, shallow parsing or part-of-speech tagging) on the following datasets:

ACE-NER. We use data from the 2005 Automatic Content Extraction task, restricting ourselves to the named-entity recognition task. The 2005 ACE data comes from 5 domains: Broadcast News (bn), Broadcast Conversations (bc), Newswire (nw), Weblog (wl), Usenet (un) and Converstaional Telephone Speech (cts).

CoNLL-NE. Similar to ACE-NER, a named-entity recognition task. The difference is: we use the 2006 ACE data as the source domain and the CoNLL 2003 NER data as the target domain.

PubMed-POS. A part-of-speech tagging problem on PubMed abstracts introduced by Blitzer et al. (2006). There are two domains: the source domain is the WSJ portion of the Penn Treebank and the target domain is PubMed.

CNN-Recap. This is a recapitalization task introduced by Chelba and Acero (2004) and also used by Daumé III and Marcu (2006). The source domain is newswire and the target domain is the output of an ASR system.

Treebank-Chunk. This is a shallow parsing task based on the data from the Penn Treebank. This data comes from a variety of domains: the standard WSJ domain (we use the same data as for CoNLL 2000), the ATIS switchboard domain, and the Brown corpus (which is, itself, assembled from six subdomains).

Treebank-Brown. This is identical to the Treebank-Chunk task, except that we consider all of the Brown corpus to be a single domain.

Table 1: Task statistics; columns are task, domain, size of the training, development and test sets, and the number of unique features in the training set.

In all cases (except for CNN-Recap), we use roughly the same feature set, which has become somewhat standardized: lexical information (words, stems, capitalization, prefixes and suffixes), membership on gazetteers, etc. For the CNN-Recap task, we use identical feature to those used by both Chelba and Acero (2004) and Daumé III and Marcu (2006): the current, previous and next word, and 1-3 letter prefixes and suffixes.

Statistics on the tasks and datasets are in Table 1.

In all cases, we use the SEARN algorithm for solving the sequence labeling problem (Daumé III et al., 2007) with an underlying averaged perceptron classifier; implementation due to (Daumé III, 2004). For structural features, we make a second-order Markov assumption and only place a bias feature on the transitions. For simplicity, we optimize and report only on label accuracy (but require that our outputs be parsimonious: we do not allow "I-NP" to follow "B-PP," for instance). We do this for three reasons. First, our focus in this work is on building better learning algorithms and introducing a more complicated measure only serves to mask these effects. Second, it is arguable that a measure like F_1 is inappropriate for chunking tasks (Manning, 2006). Third, we can easily compute statistical significance over accuracies using McNemar's test.

4.2 Experimental Results

The full—somewhat daunting—table of results is presented in Table 2. The first two columns specify the task and domain. For the tasks with only a single source and target, we simply report results on the target. For the multi-domain adaptation tasks, we report results for each setting of the target (where all other data-sets are used as different "source" domains). The next set of eight columns are the *error rates* for the task, using one of the different techniques ("AUGMENT" is our proposed technique). For each row, the error rate of the best performing technique is bolded (as are all techniques whose performance is not statistically significantly different at the 95% level). The "T<S" column is contains a "+" whenever TGTONLY outperforms SRCONLY (this will become important shortly). The final column indicates when AUGMENT comes in first.[3]

There are several trends to note in the results. Excluding for a moment the "br-*" domains on the Treebank-Chunk task, our technique always performs best. Still excluding "br-*", the clear second-place contestant is the PRIOR model, a finding consistent with prior research. When we repeat the Treebank-Chunk task, but lumping all of the "br-*" data together into a single "brown" domain, the story reverts to what we expected before: our algorithm performs best, followed by the PRIOR method.

Importantly, this simple story breaks down on the Treebank-Chunk task for the eight sections of the Brown corpus. For these, our AUGMENT technique performs rather poorly. Moreover, there is no clear winning approach on this task. Our hypothesis is that the common feature of these examples is that these are exactly the tasks for which SRCONLY outperforms TGTONLY (with one exception: CoNLL). This seems like a plausible explanation, since it implies that the source and target domains may not be that different. If the domains are so similar that a large amount of source data outperforms a small amount of target data, then it is unlikely that blow-

[3]One advantage of using the averaged perceptron for all experiments is that the only tunable hyperparameter is the number of iterations. In all cases, we run 20 iterations and choose the one with the lowest error on development data.

ing up the feature space will help.

We additionally ran the MEGAM model (Daumé III and Marcu, 2006) on these data (though not in the multi-conditional case; for this, we considered the single source as the union of all sources). The results are not displayed in Table 2 to save space. For the majority of results, MEGAM performed roughly comparably to the best of the systems in the table. In particular, it was not statistically significantly different that AUGMENT on: ACE-NER, CoNLL, PubMed, Treebank-chunk-wsj, Treebank-chunk-swbd3, CNN and Treebank-brown. It did outperform AUGMENT on the Treebank-chunk on the Treebank-chunk-br-* data sets, but only outperformed the best other model on these data sets for br-cg, br-cm and br-cp. However, despite its advantages on these data sets, it was quite significantly slower to train: a single run required about ten times longer than any of the other models (including AUGMENT), and also required five-to-ten iterations of cross-validation to tune its hyperparameters so as to achieve these results.

4.3 Model Introspection

One explanation of our model's improved performance is simply that by augmenting the feature space, we are creating a more powerful model. While this may be a partial explanation, here we show that what the model learns about the various domains actually makes some plausible sense.

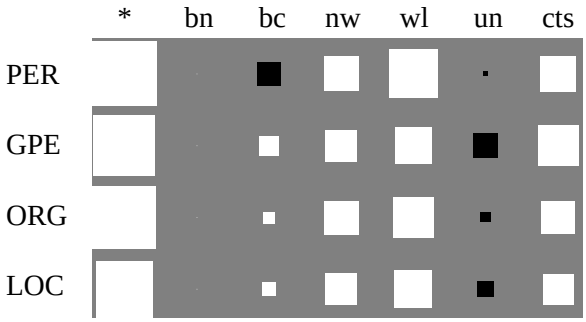

Figure 1: Hinton diagram for feature /Aa+/ at current position.

We perform this analysis only on the ACE-NER data by looking specifically at the learned weights. That is, for any given feature f, there will be seven versions of f: one corresponding to the "cross-domain" f and seven corresponding to each domain. We visualize these weights, using Hinton diagrams, to see how the weights vary across domains.

For example, consider the feature "current word has an initial capital letter and is then followed by one or more lower-case letters." This feature is presumably useless for data that lacks capitalization information, but potentially quite useful for other domains. In Figure 1 we shown a Hinton diagram for this figure. Each column in this figure correspond to a domain (the top row is the "general domain").

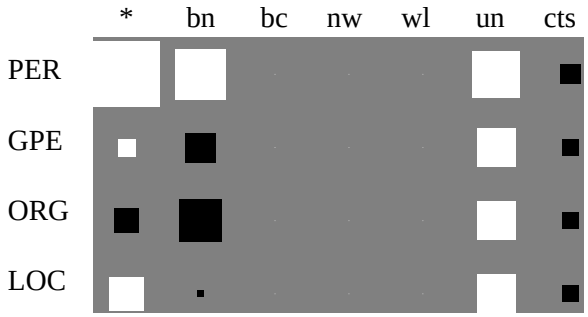

Figure 2: Hinton diagram for feature /bush/ at current position.

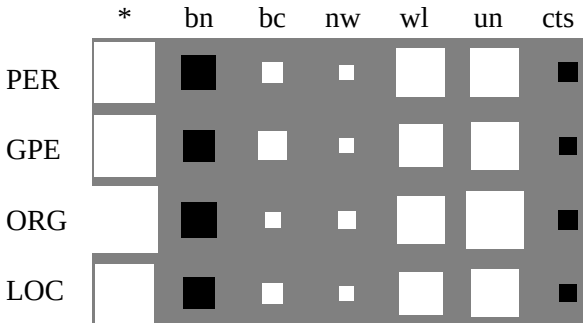

Figure 3: Hinton diagram for feature /the/ at current position.

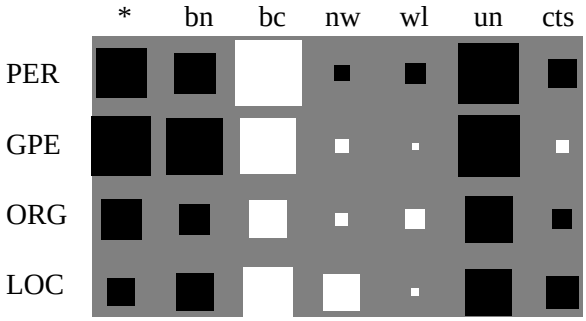

Figure 4: Hinton diagram for feature /the/ at previous position.

Each row corresponds to a class.[4] Black boxes correspond to negative weights and white boxes correspond to positive weights. The size of the box depicts the absolute value of the weight.

As we can see from Figure 1, the /Aa+/ feature is a very good indicator of entity-hood (it's value is strongly positive for all four entity classes), regardless of domain (i.e., for the "*" domain). The lack of boxes in the "bn" column means that, beyond the settings in "*", the broadcast news is agnostic with respect to this feature. This makes sense: there is no capitalization in broadcast news domain, so there would be no sense is setting these weights to anything by zero. The usenet column is filled with negative weights. While this may seem strange, it is due to the fact that many email addresses and URLs match this pattern, but are not entities.

Figure 2 depicts a similar figure for the feature "word is 'bush' at the current position" (this figure is case sensitive).[5] These weights are somewhat harder to interpret. What is happening is that "by default" the word "bush" is going to be a person—this is because it rarely appears referring to a plant and so even in the capitalized domains like broadcast conversations, if it appears at all, it is a person. The exception is that in the conversations data, people *do* actually talk about bushes as plants, and so the weights are set accordingly. The weights are high in the usenet domain because people tend to talk about the president without capitalizing his name.

Figure 3 presents the Hinton diagram for the feature "word at the current position is 'the"' (again, case-sensitive). In general, it appears, "the" is a common word in entities in all domain except for broadcast news and conversations. The exceptions are broadcast news and conversations. These exceptions crop up because of the capitalization issue.

In Figure 4, we show the diagram for the feature "previous word is 'the'." The only domain for which this is a good feature of entity-hood is broadcast conversations (to a much lesser extent, newswire). This occurs because of four phrases very common in the broadcast conversations and rare elsewhere: "the Iraqi people" ("Iraqi" is a GPE), "the Pentagon" (an ORG), "the Bush (cabinet|advisors|...)" (PER), and "the South" (LOC).

Finally, Figure 5 shows the Hinton diagram for the feature "the current word is on a list of common names" (this feature is case-*in*sensitive). All around, this is a good feature for picking out people and nothing else. The two exceptions are: it is also a good feature for other entity types for broadcast

[4]Technically there are many more classes than are shown here. We do not depict the smallest classes, and have merged the "Begin-*" and "In-*" weights for each entity type.

[5]The scale of weights across features is *not* comparable, so do not try to compare Figure 1 with Figure 2.

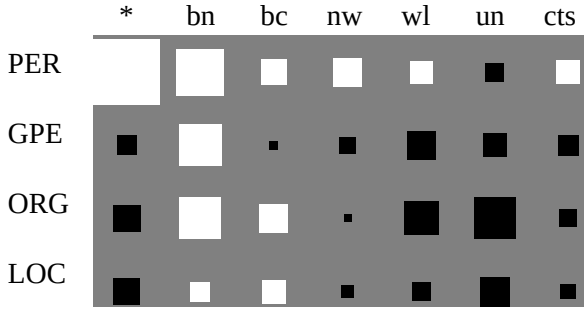

Figure 5: Hinton diagram for membership on a list of names at current position.

news and it is not quite so good for people in usenet. The first is easily explained: in broadcast news, it is very common to refer to countries and organizations by the name of their respective leaders. This is essentially a metonymy issue, but as the data is annotated, these are marked by their true referent. For usenet, it is because the list of names comes from news data, but usenet names are more diverse.

In general, the weights depicte for these features make some intuitive sense (in as much as weights for any learned algorithm make intuitive sense). It is particularly interesting to note that while there are some regularities to the patterns in the five diagrams, it is definitely *not* the case that there are, eg., two domains that behave identically across all features. This supports the hypothesis that the reason our algorithm works so well on this data is because the domains are actually quite well separated.

5 Discussion

In this paper we have described an *incredibly* simple approach to domain adaptation that—under a common and easy-to-verify condition—outperforms previous approaches. While it is somewhat frustrating that something so simple does so well, it is perhaps not surprising. By augmenting the feature space, we are essentially forcing the learning algorithm to do the adaptation for us. Good supervised learning algorithms have been developed over decades, and so we are essentially just leveraging all that previous work. Our hope is that this approach is so simple that it can be used for many more real-world tasks than we have presented here with little effort. Finally, it is very interesting to note that using our method, shallow parsing error rate on the CoNLL section of the treebank improves from 5.35 to 5.11. While this improvement is small, it is real, and may carry over to full parsing. The most important avenue of future work is to develop a formal framework under which we can analyze this (and other supervised domain adaptation models) theoretically. Currently our results only state that this augmentation procedure doesn't make the learning harder — we would like to know that it actually makes it easier. An additional future direction is to explore the kernelization interpretation further: why should we use 2 as the "similarity" between domains—we could introduce a hyperparamter α that indicates the similarity between domains and could be tuned via cross-validation.

Acknowledgments. We thank the three anonymous reviewers, as well as Ryan McDonald and John Blitzer for very helpful comments and insights.

Abstract

Domain adaptation is an important problem in natural language processing (NLP) due to the lack of labeled data in novel domains. In this paper, we study the domain adaptation problem from the instance weighting perspective. We formally analyze and characterize the domain adaptation problem from a distributional view, and show that there are two distinct needs for adaptation, corresponding to the different distributions of instances and classification functions in the source and the target domains. We then propose a general instance weighting framework for domain adaptation. Our empirical results on three NLP tasks show that incorporating and exploiting more information from the target domain through instance weighting is effective.

1 Introduction

Many natural language processing (NLP) problems such as part-of-speech (POS) tagging, named entity (NE) recognition, relation extraction, and semantic role labeling, are currently solved by supervised learning from manually labeled data. A bottleneck problem with this supervised learning approach is the lack of annotated data. As a special case, we often face the situation where we have a sufficient amount of labeled data in one domain, but have little or no labeled data in another related domain which we are interested in. We thus face the *domain adaptation* problem. Following (Blitzer et al., 2006), we call the first the *source domain*, and the second the *target domain*.

The domain adaptation problem is commonly encountered in NLP. For example, in POS tagging, the source domain may be tagged WSJ articles, and the target domain may be scientific literature that contains scientific terminology. In NE recognition, the source domain may be annotated news articles, and the target domain may be personal blogs. Another example is personalized spam filtering, where we may have many labeled spam and ham emails from publicly available sources, but we need to adapt the learned spam filter to an individual user's inbox because the user has her own, and presumably very different, distribution of emails and notion of spams.

Despite the importance of domain adaptation in NLP, currently there are no standard methods for solving this problem. An immediate possible solution is semi-supervised learning, where we simply treat the target instances as unlabeled data but do not distinguish the two domains. However, given that the source data and the target data are from different distributions, we should expect to do better by exploiting the domain difference. Recently there have been some studies addressing domain adaptation from different perspectives (Roark and Bacchiani, 2003; Chelba and Acero, 2004; Florian et al., 2004; Daumé III and Marcu, 2006; Blitzer et al., 2006). However, there have not been many studies that focus on the difference between the instance distributions in the two domains. A detailed discussion on related work is given in Section 5.

In this paper, we study the domain adaptation problem from the instance weighting perspective.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 264–271,
Prague, Czech Republic, June 2007.

In general, the domain adaptation problem arises when the source instances and the target instances are from two different, but related distributions. We formally analyze and characterize the domain adaptation problem from this distributional view. Such an analysis reveals that there are two distinct needs for adaptation, corresponding to the different distributions of instances and the different classification functions in the source and the target domains. Based on this analysis, we propose a general instance weighting method for domain adaptation, which can be regarded as a generalization of an existing approach to semi-supervised learning. The proposed method implements several adaptation heuristics with a unified objective function: (1) removing misleading training instances in the source domain; (2) assigning more weights to labeled target instances than labeled source instances; (3) augmenting training instances with target instances with predicted labels. We evaluated the proposed method with three adaptation problems in NLP, including POS tagging, NE type classification, and spam filtering. The results show that regular semi-supervised and supervised learning methods do not perform as well as our new method, which explicitly captures domain difference. Our results also show that incorporating and exploiting more information from the target domain is much more useful for improving performance than excluding misleading training examples from the source domain.

The rest of the paper is organized as follows. In Section 2, we formally analyze the domain adaptation problem and distinguish two types of adaptation. In Section 3, we then propose a general instance weighting framework for domain adaptation. In Section 4, we present the experiment results. Finally, we compare our framework with related work in Section 5 before we conclude in Section 6.

2 Domain Adaptation

In this section, we define and analyze domain adaptation from a theoretical point of view. We show that the need for domain adaptation arises from two factors, and the solutions are different for each factor. We restrict our attention to those NLP tasks that can be cast into multiclass classification problems, and we only consider discriminative models for classification. Since both are common practice in NLP, our analysis is applicable to many NLP tasks.

Let $\mathcal{X}$ be a feature space we choose to represent the observed instances, and let $\mathcal{Y}$ be the set of class labels. In the standard supervised learning setting, we are given a set of labeled instances $\{(x_i, y_i)\}_{i=1}^N$, where $x_i \in \mathcal{X}$, $y_i \in \mathcal{Y}$, and (x_i, y_i) are drawn from an unknown joint distribution $p(x, y)$. Our goal is to recover this unknown distribution so that we can predict unlabeled instances drawn from the same distribution. In discriminative models, we are only concerned with $p(y|x)$. Following the maximum likelihood estimation framework, we start with a parameterized model family $p(y|x;\theta)$, and then find the best model parameter θ^* that maximizes the expected log likelihood of the data:

$$\theta^* = \arg\max_\theta \int_{\mathcal{X}} \sum_{y\in\mathcal{Y}} p(x,y) \log p(y|x;\theta) dx.$$

Since we do not know the distribution $p(x, y)$, we maximize the empirical log likelihood instead:

$$\begin{aligned}\theta^* &\approx \arg\max_\theta \int_{\mathcal{X}} \sum_{y\in\mathcal{Y}} \tilde{p}(x,y) \log p(y|x;\theta) dx \\ &= \arg\max_\theta \frac{1}{N} \sum_{i=1}^{N} \log p(y_i|x_i;\theta).\end{aligned}$$

Note that since we use the empirical distribution $\tilde{p}(x, y)$ to approximate $p(x, y)$, the estimated θ^* is dependent on $\tilde{p}(x, y)$. In general, as long as we have sufficient labeled data, this approximation is fine because the unlabeled instances we want to classify are from the same $p(x, y)$.

2.1 Two Factors for Domain Adaptation

Let us now turn to the case of domain adaptation where the unlabeled instances we want to classify are from a different distribution than the labeled instances. Let $p_s(x, y)$ and $p_t(x, y)$ be the true underlying distributions for the source and the target domains, respectively. Our general idea is to use $p_s(x, y)$ to approximate $p_t(x, y)$ so that we can exploit the labeled examples in the source domain.

If we factor $p(x, y)$ into $p(x, y) = p(y|x)p(x)$, we can see that $p_t(x, y)$ can deviate from $p_s(x, y)$ in two different ways, corresponding to two different kinds of domain adaptation:

Case 1 (Labeling Adaptation): $p_t(y|x)$ deviates from $p_s(y|x)$ to a certain extent. In this case, it is clear that our estimation of $p_s(y|x)$ from the labeled source domain instances will not be a good estimation of $p_t(y|x)$, and therefore domain adaptation is needed. We refer to this kind of adaptation as *function/labeling adaptation*.

Case 2 (Instance Adaptation): $p_t(y|x)$ is mostly similar to $p_s(y|x)$, but $p_t(x)$ deviates from $p_s(x)$. In this case, it may appear that our estimated $p_s(y|x)$ can still be used in the target domain. However, as we have pointed out, the estimation of $p_s(y|x)$ depends on the empirical distribution $\tilde{p}_s(x, y)$, which deviates from $p_t(x, y)$ due to the deviation of $p_s(x)$ from $p_t(x)$. In general, the estimation of $p_s(y|x)$ would be more influenced by the instances with high $\tilde{p}_s(x, y)$ (i.e., high $\tilde{p}_s(x)$). If $p_t(x)$ is very different from $p_s(x)$, then we should expect $p_t(x, y)$ to be very different from $p_s(x, y)$, and therefore different from $\tilde{p}_s(x, y)$. We thus cannot expect the estimated $p_s(y|x)$ to work well on the regions where $p_t(x, y)$ is high, but $p_s(x, y)$ is low. Therefore, in this case, we still need domain adaptation, which we refer to as *instance adaptation*.

Because the need for domain adaptation arises from two different factors, we need different solutions for each factor.

2.2 Solutions for Labeling Adaptation

If $p_t(y|x)$ deviates from $p_s(y|x)$ to some extent, we have one of the following choices:

Change of representation:

It may be the case that if we change the representation of the instances, i.e., if we choose a feature space $\mathcal{X}'$ different from $\mathcal{X}$, we can bridge the gap between the two distributions $p_s(y|x)$ and $p_t(y|x)$. For example, consider domain adaptive NE recognition where the source domain contains clean newswire data, while the target domain contains broadcast news data that has been transcribed by automatic speech recognition and lacks capitalization. Suppose we use a naive NE tagger that only looks at the word itself. If we consider capitalization, then the instance *Bush* is represented differently from the instance *bush*. In the source domain, $p_s(y = \text{Person}|x = \textit{Bush})$ is high while $p_s(y = \text{Person}|x = \textit{bush})$ is low, but in the target domain, $p_t(y = \text{Person}|x = \textit{bush})$ is high. If we ignore the capitalization information, then in both domains $p(y = \text{Person}|x = \textit{bush})$ will be high provided that the source domain contains much fewer instances of *bush* than *Bush*.

Adaptation through prior:

When we use a parameterized model $p(y|x; \theta)$ to approximate $p(y|x)$ and estimate θ based on the source domain data, we can place some prior on the model parameter θ so that the estimated distribution $p(y|x; \hat{\theta})$ will be closer to $p_t(y|x)$. Consider again the NE tagging example. If we use capitalization as a feature, in the source domain where capitalization information is available, this feature will be given a large weight in the learned model because it is very useful. If we place a prior on the weight for this feature so that a large weight will be penalized, then we can prevent the learned model from relying too much on this domain specific feature.

Instance pruning:

If we know the instances x for which $p_t(y|x)$ is different from $p_s(y|x)$, we can actively remove these instances from the training data because they are "misleading".

For all the three solutions given above, we need either some prior knowledge about the target domain, or some labeled target domain instances; from only the unlabeled target domain instances, we would not know where and why $p_t(y|x)$ differs from $p_s(y|x)$.

2.3 Solutions for Instance Adaptation

In the case where $p_t(y|x)$ is similar to $p_s(y|x)$, but $p_t(x)$ deviates from $p_s(x)$, we may use the (unlabeled) target domain instances to bias the estimate of $p_s(x)$ toward a better approximation of $p_t(x)$, and thus achieve domain adaptation. We explain the idea below.

Our goal is to obtain a good estimate of θ_t^* that is optimized according to the *target* domain distribution $p_t(x, y)$. The exact objective function is thus

$$\begin{aligned}\theta_t^* &= \arg\max_\theta \int_{\mathcal{X}} \sum_{y\in\mathcal{Y}} p_t(x, y) \log p(y|x; \theta) dx \\ &= \arg\max_\theta \int_{\mathcal{X}} p_t(x) \sum_{y\in\mathcal{Y}} p_t(y|x) \log p(y|x; \theta) dx.\end{aligned}$$

Our idea of domain adaptation is to exploit the labeled instances in the *source* domain to help obtain θ_t^*.

Let $\mathcal{D}_s = \{(x_i^s, y_i^s)\}_{i=1}^{N_s}$ denote the set of labeled instances we have from the source domain. Assume that we have a (small) set of labeled and a (large) set of unlabeled instances from the target domain, denoted by $\mathcal{D}_{t,l} = \{(x_j^{t,l}, y_j^{t,l})\}_{j=1}^{N_{t,l}}$ and $\mathcal{D}_{t,u} = \{x_k^{t,u}\}_{k=1}^{N_{t,u}}$, respectively. We now show three ways to approximate the objective function above, corresponding to using three different sets of instances to approximate the instance space $\mathcal{X}$.

Using $\mathcal{D}_s$:

Using $p_s(y|x)$ to approximate $p_t(y|x)$, we obtain

$$\begin{aligned}\theta_t^* &\approx \arg\max_\theta \int_{\mathcal{X}} \frac{p_t(x)}{p_s(x)} p_s(x) \sum_{y\in\mathcal{Y}} p_s(y|x) \log p(y|x;\theta) dx \\ &\approx \arg\max_\theta \int_{\mathcal{X}} \frac{p_t(x)}{p_s(x)} \tilde{p}_s(x) \sum_{y\in\mathcal{Y}} \tilde{p}_s(y|x) \log p(y|x;\theta) dx \\ &= \arg\max_\theta \frac{1}{N_s} \sum_{i=1}^{N_s} \frac{p_t(x_i^s)}{p_s(x_i^s)} \log p(y_i^s|x_i^s;\theta).\end{aligned}$$

Here we use only the labeled instances in $\mathcal{D}_s$ but we adjust the weight of each instance by $\frac{p_t(x)}{p_s(x)}$. The major difficulty is how to accurately estimate $\frac{p_t(x)}{p_s(x)}$.

Using $\mathcal{D}_{t,l}$:

$$\begin{aligned}\theta_t^* &\approx \arg\max_\theta \int_{\mathcal{X}} \tilde{p}_{t,l}(x) \sum_{y\in\mathcal{Y}} \tilde{p}_{t,l}(y|x) \log p(y|x;\theta) dx \\ &= \arg\max_\theta \frac{1}{N_{t,l}} \sum_{j=1}^{N_{t,l}} \log p(y_j^{t,l}|x_j^{t,l};\theta)\end{aligned}$$

Note that this is the standard supervised learning method using only the small amount of labeled target instances. The major weakness of this approximation is that when $N_{t,l}$ is very small, the estimation is not accurate.

Using $\mathcal{D}_{t,u}$:

$$\begin{aligned}\theta_t^* &\approx \arg\max_\theta \int_{\mathcal{X}} \tilde{p}_{t,u}(x) \sum_{y\in\mathcal{Y}} p_t(y|x) \log p(y|x;\theta) dx \\ &= \arg\max_\theta \frac{1}{N_{t,u}} \sum_{k=1}^{N_{t,u}} \sum_{y\in\mathcal{Y}} p_t(y|x_k^{t,u}) \log p(y|x_k^{t,u};\theta),\end{aligned}$$

The challenge here is that $p_t(y|x_k^{t,u};\theta)$ is unknown to us, thus we need to estimate it. One possibility is to approximate it with a model $\hat{\theta}$ learned from $\mathcal{D}_s$ and $\mathcal{D}_{t,l}$. For example, we can set $p_t(y|x,\theta) = p(y|x;\hat{\theta})$. Alternatively, we can also set $p_t(y|x,\theta)$ to 1 if $y = \arg\max_{y'} p(y'|x;\hat{\theta})$ and 0 otherwise.

3 A Framework of Instance Weighting for Domain Adaptation

The theoretical analysis we give in Section 2 suggests that one way to solve the domain adaptation problem is through instance weighting. We propose a framework that incorporates instance pruning in Section 2.2 and the three approximations in Section 2.3. Before we show the formal framework, we first introduce some weighting parameters and explain the intuitions behind these parameters.

First, for each $(x_i^s, y_i^s) \in \mathcal{D}_s$, we introduce a parameter α_i to indicate how likely $p_t(y_i^s|x_i^s)$ is close to $p_s(y_i^s|x_i^s)$. Large α_i means the two probabilities are close, and therefore we can trust the labeled instance (x_i^s, y_i^s) for the purpose of learning a classifier for the target domain. Small α_i means these two probabilities are very different, and therefore we should probably discard the instance (x_i^s, y_i^s) in the learning process.

Second, again for each $(x_i^s, y_i^s) \in \mathcal{D}_s$, we introduce another parameter β_i that ideally is equal to $\frac{p_t(x_i^s)}{p_s(x_i^s)}$. From the approximation in Section 2.3 that uses only $\mathcal{D}_s$, it is clear that such a parameter is useful.

Next, for each $x_i^{t,u} \in \mathcal{D}_{t,u}$, and for each possible label $y \in \mathcal{Y}$, we introduce a parameter $\gamma_i(y)$ that indicates how likely we would like to assign y as a tentative label to $x_i^{t,u}$ and include $(x_i^{t,u}, y)$ as a training example.

Finally, we introduce three global parameters λ_s, $\lambda_{t,l}$ and $\lambda_{t,u}$ that are not instance-specific but are associated with $\mathcal{D}_s$, $\mathcal{D}_{t,l}$ and $\mathcal{D}_{t,u}$, respectively. These three parameters allow us to control the contribution of each of the three approximation methods in Section 2.3 when we linearly combine them together.

We now formally define our instance weighting framework. Given $\mathcal{D}_s$, $\mathcal{D}_{t,l}$ and $\mathcal{D}_{t,u}$, to learn a classifier for the target domain, we find a parameter $\hat{\theta}$ that optimizes the following objective function:

$$\hat{\theta} = \arg\max_{\theta} \Big[\lambda_s \cdot \frac{1}{C_s} \sum_{i=1}^{N_s} \alpha_i \beta_i \log p(y_i^s | x_i^s; \theta) + \lambda_{t,l} \cdot \frac{1}{C_{t,l}} \sum_{j=1}^{N_{t,l}} \log p(y_j^{t,l} | x_j^{t,l}; \theta) + \lambda_{t,u} \cdot \frac{1}{C_{t,u}} \sum_{k=1}^{N_{t,u}} \sum_{y \in \mathcal{Y}} \gamma_k(y) \log p(y | x_k^{t,u}; \theta) + \log p(\theta) \Big],$$

where $C_s = \sum_{i=1}^{N_s} \alpha_i \beta_i$, $C_{t,l} = N_{t,l}$, $C_{t,u} = \sum_{k=1}^{N_{t,u}} \sum_{y \in \mathcal{Y}} \gamma_k(y)$, and $\lambda_s + \lambda_{t,l} + \lambda_{t,u} = 1$. The last term, $\log p(\theta)$, is the log of a Gaussian prior distribution of θ, commonly used to regularize the complexity of the model.

In general, we do not know the optimal values of these parameters for the target domain. Nevertheless, the intuitions behind these parameters serve as guidelines for us to design heuristics to set these parameters. In the rest of this section, we introduce several heuristics that we used in our experiments to set these parameters.

3.1 Setting α

Following the intuition that if $p_t(y|x)$ differs much from $p_s(y|x)$, then (x, y) should be discarded from the training set, we use the following heuristic to set α^s. First, with standard supervised learning, we train a model $\hat{\theta}_{t,l}$ from $\mathcal{D}_{t,l}$. We consider $p(y|x; \hat{\theta}_{t,l})$ to be a crude approximation of $p_t(y|x)$. Then, we classify $\{x_i^s\}_{i=1}^{N_s}$ using $\hat{\theta}_{t,l}$. The top k instances that are incorrectly predicted by $\hat{\theta}_{t,l}$ (ranked by their prediction confidence) are discarded. In another word, α_i^s of the top k instances for which $y_i^s \neq \arg\max_y p(y|x_i^s; \hat{\theta}_{t,l})$ are set to 0, and α_i of all the other source instances are set to 1.

3.2 Setting β

Accurately setting β involves accurately estimating $p_s(x)$ and $p_t(x)$ from the empirical distributions. For many NLP classification tasks, we do not have a good parametric model for $p(x)$. We thus need to resort to non-parametric density estimation methods. However, for many NLP tasks, x resides in a high dimensional space, which makes it hard to apply standard non-parametric density estimation methods. We have not explored this direction, and in our experiments, we set β to 1 for all source instances.

3.3 Setting γ

Setting γ is closely related to some semi-supervised learning methods. One option is to set $\gamma_k(y) = p(y|x_k^{t,u}; \theta)$. In this case, γ is no longer a constant but is a function of θ. This way of setting γ corresponds to the entropy minimization semi-supervised learning method (Grandvalet and Bengio, 2005). Another way to set γ corresponds to bootstrapping semi-supervised learning. First, let $\hat{\theta}^{(n)}$ be a model learned from the previous round of training. We then select the top k instances from $\mathcal{D}_{t,u}$ that have the highest prediction confidence. For these instances, we set $\gamma_k(y) = 1$ for $y = \arg\max_{y'} p(y'|x_k^{t,u}; \hat{\theta}^{(n)})$, and $\gamma_k(y) = 0$ for all other y. In another word, we select the top k confidently predicted instances, and include these instances together with their predicted labels in the training set. All other instances in $\mathcal{D}_{t,u}$ are not considered. In our experiments, we only considered this bootstrapping way of setting γ.

3.4 Setting λ

λ_s, $\lambda_{t,l}$ and $\lambda_{t,u}$ control the balance among the three sets of instances. Using standard supervised learning, λ_s and $\lambda_{t,l}$ are set proportionally to C_s and $C_{t,l}$, that is, each instance is weighted the same whether it is in $\mathcal{D}_s$ or in $\mathcal{D}_{t,l}$, and $\lambda_{t,u}$ is set to 0. Similarly, using standard bootstrapping, $\lambda_{t,u}$ is set proportionally to $C_{t,u}$, that is, each target instance added to the training set is also weighted the same as a source instance. In neither case are the target instances emphasize more than source instances. However, for domain adaptation, we want to focus more on the target domain instances. So intuitively, we want to make $\lambda_{t,l}$ and $\lambda_{t,u}$ somehow larger relative to λ_s. As we will show in Section 4, this is indeed beneficial.

In general, the framework provides great flexibility for implementing different adaptation strategies through these instance weighting parameters.

4 Experiments

4.1 Tasks and Data Sets

We chose three different NLP tasks to evaluate our instance weighting method for domain adaptation. The first task is POS tagging, for which we used

6166 WSJ sentences from Sections 00 and 01 of Penn Treebank as the source domain data, and 2730 PubMed sentences from the Oncology section of the PennBioIE corpus as the target domain data. The second task is entity type classification. The setup is very similar to Daumé III and Marcu (2006). We assume that the entity boundaries have been correctly identified, and we want to classify the types of the entities. We used ACE 2005 training data for this task. For the source domain, we used the newswire collection, which contains 11256 examples, and for the target domains, we used the weblog (WL) collection (5164 examples) and the conversational telephone speech (CTS) collection (4868 examples). The third task is personalized spam filtering. We used the ECML/PKDD 2006 discovery challenge data set. The source domain contains 4000 spam and ham emails from publicly available sources, and the target domains are three individual users' inboxes, each containing 2500 emails.

For each task, we consider two experiment settings. In the first setting, we assume there are a small number of labeled target instances available. For POS tagging, we used an additional 300 Oncology sentences as labeled target instances. For NE typing, we used 500 labeled target instances and 2000 unlabeled target instances for each target domain. For spam filtering, we used 200 labeled target instances and 1800 unlabeled target instances. In the second setting, we assume there is no labeled target instance. We thus used all available target instances for testing in all three tasks.

We used logistic regression as our model of $p(y|x;\theta)$ because it is a robust learning algorithm and widely used.

We now describe three sets of experiments, corresponding to three heuristic ways of setting α, $\lambda_{t,l}$ and $\lambda_{t,u}$.

4.2 Removing "Misleading" Source Domain Instances

In the first set of experiments, we gradually remove "misleading" labeled instances from the source domain, using the small number of labeled target instances we have. We follow the heuristic we described in Section 3.1, which sets the α for the top k misclassified source instances to 0, and the α for all the other source instances to 1. We also set $\lambda_{t,l}$ and $\lambda_{t,l}$ to 0 in order to focus only on the effect of removing "misleading" instances. We compare with a baseline method which uses all source instances with equal weight but no target instances. The results are shown in Table 1.

From the table, we can see that in most experiments, removing these predicted "misleading" examples improved the performance over the baseline. In some experiments (Oncology, CTS, u00, u01), the largest improvement was achieved when all misclassified source instances were removed. In the case of weblog NE type classification, however, removing the source instances hurt the performance. A possible reason for this is that the set of labeled target instances we use is a biased sample from the target domain, and therefore the model trained on these instances is not always a good predictor of "misleading" source instances.

4.3 Adding Labeled Target Domain Instances with Higher Weights

The second set of experiments is to add the labeled target domain instances into the training set. This corresponds to setting $\lambda_{t,l}$ to some non-zero value, but still keeping $\lambda_{t,u}$ as 0. If we ignore the domain difference, then each labeled target instance is weighted the same as a labeled source instance ($\frac{\lambda_{u,l}}{\lambda_s} = \frac{C_{u,l}}{C_s}$), which is what happens in regular supervised learning. However, based on our theoretical analysis, we can expect the labeled target instances to be more representative of the target domain than the source instances. We can therefore assign higher weights for the target instances, by adjusting the ratio between $\lambda_{t,l}$ and λ_s. In our experiments, we set $\frac{\lambda_{t,l}}{\lambda_s} = a\frac{C_{t,l}}{C_s}$, where a ranges from 2 to 20. The results are shown in Table 2.

As shown from the table, adding some labeled target instances can greatly improve the performance for all tasks. And in almost all cases, weighting the target instances more than the source instances performed better than weighting them equally.

We also tested another setting where we first removed the "misleading" source examples as we showed in Section 4.2, and then added the labeled target instances. The results are shown in the last row of Table 2. However, although both removing "misleading" source instances and adding labeled

Table 2: Accuracy on the unlabeled target instances after adding the labeled target instances.

target instances work well individually, when combined, the performance in most cases is not as good as when no source instances are removed. We hypothesize that this is because after we added some labeled target instances with large weights, we already gained a good balance between the source data and the target data. Further removing source instances would push the emphasis more on the set of labeled target instances, which is only a biased sample of the whole target domain.

The POS data set and the CTS data set have previously been used for testing other adaptation methods (Daumé III and Marcu, 2006; Blitzer et al., 2006), though the setup there is different from ours. Our performance using instance weighting is comparable to their best performance (slightly worse for POS and better for CTS).

4.4 Bootstrapping with Higher Weights

In the third set of experiments, we assume that we do not have any labeled target instances. We tried two bootstrapping methods. The first is a *standard* bootstrapping method, in which we gradually added the most confidently predicted unlabeled target instances with their predicted labels to the training set. Since we believe that the target instances should in general be given more weight because they better represent the target domain than the source instances, in the second method, we gave the added target instances more weight in the objective function. In particular, we set $\lambda_{t,u} = \lambda_s$ such that the total contribution of the added target instances is equal to that of all the labeled source instances. We call this second method the *balanced* bootstrapping method. Table 3 shows the results.

As we can see, while bootstrapping can generally improve the performance over the baseline where no unlabeled data is used, the balanced bootstrapping method performed slightly better than the standard bootstrapping method. This again shows that weighting the target instances more is a right direction to go for domain adaptation.

5 Related Work

There have been several studies in NLP that address domain adaptation, and most of them need labeled data from both the source domain and the target domain. Here we highlight a few representative ones.

For generative syntactic parsing, Roark and Bacchiani (2003) have used the source domain data to construct a Dirichlet prior for MAP estimation of the PCFG for the target domain. Chelba and Acero (2004) use the parameters of the maximum entropy model learned from the source domain as the means of a Gaussian prior when training a new model on the target data. Florian et al. (2004) first train a NE tagger on the source domain, and then use the tagger's predictions as features for training and testing on the target domain.

The only work we are aware of that directly mod-

Table 3: Accuracy on the target domain without using labeled target instances. In balanced bootstrapping, more weights are put on the target instances in the objective function than in standard bootstrapping.

els the different distributions in the source and the target domains is by Daumé III and Marcu (2006). They assume a "truly source domain" distribution, a "truly target domain" distribution, and a "general domain" distribution. The source (target) domain data is generated from a mixture of the "truly source (target) domain" distribution and the "general domain" distribution. In contrast, we do not assume such a mixture model.

None of the above methods would work if there were no labeled target instances. Indeed, all the above methods do not make use of the unlabeled instances in the target domain. In contrast, our instance weighting framework allows unlabeled target instances to contribute to the model estimation.

Blitzer et al. (2006) propose a domain adaptation method that uses the unlabeled target instances to infer a good feature representation, which can be regarded as weighting the features. In contrast, we weight the instances. The idea of using $\frac{p_t(x)}{p_s(x)}$ to weight instances has been studied in statistics (Shimodaira, 2000), but has not been applied to NLP tasks.

6 Conclusions and Future Work

Domain adaptation is a very important problem with applications to many NLP tasks. In this paper, we formally analyze the domain adaptation problem and propose a general instance weighting framework for domain adaptation. The framework is flexible to support many different strategies for adaptation. In particular, it can support adaptation with some target domain labeled instances as well as that without any labeled target instances. Experiment results on three NLP tasks show that while regular semi-supervised learning methods and supervised learning methods can be applied to domain adaptation without considering domain difference, they do not perform as well as our new method, which explicitly captures domain difference. Our results also show that incorporating and exploiting more information from the target domain is much more useful than excluding misleading training examples from the source domain. The framework opens up many interesting future research directions, especially those related to how to more accurately set/estimate those weighting parameters.

The Infinite Tree

Jenny Rose Finkel, Trond Grenager, and Christopher D. Manning
Computer Science Department, Stanford University
Stanford, CA 94305
{jrfinkel, grenager, manning}@cs.stanford.edu

Abstract

Historically, unsupervised learning techniques have lacked a principled technique for selecting the number of unseen components. Research into non-parametric priors, such as the Dirichlet process, has enabled instead the use of *infinite models*, in which the number of hidden categories is not fixed, but can grow with the amount of training data. Here we develop the *infinite tree*, a new infinite model capable of representing recursive branching structure over an arbitrarily large set of hidden categories. Specifically, we develop three infinite tree models, each of which enforces different independence assumptions, and for each model we define a simple *direct assignment* sampling inference procedure. We demonstrate the utility of our models by doing unsupervised learning of part-of-speech tags from treebank dependency skeleton structure, achieving an accuracy of 75.34%, and by doing unsupervised splitting of part-of-speech tags, which increases the accuracy of a generative dependency parser from 85.11% to 87.35%.

1 Introduction

Model-based unsupervised learning techniques have historically lacked good methods for choosing the number of unseen components. For example, k-means or EM clustering require advance specification of the number of mixture components. But the introduction of nonparametric priors such as the *Dirichlet process* (Ferguson, 1973) enabled development of *infinite mixture models*, in which the number of hidden components is not fixed, but emerges naturally from the training data (Antoniak, 1974).

Teh et al. (2006) proposed the hierarchical Dirichlet process (HDP) as a way of applying the Dirichlet process (DP) to more complex model forms, so as to allow multiple, group-specific, infinite mixture models to *share* their mixture components. The closely related *infinite hidden Markov model* is an HMM in which the transitions are modeled using an HDP, enabling unsupervised learning of sequence models when the number of hidden states is unknown (Beal et al., 2002; Teh et al., 2006).

We extend this work by introducing the *infinite tree model*, which represents recursive branching structure over a potentially infinite set of hidden states. Such models are appropriate for the syntactic dependency structure of natural language. The hidden states represent word categories ("tags"), the observations they generate represent the words themselves, and the tree structure represents syntactic dependencies between pairs of tags.

To validate the model, we test unsupervised learning of tags conditioned on a given dependency tree structure. This is useful, because coarse-grained syntactic categories, such as those used in the Penn Treebank (PTB), make insufficient distinctions to be the basis of accurate syntactic parsing (Charniak, 1996). Hence, state-of-the-art parsers either supplement the part-of-speech (POS) tags with the lexical forms themselves (Collins, 2003; Charniak, 2000), manually split the tagset into a finer-grained one (Klein and Manning, 2003a), or learn finer grained tag distinctions using a heuristic learning procedure (Petrov et al., 2006). We demonstrate that the tags learned with our model are correlated with the PTB POS tags, and furthermore that they improve the accuracy of an automatic parser when used in training.

2 Finite Trees

We begin by presenting three *finite* tree models, each with different independence assumptions.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 272–279,
Prague, Czech Republic, June 2007.

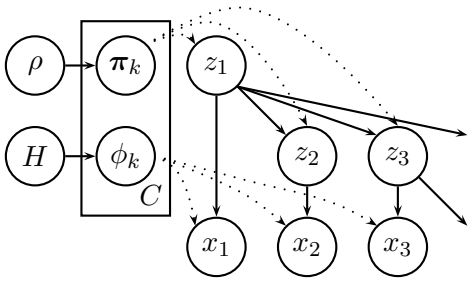

Figure 1: A graphical representation of the *finite* Bayesian tree model with independent children. The *plate* (rectangle) indicates that there is one copy of the model parameter variables for each state $k \leq C$.

2.1 Independent Children

In the first model, children are generated independently of each other, conditioned on the parent. Let t denote both the tree and its root node, $c(t)$ the list of children of t, $c_i(t)$ the i^{th} child of t, and $p(t)$ the parent of t. Each tree t has a hidden state z_t (in a syntax tree, the tag) and an observation x_t (the word).[1] The probability of a tree is given by the recursive definition:[2]

$$\mathrm{P}_{tr}(t) = \mathrm{P}(x_t|z_t) \prod_{t' \in c(t)} \mathrm{P}(z_{t'}|z_t) \mathrm{P}_{tr}(t')$$

To make the model Bayesian, we must define random variables to represent each of the model's parameters, and specify prior distributions for them. Let each of the hidden state variables have C possible values which we will index with k. Each state k has a distinct distribution over observations, parameterized by ϕ_k, which is distributed according to a prior distribution over the parameters H:

$$\phi_k|H \sim H$$

We generate each observation x_t from some distribution $F(\phi_{z_t})$ parameterized by ϕ_{z_t} specific to its corresponding hidden state z_t. If $F(\phi_k)$s are multinomials, then a natural choice for H would be a Dirichlet distribution.[3]

The hidden state $z_{t'}$ of each child is distributed according to a multinomial distribution π_{z_t} specific to the hidden state z_t of the parent:

$$x_t|z_t \sim F(\phi_{z_t})$$
$$z_{t'}|z_t \sim \text{Multinomial}(\pi_{z_t})$$

Each multinomial over children $\boldsymbol{\pi}_k$ is distributed according to a Dirichlet distribution with parameter ρ:

$$\boldsymbol{\pi}_k|\rho \sim \text{Dirichlet}(\rho, \ldots, \rho)$$

This model is presented graphically in Figure 1.

2.2 Simultaneous Children

The independent child model adopts strong independence assumptions, and we may instead want models in which the children are conditioned on more than just the parent's state. Our second model thus generates the states of all of the children $c(t)$ simultaneously:

$$\mathrm{P}_{tr}(t) = \mathrm{P}(x_t|z_t)\mathrm{P}((z_{t'})_{t' \in c(t)}|z_t) \prod_{t' \in c(t)} \mathrm{P}_{tr}(t')$$

where $(z_{t'})_{t' \in c(t)}$ indicates the list of tags of the children of t. To parameterize this model, we replace the multinomial distribution $\boldsymbol{\pi_k}$ over states with a multinomial distribution $\boldsymbol{\lambda_k}$ over lists of states.[4]

2.3 Markov Children

The very large domain size of the child lists in the simultaneous child model may cause problems of sparse estimation. Another alternative is to use a first-order Markov process to generate children, in which each child's state is conditioned on the previous child's state:

$$\mathrm{P}_{tr}(t) = \mathrm{P}(x_t|z_t) \prod_{i=1}^{|c(t)|} \mathrm{P}(z_{c_i(t)}|z_{c_{i-1}(t)}, z_t) \mathrm{P}_{tr}(t')$$

For this model, we augment all child lists with a distinguished *start node*, $c_0(t)$, which has as its state a distinguished *start state*, allowing us to capture the unique behavior of the first (observed) child. To parameterize this model, note that we will need to define $C(C+1)$ multinomials, one for each parent state and preceding child state (or a distinguished start state).

3 To Infinity, and Beyond ...

This section reviews needed background material for our approach to making our tree models infinite.

3.1 The Dirichlet Process

Suppose we model a document as a *bag of words* produced by a mixture model, where the mixture components might be *topics* such as business, politics, sports, etc. Using this model we can generate a

[1] To model length, every child list ends with a distinguished *stop node*, which has as its state a distinguished *stop state*.

[2] We also define a distinguished node t_0, which generates the root of the entire tree, and $P(x_{t_0}|z_{t_0}) = 1$.

[3] A Dirichlet *distribution* is a distribution over the possible parameters of a multinomial distributions, and is distinct from the Dirichlet *process*.

[4] This requires stipulating a maximum list length.

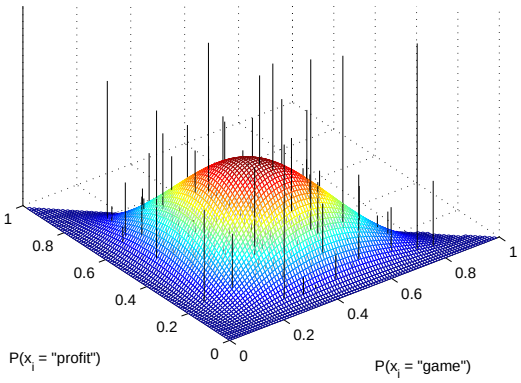

Figure 2: Plot of the density function of a Dirichlet distribution H (the surface) as well as a draw G (the vertical lines, or *sticks*) from a Dirichlet process $\text{DP}(\alpha_0, H)$ which has H as a base measure. Both distributions are defined over a simplex in which each point corresponds to a particular multinomial distribution over three possible words: "profit", "game", and "election". The placement of the sticks is drawn from the distribution H, and is independent of their lengths, which is drawn from a *stick-breaking* process with parameter α_0.

document by first generating a distribution over topics $\boldsymbol{\pi}$, and then for each position i in the document, generating a topic z_i from $\boldsymbol{\pi}$, and then a word x_i from the topic specific distribution ϕ_{z_i}. The word distributions ϕ_k for each topic k are drawn from a base distribution H. In Section 2, we sample C multinomials ϕ_k from H. In the infinite mixture model we sample an infinite number of multinomials from H, using the Dirichlet process.

Formally, given a base distribution H and a concentration parameter α_0 (loosely speaking, this controls the relative sizes of the topics), a Dirichlet process $\text{DP}(\alpha_0, H)$ is the distribution of a discrete random probability measure G over the same (possibly continuous) space that H is defined over; thus *it is a measure over measures*. In Figure 2, the sticks (vertical lines) show a draw G from a Dirichlet process where the base measure H is a Dirichlet distribution over 3 words. A draw comprises of an infinite number of sticks, and each corresponding topic.

We factor G into two coindexed distributions: $\boldsymbol{\pi}$, a distribution over the integers, where the integer represents the index of a particular topic (i.e., the height of the sticks in the figure represent the probability of the topic indexed by that stick) and $\boldsymbol{\phi}$, representing the word distribution of each of the topics (i.e., the location of the sticks in the figure). To generate $\boldsymbol{\pi}$ we first generate an infinite sequence of variables $\boldsymbol{\pi'} = (\pi'_k)_{k=1}^{\infty}$, each of which is distributed according to the Beta distribution:

$$\pi'_k | \alpha_0 \sim \text{Beta}(1, \alpha_0)$$

Then $\boldsymbol{\pi} = (\pi_k)_{k=1}^{\infty}$ is defined as:

$$\pi_k = \pi'_k \prod_{i=1}^{k-1} (1 - \pi'_i)$$

Following Pitman (2002) we refer to this process as $\pi \sim \text{GEM}(\alpha_0)$. It should be noted that $\sum_{k=1}^{\infty} \pi_k = 1$,[5] and $P(i) = \pi_i$. Then, according to the DP, $P(\phi_i) = \pi_i$. The complete model, is shown graphically in Figure 3(a).

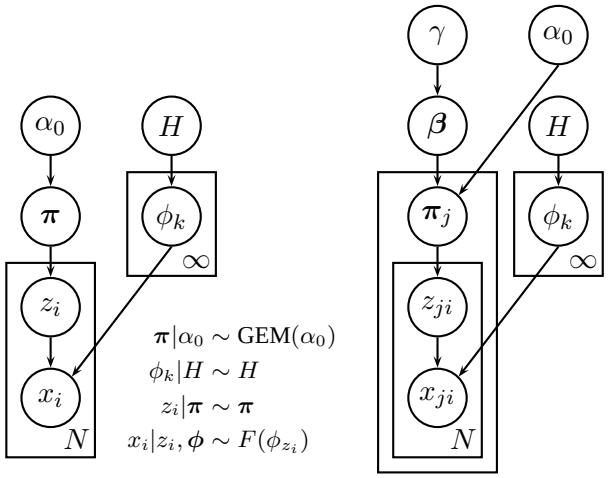

Figure 3: A graphical representation of a simple Dirichlet process mixture model (left) and a hierarchical Dirichlet process model (right). Note that we show the *stick-breaking* representations of the models, in which we have factored $G \sim \text{DP}(\alpha_0, H)$ into two sets of variables: π and ϕ.

To build intuition, we walk through the process of generating from the infinite mixture model for the document example, where x_i is the word at position i, and z_i is its topic. F is a multinomial distribution parameterized by $\boldsymbol{\phi}$, and H is a Dirichlet distribution. Instead of generating all of the infinite mixture components $(\pi_k)_{k=1}^{\infty}$ at once, we can build them up incrementally. If there are K known topics, we represent only the known elements $(\pi_k)_{k=1}^{K}$ and represent the remaining probability mass $\pi_u =$

[5] This is called the *stick-breaking* construction: we start with a stick of unit length, representing the entire probability mass, and successively break bits off the end of the stick, where the proportional amount broken off is represented by π'_k and the absolute amount is represented by π_k.

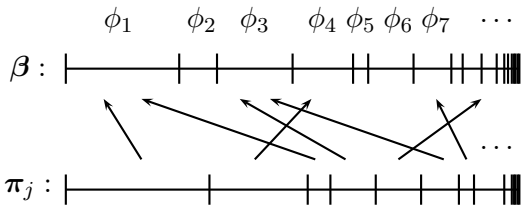

Figure 4: A graphical representation of $\boldsymbol{\pi}_j$, a broken stick, which is distributed according to a DP with a broken stick $\boldsymbol{\beta}$ as a base measure. Each β_k corresponds to a ϕ_k.

$1 - (\sum_{k=1}^{K} \pi_k)$. Initially we have $\pi_u = 1$ and $\boldsymbol{\phi} = ()$.

For the ith position in the document, we first draw a topic $z_i \sim \boldsymbol{\pi}$. If $z_i \neq u$, then we find the coindexed topic ϕ_{z_i}. If $z_i = u$, the unseen topic, we make a draw $b \sim \text{Beta}(1, \alpha_0)$ and set $\pi_{K+1} = b\pi_u$ and $\pi_u^{new} = (1-b)\pi_u$. Then we draw a parameter $\phi_{K+1} \sim H$ for the new topic, resulting in $\boldsymbol{\pi} = (\pi_1, \ldots, \pi_{K+1}, \pi_u^{new})$ and $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_{K+1})$. A word is then drawn from this topic and emitted by the document.

3.2 The Hierarchical Dirichlet Process

Let's generalize our previous example to a corpus of documents. As before, we have a set of shared topics, but now each document has its *own characteristic distribution* over these topics. We represent topic distributions both locally (for each document) and globally (across all documents) by use of a hierarchical Dirichlet process (HDP), which has a local DP for each document, in which *the base measure is itself a draw from another, global, DP.*

The complete HDP model is represented graphically in Figure 3(b). Like the DP, it has global broken stick $\boldsymbol{\beta} = (\beta_k)_{k=1}^{\infty}$ and topic specific word distribution parameters $\boldsymbol{\phi} = (\phi_k)_{k=1}^{\infty}$, which are coindexed. It differs from the DP in that it also has local broken sticks $\boldsymbol{\pi}_j$ for each group j (in our case documents). While the global stick $\boldsymbol{\beta} \sim \text{GEM}(\gamma)$ is generated as before, the local sticks $\boldsymbol{\pi}_j$ are distributed according to a DP with base measure $\boldsymbol{\beta}$: $\boldsymbol{\pi}_j \sim \text{DP}(\alpha_0, \boldsymbol{\beta})$.

We illustrate this generation process in Figure 4. The upper unit line represents $\boldsymbol{\beta}$, where the size of segment k represents the value of element β_k, and the lower unit line represents $\boldsymbol{\pi}_j \sim \text{DP}(\alpha_0, \boldsymbol{\beta})$ for a particular group j. Each element of the lower stick was sampled from a particular element of the upper stick, and elements of the upper stick may be sampled multiple times or not at all; on average, larger elements will be sampled more often. Each element $\boldsymbol{\beta}_k$, as well as all elements of $\boldsymbol{\pi}_j$ that were sampled from it, corresponds to a particular ϕ_k. Critically, several distinct $\boldsymbol{\pi}_j$ can be sampled from the same β_k and hence share ϕ_k; *this is how components are shared among groups.*

For concreteness, we show how to generate a corpus of documents from the HDP, generating one document at a time, and incrementally constructing our infinite objects. Initially we have $\beta_u = 1$, $\boldsymbol{\phi} = ()$, and $\pi_{ju} = 1$ for all j. We start with the first position of the first document and draw a local topic $y_{11} \sim \boldsymbol{\pi}_1$, which will return u with probability 1. Because $y_{11} = u$ we must make a draw from the base measure, $\boldsymbol{\beta}$, which, because this is the first document, will also return u with probability 1. We must now break β_u into β_1 and β_u^{new}, and break π_{1u} into π_{11} and π_{1u}^{new} in the same manner presented for the DP. Since π_{11} now corresponds to global topic 1, we sample the word $x_{11} \sim \text{Multinomial}(\phi_1)$. To sample each subsequent word i, we first sample the local topic $y_{1i} \sim \boldsymbol{\pi}_1$. If $y_{1i} \neq u$, and $\pi_{1y_{1i}}$ corresponds to β_k in the global stick, then we sample the word $x_{1i} \sim \text{Multinomial}(\phi_k)$. Once the first document has been sampled, subsequent documents are sampled in a similar manner; initially $\pi_{ju} = 1$ for document j, while $\boldsymbol{\beta}$ continues to grow as more documents are sampled.

4 Infinite Trees

We now use the techniques from Section 3 to create infinite versions of each tree model from Section 2.

4.1 Independent Children

The changes required to make the Bayesian independent children model infinite don't affect its basic structure, as can be witnessed by comparing the graphical depiction of the infinite model in Figure 5 with that of the finite model in Figure 1. The instance variables z_t and x_t are parameterized as before. The primary change is that the number of copies of the state plate is infinite, as are the number of variables $\boldsymbol{\pi}_k$ and ϕ_k.

Note also that each distribution over possible child states $\boldsymbol{\pi}_k$ must also be infinite, since the number of possible child states is potentially infinite. We achieve this by representing each of the $\boldsymbol{\pi}_k$ variables as a broken stick, and adopt the same approach of

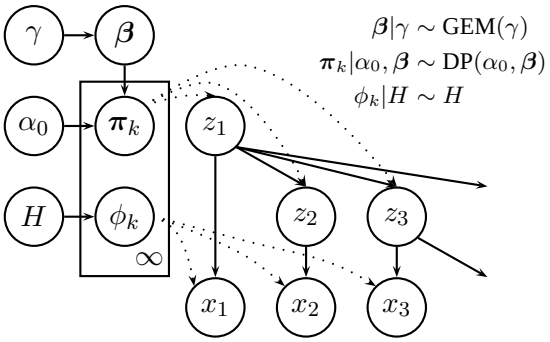

Figure 5: A graphical representation of the *infinite* independent child model.

sampling each $\boldsymbol{\pi}_k$ from a DP with base measure $\boldsymbol{\beta}$. For the dependency tree application, ϕ_k is a vector representing the parameters of a multinomial over words, and H is a Dirichlet distribution.

The infinite hidden Markov model (iHMM) or HDP-HMM (Beal et al., 2002; Teh et al., 2006) is a model of sequence data with transitions modeled by an HDP.[6] The iHMM can be viewed as a special case of this model, where each state (except the stop state) produces exactly one child.

4.2 Simultaneous Children

The key problem in the definition of the simultaneous children model is that of defining a distribution over the lists of children produced by each state, since each child in the list has as its domain the positive integers, representing the infinite set of possible states. Our solution is to construct a distribution L_k over lists of states from the distribution over individual states $\boldsymbol{\pi}_k$. The obvious approach is to sample the states at each position i.i.d.:

$$\text{P}((z_{t'})_{t' \in c(t)}|\boldsymbol{\pi}) = \prod_{t' \in c(t)} \text{P}(z_{t'}|\boldsymbol{\pi}) = \prod_{t' \in c(t)} \pi_{z_{t'}}$$

However, we want our model to be able to represent the fact that some child lists, $\boldsymbol{c}_t$, are more or less probable than the product of the individual child probabilities would indicate. To address this, we can sample a state-conditional distribution over child lists λ_k from a DP with L_k as a base measure. Thus, we augment the basic model given in the previous section with the variables ζ, L_k, and λ_k:

$$\begin{aligned} L_k|\boldsymbol{\pi}_k &\sim \text{Deterministic, as described above} \\ \lambda_k|\zeta, L_k &\sim \text{DP}(\zeta, L_k) \\ \boldsymbol{c}_t|\lambda_k &\sim \lambda_k \end{aligned}$$

An important consequence of defining L_k locally (instead of globally, using $\boldsymbol{\beta}$ instead of the $\boldsymbol{\pi}_k$s) is that the model captures not only what sequences of children a state prefers, but also the individual children that state prefers; if a state gives high probability to some particular sequence of children, then it is likely to also give high probability to other sequences containing those same states, or a subset thereof.

4.3 Markov Children

In the Markov children model, more copies of the variable $\boldsymbol{\pi}$ are needed, because each child state must be conditioned both on the parent state and on the state of the preceding child. We use a new set of variables $\boldsymbol{\pi}_{ki}$, where $\boldsymbol{\pi}$ is determined by the parent state k and the state of the preceding sibling i. Each of the $\boldsymbol{\pi}_{ki}$ is distributed as $\boldsymbol{\pi}_k$ was in the basic model: $\boldsymbol{\pi}_{ki} \sim \text{DP}(\alpha_0, \boldsymbol{\beta})$.

5 Inference

Our goal in inference is to draw a sample from the posterior over assignments of states to observations. We present an inference procedure for the infinite tree that is based on Gibbs sampling in the *direct assignment* representation, so named because we directly assign global state indices to observations.[7]

Before we present the procedure, we define a few count variables. Recall from Figure 4 that each state k has a local stick $\boldsymbol{\pi}_k$, each element of which corresponds to an element of $\boldsymbol{\beta}$. In our sampling procedure, we only keep elements of $\boldsymbol{\pi}_k$ and $\boldsymbol{\beta}$ which correspond to states observed in the data. We define the variable m_{jk} to be the number of elements of the finite observed portion of $\boldsymbol{\pi}_k$ which correspond to β_j and n_{jk} to be the number of observations with state k whose parent's state is j.

We also need a few model-specific counts. For the simultaneous children model we need $\overline{n}_{j\boldsymbol{z}}$, which is

[6] The original iHMM paper (Beal et al., 2002) predates, and was the motivation for, the work presented in Teh et al. (2006), and is the origin of the term *hierarchical Dirichlet process*. However, they used the term to mean something slightly different than the HDP presented in Teh et al. (2006), and presented a sampling scheme for inference that was a heuristic approximation of a Gibbs sampler.

[7] We adapt one of the sampling schemes mentioned by Teh et al. (2006) for use in the iHMM. This paper suggests two sampling schemes for inference, but does not explicitly present them. Upon discussion with one of the authors (Y. W. Teh, 2006, p.c.), it became clear that inference using the augmented representation is much more complicated than initially thought.

the number of times the state sequence $\boldsymbol{z}$ occurred as the children of state j. For the Markov children model we need the count variable $\hat{n}_{jik}$ which is the number of observations for a node with state k whose parent's state is j and whose previous sibling's state is i. In all cases we represent marginal counts using dot-notation, e.g., $n_{\cdot k}$ is the total number of nodes with state k, regardless of parent.

Our procedure alternates between three distinct sampling stages: (1) sampling the state assignments z, (2) sampling the counts m_{jk}, and (3) sampling the global stick $\boldsymbol{\beta}$. The only modification of the procedure that is required for the different tree models is the method for computing the probability of the child state sequence given the parent state $\mathrm{P}((z_{t'})_{t' \in c(t)}|z_t)$, defined separately for each model.

Sampling z. In this stage we sample a state for each tree node. The probability of node t being assigned state k is given by:

$$\mathrm{P}(z_t = k|\boldsymbol{z}^{-t}, \boldsymbol{\beta}) \propto \mathrm{P}(z_t = k, (z_{t'})_{t' \in s(t)}|z_{p(t)}) \cdot \mathrm{P}((z_{t'})_{t' \in c(t)}|z_t = k) \cdot f_k^{-x_t}(x_t)$$

where $s(t)$ denotes the set of siblings of t, $f_k^{-x_t}(x_t)$ denotes the posterior probability of observation x_t given all other observations assigned to state k, and $\boldsymbol{z}^{-t}$ denotes all state assignments except z_t. In other words, the probability is proportional to the product of three terms: the probability of the states of t and its siblings given its parent $z_{p(t)}$, the probability of the states of the children $c(t)$ given z_t, and the posterior probability of observation x_t given z_t. Note that if we sample z_t to be a previously unseen state, we will need to extend $\boldsymbol{\beta}$ as discussed in Section 3.2.

Now we give the equations for $\mathrm{P}((z_{t'})_{t' \in c(t)}|z_t)$ for each of the models. In the independent child model the probability of generating each child is:

$$\mathrm{P}_{\text{ind}}(z_{c_i(t)} = k|z_t = j) = \frac{n_{jk} + \alpha_0 \beta_k}{n_{j\cdot} + \alpha_0}$$

$$\mathrm{P}_{\text{ind}}((z_{t'})_{t' \in c(t)}|z_t = j) = \prod\nolimits_{t' \in c(t)} \mathrm{P}_{\text{ind}}(z_{t'}|z_t = j)$$

For the simultaneous child model, the probability of generating a sequence of children, $\mathbf{z}$, takes into account how many times that sequence has been generated, along with the likelihood of regenerating it:

$$\mathrm{P}_{\text{sim}}((z_{t'})_{t' \in c(t)} = \mathbf{z}|z_t = j) = \frac{\overline{n}_{j\mathbf{z}} + \zeta \mathrm{P}_{\text{ind}}(\mathbf{z}|z_t = j)}{\overline{n}_{j\cdot} + \zeta}$$

Recall that ζ denotes the concentration parameter for the sequence generating DP. Lastly, we have the Markov child model:

$$\mathrm{P}_{\text{m}}(z_{c_i(t)} = k|z_{c_{i-1}(t)} = i, z_t = j) = \frac{\hat{n}_{jik} + \alpha_0 \beta_k}{\hat{n}_{ji\cdot} + \alpha_0}$$

$$\mathrm{P}_{\text{m}}((z_{t'})_{t' \in c(t)}|z_t) = \prod\nolimits_{i=1}^{|c(t)|} \mathrm{P}_{\text{m}}(z_{c_i(t)}|z_{c_{i-1}(t)}, z_t)$$

Finally, we give the posterior probability of an observation, given that $F(\phi_k)$ is Multinomial(ϕ_k), and that H is Dirichlet$(\rho, \ldots, \rho)$. Let N be the vocabulary size and $\dot{n}_k$ be the number of observations x with state k. Then:

$$f_k^{-x_t}(x_t) = \frac{\dot{n}_{x_t k} + \rho}{\dot{n}_{\cdot k} + N\rho}$$

Sampling m. We use the following procedure, which slightly modifies one from (Y. W. Teh, 2006, p.c.), to sample each m_{jk}:

SAMPLEM(j, k)
1 **if** $n_{jk} = 0$
2 **then** $m_{jk} = 0$
3 **else** $m_{jk} = 1$
4 **for** $i \leftarrow 2$ **to** n_{jk}
5 **do if** rand() $< \frac{\alpha_0}{\alpha_0 + i - 1}$
6 **then** $m_{jk} = m_{jk} + 1$
7 **return** m_{jk}

Sampling β. Lastly, we sample $\boldsymbol{\beta}$ using the Dirichlet distribution:

$$(\beta_1, \ldots, \beta_K, \beta_u) \sim \text{Dirichlet}(m_{\cdot 1}, \ldots, m_{\cdot K}, \alpha_0)$$

Figure 6: An example of a syntactic dependency tree where the dependencies are between tags (hidden states), and each tag generates a word (observation).

6 Experiments

We demonstrate infinite tree models on two distinct syntax learning tasks: unsupervised POS learning conditioned on untagged dependency trees and learning a split of an existing tagset, which improves the accuracy of an automatic syntactic parser.

For both tasks, we use a simple modification of the basic model structure, to allow the trees to generate dependents on the left and the right with different distributions – as is useful in modeling natural language. The modification of the independent child tree is trivial: we have two copies of each of

the variables $\boldsymbol{\pi}_k$, one each for the left and the right. Generation of dependents on the right is completely independent of that for the left. The modifications of the other models are similar, but now there are separate *sets* of π_k variables for the Markov child model, and separate L_k and λ_k variables for the simultaneous child model, for each of the left and right.

For both experiments, we used dependency trees extracted from the Penn Treebank (Marcus et al., 1993) using the head rules and dependency extractor from Yamada and Matsumoto (2003). As is standard, we used WSJ sections 2–21 for training, section 22 for development, and section 23 for testing.

6.1 Unsupervised POS Learning

In the first experiment, we do unsupervised part-of-speech learning conditioned on dependency trees. To be clear, the input to our algorithm is the dependency structure skeleton of the corpus, but not the POS tags, and the output is a labeling of each of the words in the tree for word class. Since the model knows nothing about the POS annotation, the new classes have arbitrary integer names, and are not guaranteed to correlate with the POS tag definitions. We found that the choice of α_0 and β (the concentration parameters) did not affect the output much, while the value of ρ (the parameter for the base Dirichlet distribution) made a much larger difference. For all reported experiments, we set $\alpha_0 = \beta = 10$ and varied ρ.

We use several metrics to evaluate the word classes. First, we use the standard approach of greedily assigning each of the learned classes to the POS tag with which it has the greatest overlap, and then computing tagging accuracy (Smith and Eisner, 2005; Haghighi and Klein, 2006).[8] Additionally, we compute the mutual information of the learned clusters with the gold tags, and we compute the cluster F-score (Ghosh, 2003). See Table 1 for results of the different models, parameter settings, and metrics. Given the variance in the number of classes learned it is a little difficult to interpret these results, but it is clear that the Markov child model is the best; it achieves superior performance to the independent child model on all metrics, while learning fewer word classes. The poor performance of the simultaneous model warrants further investigation, but we observed that the distributions learned by that model are far more spiked, potentially due to double counting of tags, since the sequence probabilities are already based on the local probabilities.

[8]The advantage of this metric is that it's comprehensible. The disadvantage is that it's easy to inflate by adding classes.

Model	ρ	# Classes	Acc.	MI	F1
Indep.	0.01	943	67.89	2.00	48.29
	0.001	1744	73.61	2.23	40.80
	0.0001	2437	74.64	2.27	39.47
Simul.	0.01	183	21.36	0.31	21.57
	0.001	430	15.77	0.09	13.80
	0.0001	549	16.68	0.12	14.29
Markov	0.01	613	68.53	2.12	49.82
	0.001	894	75.34	2.31	48.73

Table 1: Results of part unsupervised POS tagging on the different models, using a greedy accuracy measure.

For comparison, Haghighi and Klein (2006) report an unsupervised baseline of 41.3%, and a best result of 80.5% from using hand-labeled prototypes and distributional similarity. However, they train on less data, and learn fewer word classes.

6.2 Unsupervised POS Splitting

In the second experiment we use the infinite tree models to learn a refinement of the PTB tags. We initialize the set of hidden states to the set of PTB tags, and then, during inference, constrain the sampling distribution over hidden state z_t at each node t to include only states that are a refinement of the annotated PTB tag at that position. The output of this training procedure is a new annotation of the words in the PTB with the learned tags. We then compare the performance of a generative dependency parser trained on the new refined tags with one trained on the base PTB tag set. We use the generative dependency parser distributed with the Stanford factored parser (Klein and Manning, 2003b) for the comparison, since it performs simultaneous tagging and parsing during testing. In this experiment, unlabeled, directed, dependency parsing accuracy for the best model increased from 85.11% to 87.35%, a 15% error reduction. See Table 2 for the full results over all models and parameter settings.

7 Related Work

The HDP-PCFG (Liang et al., 2007), developed at the same time as this work, aims to learn state splits for a binary-branching PCFG. It is similar to our simultaneous child model, but with several important distinctions. As discussed in Section 4.2, in our model each state has a DP over sequences, with a base distribution that is defined over the local child

Model	ρ	Accuracy

state probabilities. In contrast, Liang et al. (2007) define a global DP over sequences, with the base measure defined over the global state probabilities, β; locally, each state has an HDP, with this global DP as the base measure. We believe our choice to be more linguistically sensible: in our model, for a particular state, dependent sequences which are similar to one another increase one another's likelihood. Additionally, their modeling decision made it difficult to define a Gibbs sampler, and instead they use variational inference. Earlier, Johnson et al. (2007) presented *adaptor grammars*, which is a very similar model to the HDP-PCFG. However they did not confine themselves to a binary branching structure and presented a more general framework for defining the process for splitting the states.

8 Discussion and Future Work

We have presented a set of novel infinite tree models and associated inference algorithms, which are suitable for representing syntactic dependency structure. Because the models represent a potentially infinite number of hidden states, they permit unsupervised learning algorithms which naturally select a number of word classes, or tags, based on qualities of the data. Although they require substantial technical background to develop, the learning algorithms based on the models are actually simple in form, requiring only the maintenance of counts, and the construction of sampling distributions based on these counts. Our experimental results are preliminary but promising: they demonstrate that the model is capable of capturing important syntactic structure.

Much remains to be done in applying infinite models to language structure, and an interesting extension would be to develop inference algorithms that permit completely unsupervised learning of dependency structure.

Guiding Semi-Supervision with Constraint-Driven Learning

Abstract

Over the last few years, two of the main research directions in machine learning of natural language processing have been the study of semi-supervised learning algorithms as a way to train classifiers when the labeled data is scarce, and the study of ways to exploit knowledge and global information in structured learning tasks. In this paper, we suggest a method for incorporating domain knowledge in semi-supervised learning algorithms. Our novel framework unifies and can exploit several kinds of *task specific constraints*. The experimental results presented in the information extraction domain demonstrate that applying constraints helps the model to generate better feedback during learning, and hence the framework allows for high performance learning with significantly less training data than was possible before on these tasks.

1 Introduction

Natural Language Processing (NLP) systems typically require large amounts of knowledge to achieve good performance. Acquiring labeled data is a difficult and expensive task. Therefore, an increasing attention has been recently given to semi-supervised learning, where large amounts of unlabeled data are used to improve the models learned from a small training set (Collins and Singer, 1999; Thelen and Riloff, 2002). The hope is that semi-supervised or even unsupervised approaches, when given enough knowledge about the *structure* of the problem, will be competitive with the supervised models trained on large training sets. However, in the general case, semi-supervised approaches give mixed results, and sometimes even degrade the model performance (Nigam et al., 2000). In many cases, improving semi-supervised models was done by *seeding* these models with domain information taken from dictionaries or ontology (Cohen and Sarawagi, 2004; Collins and Singer, 1999; Haghighi and Klein, 2006; Thelen and Riloff, 2002). On the other hand, in the supervised setting, it has been shown that incorporating domain and problem specific structured information can result in substantial improvements (Toutanova et al., 2005; Roth and Yih, 2005).

This paper proposes a novel constraints-based learning protocol for guiding semi-supervised learning. We develop a formalism for constraints-based learning that unifies several kinds of constraints: unary, dictionary based and n-ary constraints, which encode structural information and interdependencies among possible labels. One advantage of our formalism is that it allows capturing different levels of constraint violation. Our protocol can be used in the presence of any learning model, including those that acquire additional statistical constraints from observed data while learning (see Section 5. In the experimental part of this paper we use HMMs as the underlying model, and exhibit significant reduction in the number of training examples required in two information extraction problems.

As is often the case in semi-supervised learning, the algorithm can be viewed as a process that improves the model by generating feedback through

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 280–287,
Prague, Czech Republic, June 2007.

labeling unlabeled examples. Our algorithm pushes this intuition further, in that the use of constraints allows us to better exploit domain information as a way to label, along with the current learned model, unlabeled examples. Given a small amount of labeled data and a large unlabeled pool, our framework initializes the model with the labeled data and then repeatedly:
(1) Uses *constraints* and the learned model to label the instances in the pool.
(2) Updates the model by newly labeled data.

This way, we can generate *better* "training" examples during the semi-supervised learning process. The core of our approach, (1), is described in Section 5. The task is described in Section 3 and the Experimental study in Section 6. It is shown there that the improvement on the training examples via the constraints indeed boosts the learned model and the proposed method significantly outperforms the traditional semi-supervised framework.

2 Related Work

In the semi-supervised domain there are two main approaches for injecting domain specific knowledge. One is using the prior knowledge to accurately tailor the generative model so that it captures the domain structure. For example, (Grenager et al., 2005) proposes *Diagonal Transition Models* for sequential labeling tasks where neighboring words tend to have the same labels. This is done by constraining the HMM transition matrix, which can be done also for other models, such as CRF. However (Roth and Yih, 2005) showed that reasoning with more expressive, non-sequential constraints can improve the performance for the supervised protocol.

A second approach has been to use a small high-accuracy set of labeled tokens as a way to seed and bootstrap the semi-supervised learning. This was used, for example, by (Thelen and Riloff, 2002; Collins and Singer, 1999) in information extraction, and by (Smith and Eisner, 2005) in POS tagging. (Haghighi and Klein, 2006) extends the dictionary-based approach to sequential labeling tasks by propagating the information given in the seeds with contextual word similarity. This follows a conceptually similar approach by (Cohen and Sarawagi, 2004) that uses a large named-entity dictionary, where the similarity between the candidate named-entity and its matching prototype in the dictionary is encoded as a feature in a supervised classifier.

In our framework, dictionary lookup approaches are viewed as unary constraints on the output states. We extend these kinds of constraints and allow for more general, n-ary constraints.

In the supervised learning setting it has been established that incorporating global information can significantly improve performance on several NLP tasks, including information extraction and semantic role labeling. (Punyakanok et al., 2005; Toutanova et al., 2005; Roth and Yih, 2005). Our formalism is most related to this last work. But, we develop a semi-supervised learning protocol based on this formalism. We also make use of *soft* constraints and, furthermore, extend the notion of soft constraints to account for multiple levels of constraints' violation. Conceptually, although not technically, the most related work to ours is (Shen et al., 2005) that, in a somewhat ad-hoc manner uses soft constraints to guide an unsupervised model that was crafted for mention tracking. To the best of our knowledge, we are the first to suggest a general semi-supervised protocol that is driven by soft constraints.

We propose learning with constraints - a framework that combines the approaches described above in a unified and intuitive way.

3 Tasks, Examples and Datasets

In Section 4 we will develop a general framework for semi-supervised learning with constraints. However, it is useful to illustrate the ideas on concrete problems. Therefore, in this section, we give a brief introduction to the two domains on which we tested our algorithms. We study two information extraction problems in each of which, given text, a set of pre-defined fields is to be identified. Since the fields are typically related and interdependent, these kinds of applications provide a good test case for an approach like ours.[1]

The first task is to identify fields from citations (McCallum et al., 2000) . The data originally included 500 labeled references, and was later extended with 5,000 unannotated citations collected from papers found on the Internet (Grenager et al., 2005). Given a citation, the task is to extract the

Figure 1: Error analysis of a HMM model. The labels are annotated by underline and are to the right of each open bracket. The correct assignment was shown in (a). While the predicted label assignment (b) is generally coherent, some constraints are violated. Most obviously, punctuation marks are ignored as cues for state transitions. The constraint "Fields cannot end with stop words (such as "the")" may be also good.

fields that appear in the given reference. See Fig. 1. There are 13 possible fields including author, title, location, etc.

To gain an insight to how the constraints can guide semi-supervised learning, assume that the sentence shown in Figure 1 appears in the unlabeled data pool. Part (a) of the figure shows the correct labeled assignment and part (b) shows the assignment labeled by a HMM trained on 30 labels. However, if we apply the constraint that state transition can occur only on punctuation marks, the same HMM model parameters will result in the correct labeling (a). Therefore, by adding the improved labeled assignment we can generate better training samples during semi-supervised learning. In fact, the punctuation marks are only some of the constraints that can be applied to this problem. The set of constraints we used in our experiments appears in Table 1. Note that some of the constraints are non-local and are very intuitive for people, yet it is very difficult to inject this knowledge into most models.

The second problem we consider is extracting fields from advertisements (Grenager et al., 2005). The dataset consists of 8,767 advertisements for apartment rentals in the San Francisco Bay Area downloaded in June 2004 from the Craigslist website. In the dataset, only 302 entries have been labeled with 12 fields, including *size, rent, neighborhood, features*, and so on. The data was preprocessed using regular expressions for phone numbers, email addresses and URLs. The list of the constraints for this domain is given in Table 1. We implement some global constraints and include unary constraints which were largely imported from the list of seed words used in (Haghighi and Klein, 2006). We slightly modified the seedwords due to difference in preprocessing.

4 Notation and Definitions

Consider a structured classification problem, where given an input sequence $x = (x_1, \ldots, x_N)$, the task is to find the best assignment to the output variables $y = (y_1, \ldots, y_M)$. We denote $\mathcal{X}$ to be the space of the possible input sequences and $\mathcal{Y}$ to be the set of possible output sequences.

We define a structured output classifier as a function $h : \mathcal{X} \rightarrow \mathcal{Y}$ that uses a global scoring function $f : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ to assign scores to each possible input/output pair. Given an input x, a desired function f will assign the correct output y the highest score among all the possible outputs. The global scoring function is often decomposed as a weighted sum of feature functions,

$$f(x, y) = \sum_{i=1}^{M} \lambda_i f_i(x, y) = \boldsymbol{\lambda} \cdot F(x, y).$$

This decomposition applies both to discriminative linear models and to generative models such as HMMs and CRFs, in which case the linear sum corresponds to log likelihood assigned to the input/output pair by the model (for details see (Roth, 1999) for the classification case and (Collins, 2002) for the structured case). Even when not dictated by the model, the feature functions $f_i(x, y)$ used are local to allow inference tractability. Local feature function can capture some context for each input or output variable, yet it is very limited to allow dynamic programming decoding during inference.

Now, consider a scenario where we have a set of constraints $C_1, \ldots, C_K$. We define a constraint $C : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$ as a function that indicates whether the input/output sequence violates some desired properties. When the constraints are hard, the solution is given by

$$\operatorname*{argmax}_{y \in 1_{C(x)}} \boldsymbol{\lambda} \cdot F(x, y),$$

(a)-Citations

1) Each field must be a consecutive list of words, and can appear at most once in a citation.
2) State transitions must occur on punctuation marks.

Table 1: The list of constraints for extracting fields from citations and advertisements. Some constraints (represented in the first block of each domain) are global and are relatively difficult to inject into traditional models. While all the constraints hold for the vast majority of the data, some of them are violated by some correct labeled assignments.

where $1_{C(x)}$ is a subset of $\mathcal{Y}$ for which all C_i assign the value 1 for the given (x, y).

When the constraints are soft, we want to incur some penalty for their violation. Moreover, we want to incorporate into our cost function a measure for the *amount* of violation incurred by violating the constraint. A generic way to capture this intuition is to introduce a distance function $d(y, 1_{C_i(x)})$ between the space of outputs that respect the constraint,$1_{C_i(x)}$, and the given output sequence y. One possible way to implement this distance function is as the minimal Hamming distance to a sequence that respects the constraint C_i, that is: $d(y, 1_{C_i(x)}) = \min_{(y' \in 1_{C(x)})} H(y, y')$. If the penalty for violating the soft constraint C_i is ρ_i, we write the score function as:

$$\operatorname*{argmax}_y \boldsymbol{\lambda} \cdot F(x, y) - \sum_{i=1}^{K} \rho_i d(y, 1_{C_i(x)}) \qquad (1)$$

We refer to $d(y, 1_{C(x)})$ as the *valuation* of the constraint C on (x, y). The intuition behind (1) is as follows. Instead of merely maximizing the model's likelihood, we also want to bias the model using some knowledge. The first term of (1) is used to learn from data. The second term biases the mode by using the knowledge encoded in the constraints. Note that we do not normalize our objective function to be a true probability distribution.

5 Learning and Inference with Constraints

In this section we present a new constraint-driven learning algorithm (**CODL**) for using constraints to guide semi-supervised learning. The task is to learn the parameter vector $\boldsymbol{\lambda}$ by using the new objective function (1). While our formulation allows us to train also the coefficients of the constraints valuation, ρ_i, we choose not to do it, since we view this as a way to bias (or enforce) the prior knowledge into the learned model, rather than allowing the data to brush it away. Our experiments demonstrate that the proposed approach is robust to inaccurate approximation of the prior knowledge (assigning the same penalty to all the ρ_i).

We note that in the presence of constraints, the inference procedure (for finding the output y that maximizes the cost function) is usually done with search techniques (rather than Viterbi decoding, see (Toutanova et al., 2005; Roth and Yih, 2005) for a discussion), we chose beamsearch decoding.

The semi-supervised learning with constraints is done with an EM-like procedure. We initialize the model with traditional supervised learning (ignoring the constraints) on a small labeled set. Given an unlabeled set U, in the estimation step, the traditional EM algorithm assigns a distribution over labeled assignments $\mathcal{Y}$ of each $x \in U$, and in the maximization step, the set of model parameters is learned from the distributions assigned in the estimation step.

However, in the presence of constraints, assigning the complete distributions in the estimation step is infeasible since the constraints reshape the distribution in an arbitrary way. As in existing methods for training a model by maximizing a linear cost function (maximize likelihood or discriminative maxi-

mization), the distribution over $\mathcal{Y}$ is represented as the set of scores assigned to it; rather than considering the score assigned to *all* $y's$, we truncate the distribution to the top K assignments as returned by the search. Given a set of K top assignments $y^1, \ldots, y^K$, we approximate the estimation step by assigning uniform probability to the top K candidates, and zero to the other output sequences. We denote this algorithm *top-K hard EM*. In this paper, we use beamsearch to generate K candidates according to (1).

Our training algorithm is summarized in Figure 2. Several things about the algorithm should be clarified: the Top-K-Inference procedure in line 7, the learning procedure in line 9, and the new parameter estimation in line 9.

The Top-K-Inference is a procedure that returns the K labeled assignments that maximize the new objective function (1). In our case we used the top-K elements in the beam, but this could be applied to any other inference procedure. The fact that the constraints are used in the inference procedure (in particular, for generating new training examples) allows us to use a learning algorithm that ignores the constraints, which is a lot more efficient (although algorithms that do take the constraints into account can be used too). We used maximum likelihood estimation of $\boldsymbol{\lambda}$ but, in general, perceptron or quasi-Newton can also be used.

It is known that traditional semi-supervised training can degrade the learned model's performance. (Nigam et al., 2000) has suggested to balance the contribution of labeled and unlabeled data to the parameters. The intuition is that when iteratively estimating the parameters with EM, we disallow the parameters to drift too far from the supervised model. The parameter re-estimation in line 9, uses a similar intuition, but instead of weighting data instances, we introduced a smoothing parameter γ which controls the convex combination of models induced by the labeled and the unlabeled data. Unlike the technique mentioned above which focuses on naive Bayes, our method allows us to weight linear models generated by different learning algorithms.

Another way to look the algorithm is from the self-training perspective (McClosky et al., 2006). Similarly to self-training, we use the current model to generate new training examples from the unlabeled set. However, there are two important differences. One is that in self-training, once an unlabeled sample was labeled, it is never labeled again. In our case all the samples are relabeled in each iteration. In self-training it is often the case that only high-confidence samples are added to the labeled data pool. While we include all the samples in the training pool, we could also limit ourselves to the high-confidence samples. The second difference is that each unlabeled example generates K labeled instances. The case of one iteration of *top-1 hard EM* is equivalent to self training, where all the unlabeled samples are added to the labeled pool.

Input:
$Cycles$: learning cycles
$Tr = \{x, y\}$: labeled training set.
U: unlabeled dataset
F: set of feature functions.
$\{\rho_i\}$: set of penalties.
$\{C_i\}$: set of constraints.
γ: balancing parameter with the supervised model.
$learn(Tr, F)$: supervised learning algorithm
Top-K-Inference:
returns top-K labeled scored by the cost function (1)

CODL:
1. Initialize $\boldsymbol{\lambda}_0 = learn(Tr, F)$.
2. $\boldsymbol{\lambda} = \boldsymbol{\lambda}_0$.
3. For $Cycles$ iterations do:
4. $T = \phi$
5. For each $x \in U$
6. $\{(x, y^1), \ldots, (x, y^K)\} =$
7. Top-K-Inference$(x, \boldsymbol{\lambda}, F, \{C_i\}, \{\rho_i\})$
8. $T = T \cup \{(x, y^1), \ldots, (x, y^K)\}$
9. $\boldsymbol{\lambda} = \gamma\boldsymbol{\lambda}_0 + (1 - \gamma)learn(T, F)$

Figure 2: **CO**nstraint **D**riven **L**earning (CODL). In Top-K-Inference, we use beamsearch to find the K-best solution according to Eq. (1).

There are several possible benefits to using $K > 1$ samples. (1) It effectively increases the training set by a factor of K (albeit by somewhat noisy examples). In the structured scenario, each of the top-K assignments is likely to have some good components so generating top-K assignments helps leveraging the noise. (2) Given an assignment that does not satisfy some constraints, using top-K allows for multiple ways to correct it. For example, consider the output 11101000 with the constraint that it should belong to the language 1^*0^*. If the two top scoring corrections are 11111000 and 11100000, considering only one of those can negatively bias the model.

6 Experiments and Results

In this section, we present empirical results of our algorithms on two domains: *citations* and *advertisements*. Both problems are modeled with a simple token-based HMM. We stress that token-based HMM cannot represent many of our constraints. The function $d(y, 1_{C(x)})$ used is an approximation of a Hamming distance function, discussed in Section 7. For both domains, and all the experiments, γ was set to 0.1. The constraints violation penalty ρ is set to $-\log 10^{-4}$ and $-\log 10^{-1}$ for citations and advertisements, resp.[2] Note that all constraints share the same penalty. The number of semi-supervised training cycles (line 3 of Figure 2) was set to 5. The constraints for the two domains are listed in Table 1.

We trained models on training sets of size varying from 5 to 300 for the citations and from 5 to 100 for the advertisements. Additionally, in all the semi-supervised experiments, 1000 unlabeled examples are used. We report token-based[3] accuracy on 100 held-out examples (which do not overlap neither with the training nor with the unlabeled data). We ran 5 experiments in each setting, randomly choosing the training set. The results reported below are the averages over these 5 runs.

To verify our claims we implemented several baselines. The first baseline is the supervised learning protocol denoted by **sup**. The second baseline was a traditional **top-1 Hard EM** also known as truncated EM[4] (denoted by **H** for Hard). In the third baseline, denoted **H&W**, we balanced the weight of the supervised and unsupervised models as described in line 9 of Figure 2. We compare these baselines to our proposed protocol, **H&W&C**, where we added the constraints to guide the **H&W** protocol. We experimented with two flavors of the algorithm: the top-1 and the top-K version. In the top-K version, the algorithm uses K-best predictions (K=50) for each instance in order to update the model as described in Figure 2.

The experimental results for both domains are in given Table 2. As hypothesized, hard EM sometimes degrade the performance. Indeed, with 300 labeled examples in the citations domain, the performance decreases from 86.1 to 80.7. The usefulness of injecting constraints in semi-supervised learning is exhibited in the two right most columns: using constraints **H&W&C** improves the performance over **H&W** quite significantly.

Table 2: Experimental results for extracting fields from citations and advertisements. N is the number of labeled samples. **H** is the traditional hard-EM and **H&W** weighs labeled and unlabeled data as mentioned in Sec. 5. Our proposed model is **H&W&C**, which uses constraints in the learning procedure. **I** refers to using constraints during inference at evaluation time. Note that adding constraints improves the accuracy during both learning and inference.

We carefully examined the contribution of using constraints to the learning stage and the testing stage, and two separate results are presented: testing with constraints (denoted *I* for inference) and without constraints (*no I*). The *I* results are consistently better. And, it is also clear from Table 2, that using constraints in training always improves

[2] The guiding intuition is that $\boldsymbol{\lambda} F(x, y)$ corresponds to a log-likelihood of a HMM model and ρ to a crude estimation of the log probability that a constraint does not hold. ρ was tuned on a development set and kept fixed in all experiments.

[3] Each token (word or punctuation mark) is assigned a state.

[4] We also experimented with (soft) EM without constraints, but the results were generally worse.

the model and the amount of improvement depends on the amount of labeled data.

Figure 3 compares two protocols on the advertisements domain: **H&W+I**, where we first run the **H&W** protocol and then apply the constraints during testing stage, and **H&W&C+I**, which uses constraints to guide the model during learning and uses it also in testing. Although injecting constraints in the learning process helps, testing with constraints is more important than using constraints during learning, especially when the labeled data size is large. This confirms results reported for the supervised learning case in (Punyakanok et al., 2005; Roth and Yih, 2005). However, as shown, our proposed algorithm **H&W&C** for *training with constraints* is critical when the amount labeled data is small.

Figure 4 further strengthens this point. In the citations domain, **H&W&C+I** achieves with 20 labeled samples similar performance to the supervised version without constraints with 300 labeled samples.

(Grenager et al., 2005) and (Haghighi and Klein, 2006) also report results for semi-supervised learning for these domains. However, due to different preprocessing, the comparison is not straightforward. For the citation domain, when 20 labeled and 300 unlabeled samples are available, (Grenager et al., 2005) observed an increase from 65.2% to 71.3%. Our improvement is from 70.1% to 79.4%. For the advertisement domain, they observed no improvement, while our model improves from 68.1% to 74.6% with 20 labeled samples. Moreover, we successfully use out-of-domain data (web data) to improve our model, while they report that this data did not improve their unsupervised model.

(Haghighi and Klein, 2006) also worked on one of our data sets. Their underlying model, Markov Random Fields, allows more expressive features. Nevertheless, when they use only unary constraints they get 53.75%. When they use their final model, along with a mechanism for extending the prototypes to other tokens, they get results that are comparable to our model with 10 labeled examples. Additionally, in their framework, it is not clear how to use small amounts of labeled data when available. Our model outperforms theirs once we add 10 more examples.

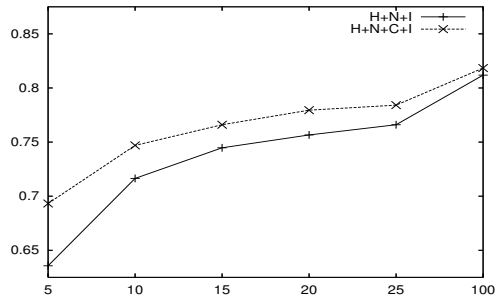

Figure 3: Comparison between **H&W+I** and **H&W&C+I** on the *advertisements* domain. When there is a lot of labeled data, inference with constraints is more important than using constraints during learning. However, it is important to train with constraints when the amount of labeled data is small.

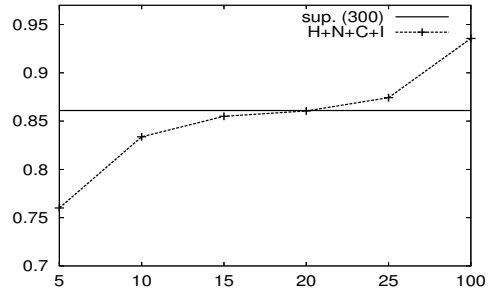

Figure 4: With 20 labeled citations, our algorithm performs competitively to the supervised version trained on 300 samples.

7 Soft Constraints

This section discusses the importance of using soft constraints rather than hard constraints, the choice of Hamming distance for $d(y, 1_{C(x)})$ and how we approximate it. We use two constraints to illustrate the ideas. *(C_1):* "state transitions can only occur on punctuation marks or newlines", and *(C_2):* "the field *TITLE* must appear".

First, we claim that defining $d(y, 1_{C(x)})$ to be the Hamming distance is superior to using a binary value, $d(y, 1_{C(x)}) = 0$ if $y \in 1_{C(x)}$ and 1 otherwise. Consider, for example, the constraint C_1 in the advertisements domain. While the vast majority of the instances satisfy the constraint, some violate it in more than one place. Therefore, once the binary distance is set to 1, the algorithm looses the ability to discriminate constraint violations in other locations

of the same instance. This may hurt the performance in both the inference and the learning stage.

Computing the Hamming distance exactly can be a computationally hard problem. Furthermore, it is unreasonable to implement the exact computation for each constraint. Therefore, we implemented a generic approximation for the hamming distance assuming only that we are given a boolean function $\phi_C(y_N)$ that returns whether labeling the token x_N with state y_N violates constraint with respect to an already labeled sequence $(x_1, \ldots, x_{N-1}, y_1, \ldots, y_{N-1})$. Then $d(y, 1_{C(x)}) = \sum_{i=1}^{N} \phi_C(y_i)$. For example, consider the prefix x_1, x_2, x_3, x_4, which contains no punctuation or newlines and was labeled $AUTH, AUTH, DATE, DATE$. This labeling violates C_1, the minimal hamming distance is 2, and our approximation gives 1, (since there is only one transition that violates the constraint.)

For constraints which cannot be validated based on prefix information, our approximation resorts to binary violation count. For instance, the constraint C_2 cannot be implemented with prefix information when the assignment is not complete. Otherwise, it would mean that the field TITLE should appear as early as possible in the assignment.

While (Roth and Yih, 2005) showed the significance of using hard constraints, our experiments show that using soft constraints is a superior option. For example, in the advertisements domain, C_1 holds for the large majority of the gold-labeled instances, but is sometimes violated. In supervised training with 100 labeled examples on this domain, **sup** gave 76.3% accuracy. When the constraint violation penalty ρ was *infinity* (equivalent to hard constraint), the accuracy improved to 78.7%, but when the penalty was set to $-log(0.1)$, the accuracy of the model jumped to 80.6%.

8 Conclusions and Future Work

We proposed to use constraints as a way to guide semi-supervised learning. The framework developed is general both in terms of the representation and expressiveness of the constraints, and in terms of the underlying model being learned – HMM in the current implementation. Moreover, our framework is a useful tool when the domain knowledge cannot be expressed by the model.

The results show that constraints improve not only the performance of the final inference stage but also propagate useful information during the semi-supervised learning process and that training with the constraints is especially significant when the number of labeled training data is small.

Abstract

Until quite recently, extending Phrase-based Statistical Machine Translation (PBSMT) with syntactic structure caused system performance to deteriorate. In this work we show that incorporating lexical syntactic descriptions in the form of supertags can yield significantly better PBSMT systems. We describe a novel PBSMT model that integrates supertags into the target language model and the target side of the translation model. Two kinds of supertags are employed: those from Lexicalized Tree-Adjoining Grammar and Combinatory Categorial Grammar. Despite the differences between these two approaches, the supertaggers give similar improvements. In addition to supertagging, we also explore the utility of a surface global grammaticality measure based on combinatory operators. We perform various experiments on the Arabic to English NIST 2005 test set addressing issues such as sparseness, scalability and the utility of system subcomponents. Our best result (0.4688 BLEU) improves by 6.1% relative to a state-of-the-art PBSMT model, which compares very favourably with the leading systems on the NIST 2005 task.

1 Introduction

Within the field of Machine Translation, by far the most dominant paradigm is Phrase-based Statistical Machine Translation (PBSMT) (Koehn et al., 2003; Tillmann & Xia, 2003). However, unlike in rule- and example-based MT, it has proven difficult to date to incorporate linguistic, syntactic knowledge in order to improve translation quality. Only quite recently have (Chiang, 2005) and (Marcu et al., 2006) shown that incorporating some form of syntactic structure could show improvements over a baseline PBSMT system. While (Chiang, 2005) avails of structure which is not linguistically motivated, (Marcu et al., 2006) employ syntactic structure to enrich the entries in the phrase table.

In this paper we explore a novel approach towards extending a standard PBSMT system with syntactic descriptions: we inject *lexical* descriptions into both the target side of the phrase translation table and the target language model. Crucially, the kind of lexical descriptions that we employ are those that are commonly devised within lexicon-driven approaches to linguistic syntax, e.g. Lexicalized Tree-Adjoining Grammar (Joshi & Schabes, 1992; Bangalore & Joshi, 1999) and Combinary Categorial Grammar (Steedman, 2000). In these linguistic approaches, it is assumed that the grammar consists of a very rich lexicon and a tiny, *impoverished*[1] set of combinatory operators that assemble lexical entries together into parse-trees. The lexical entries consist of syntactic constructs ('supertags') that describe information such as the POS tag of the word, its subcategorization information and the hierarchy of phrase categories that the word projects upwards. In this work we employ the lexical entries but exchange the algebraic combinatory operators with the more robust

[1] These operators neither carry nor presuppose further linguistic knowledge beyond what the lexicon contains.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 288–295,
Prague, Czech Republic, June 2007.

and efficient *supertagging* approach: like standard taggers, supertaggers employ probabilities based on local context and can be implemented using finite state technology, e.g. Hidden Markov Models (Bangalore & Joshi, 1999).

There are currently two supertagging approaches available: LTAG-based (Bangalore & Joshi, 1999) and CCG-based (Clark & Curran, 2004). Both the LTAG (Chen et al., 2006) and the CCG supertag sets (Hockenmaier, 2003) were acquired from the WSJ section of the Penn-II Treebank using hand-built extraction rules. Here we test both the LTAG and CCG supertaggers. We interpolate (log-linearly) the supertagged components (language model and phrase table) with the components of a standard PBSMT system. Our experiments on the Arabic–English NIST 2005 test suite show that each of the supertagged systems significantly improves over the baseline PBSMT system. Interestingly, combining the two taggers together diminishes the benefits of supertagging seen with the individual LTAG and CCG systems. In this paper we discuss these and other empirical issues.

The remainder of the paper is organised as follows: in section 2 we discuss the related work on enriching PBSMT with syntactic structure. In section 3, we describe the baseline PBSMT system which our work extends. In section 4, we detail our approach. Section 5 describes the experiments carried out, together with the results obtained. Section 6 concludes, and provides avenues for further work.

2 Related Work

Until very recently, the experience with adding syntax to PBSMT systems was negative. For example, (Koehn et al., 2003) demonstrated that adding syntax actually harmed the quality of their SMT system. Among the first to demonstrate improvement when adding recursive structure was (Chiang, 2005), who allows for hierarchical phrase probabilities that handle a range of reordering phenomena in the correct fashion. Chiang's derived grammar does not rely on any linguistic annotations or assumptions, so that the 'syntax' induced is not linguistically motivated.

Coming right up to date, (Marcu et al., 2006) demonstrate that 'syntactified' target language phrases can improve translation quality for Chinese–English. They employ a stochastic, top-down transduction process that assigns a joint probability to a source sentence and each of its alternative translations when rewriting the target parse-tree into a source sentence. The rewriting/transduction process is driven by "xRS rules", each consisting of a pair of a source phrase and a (possibly only partially) lexicalized syntactified target phrase. In order to extract xRS rules, the word-to-word alignment induced from the parallel training corpus is used to guide heuristic tree 'cutting' criteria.

While the research of (Marcu et al., 2006) has much in common with the approach proposed here (such as the syntactified target phrases), there remain a number of significant differences. Firstly, rather than induce millions of xRS rules from parallel data, we extract phrase pairs in the standard way (Och & Ney, 2003) and associate with each phrase-pair a set of target language syntactic structures based on supertag sequences. Relative to using arbitrary parse-chunks, the power of supertags lies in the fact that they are, syntactically speaking, rich lexical descriptions. A supertag can be assigned to every word in a phrase. On the one hand, the correct sequence of supertags could be assembled together, using only impoverished combinatory operators, into a small set of constituents/parses ('almost' a parse). On the other hand, because supertags are lexical entries, they facilitate robust syntactic processing (using Markov models, for instance) which does not necessarily aim at building a fully connected graph.

A second major difference with xRS rules is that our supertag-enriched target phrases *need not* be generalized into (xRS or any other) rules that work with abstract categories. Finally, like POS tagging, supertagging is more efficient than actual parsing or tree transduction.

3 Baseline Phrase-Based SMT System

We present the baseline PBSMT model which we extend with supertags in the next section. Our baseline PBSMT model uses GIZA++[2] to obtain word-level alignments in both language directions. The bidirectional word alignment is used to obtain phrase translation pairs using heuristics presented in

[2] http://www.fjoch.com/GIZA++.html

(Och & Ney, 2003) and (Koehn et al., 2003), and the Moses decoder was used for phrase extraction and decoding.[3]

Let t and s be the target and source language sentences respectively. Any (target or source) sentence x will consist of two parts: a bag of elements (words/phrases etc.) and an order over that bag. In other words, $x = \langle \phi_x, O_x \rangle$, where ϕ_x stands for the bag of phrases that constitute x, and O_x for the order of the phrases as given in x (O_x can be implemented as a function from a bag of tokens ϕ_x to a set with a finite number of positions). Hence, we may separate order from content:

$$\arg\max_t P(t|s) = \arg\max_t P(s \mid t)P(t) \quad (1)$$

$$= \arg\max_{\langle \phi_t, O_t \rangle} \overbrace{P(\phi_s \mid \phi_t)}^{TM} \overbrace{P(O_s \mid O_t)}^{distortion} \overbrace{P_w(t)}^{LM} \quad (2)$$

Here, $P_w(t)$ is the target language model, $P(O_s|O_t)$ represents the conditional (order) linear distortion probability, and $P(\phi_s|\phi_t)$ stands for a probabilistic translation model from target language bags of phrases to source language bags of phrases using a phrase translation table. As commonly done in PB-SMT, we interpolate these models log-linearly (using different λ weights) together with a word penalty weight which allows for control over the length of the target sentence t:

$$\arg\max_{\langle \phi_t, O_t \rangle} P(\phi_s \mid \phi_t)\ P(O_s \mid O_t)^{\lambda_o}$$
$$P_w(t)^{\lambda_{lm}}\ exp^{|t|\lambda_w}$$

For convenience of notation, the interpolation factor for the bag of phrases translation model is shown in formula (3) at the phrase level (but that does not entail any difference). For a bag of phrases ϕ_t consisting of phrases t_i, and bag ϕ_s consisting of phrases s_i, the phrase translation model is given by:

$$P(\phi_s \mid \phi_t) = \prod_{\substack{s_i \\ t_i}} P(s_i|t_i)$$

$$P(s_i|\ t_i) = P_{ph}(s_i|t_i)^{\lambda_{t1}} P_w(s_i|t_i)^{\lambda_{t2}} P_r(t_i|s_i)^{\lambda_{t3}} \quad (3)$$

where P_{ph} and P_r are the phrase-translation probability and its reverse probability, and P_w is the lexical translation probability.

4 Our Approach: Supertagged PBSMT

We extend the baseline model with lexical linguistic representations (*supertags*) both in the language model as well as in the phrase translation model. Before we describe how our model extends the baseline, we shortly review the supertagging approaches in Lexicalized Tree-Adjoining Grammar and Combinatory Categorial Grammar.

4.1 Supertags: Lexical Syntax

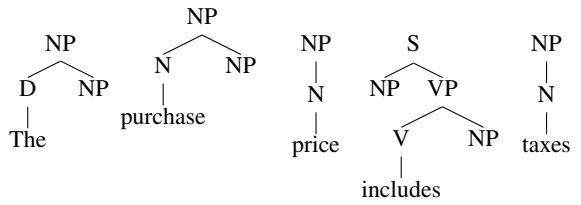

Figure 1: An LTAG supertag sequence for the sentence *The purchase price includes taxes*. The subcategorization information is most clearly available in the verb *includes* which takes a subject NP to its left and an object NP to its right.

Modern linguistic theory proposes that a syntactic parser has access to an extensive lexicon of word-structure pairs and a small, impoverished set of operations to manipulate and combine the lexical entries into parses. Examples of formal instantiations of this idea include CCG and LTAG. The lexical entries are syntactic constructs (graphs) that specify information such as POS tag, subcategorization/dependency information and other syntactic constraints at the level of agreement features. One important way of portraying such lexical descriptions is via the supertags devised in the LTAG and CCG frameworks (Bangalore & Joshi, 1999; Clark & Curran, 2004).

A supertag (see Figure 1) represents a complex, linguistic word category that encodes a syntactic structure expressing a specific local behaviour of a word, in terms of the arguments it takes (e.g. subject, object) and the syntactic environment in which it appears. In fact, in LTAG a supertag is an elementary tree and in CCG it is a CCG lexical category. Both descriptions can be viewed as closely related functional descriptions.

The term "supertagging" (Bangalore & Joshi, 1999) refers to tagging the words of a sentence, each

with a supertag. When well-formed, an ordered sequence of supertags can be viewed as a compact representation of a small set of constituents/parses that can be obtained by assembling the supertags together using the appropriate combinatory operators (such as substitution and adjunction in LTAG or function application and combination in CCG). Akin to POS tagging, the process of *supertagging* an input utterance proceeds with statistics that are based on the probability of a word-supertag pair given their Markovian or local context (Bangalore & Joshi, 1999; Clark & Curran, 2004). This is the main difference with full parsing: supertagging the input utterance need not result in a fully connected graph.

The LTAG-based supertagger of (Bangalore & Joshi, 1999) is a standard HMM tagger and consists of a (second-order) Markov language model over supertags and a lexical model conditioning the probability of every word on its own supertag (just like standard HMM-based POS taggers).

The CCG supertagger (Clark & Curran, 2004) is based on log-linear probabilities that condition a supertag on features representing its context. The CCG supertagger does not constitute a language model nor are the Maximum Entropy estimates directly interpretable as such. In our model we employ the CCG supertagger to obtain the best sequences of supertags for a corpus of sentences from which we obtain language model statistics. Besides the difference in probabilities and statistical estimates, these two supertaggers differ in the way the supertags are extracted from the Penn Treebank, cf. (Hockenmaier, 2003; Chen et al., 2006). Both supertaggers achieve a supertagging accuracy of 90–92%.

Three aspects make supertags attractive in the context of SMT. Firstly, supertags are rich syntactic constructs that exist for individual words and so they are easy to integrate into SMT models that can be based on any level of granularity, be it word- or phrase-based. Secondly, supertags specify the local syntactic constraints for a word, which resonates well with sequential (finite state) statistical (e.g. Markov) models. Finally, because supertags are rich lexical descriptions that represent underspecification in parsing, it is possible to have some of the benefits of full parsing without imposing the strict connectedness requirements that it demands.

4.2 A Supertag-Based SMT model

We employ the aforementioned supertaggers to enrich the English side of the parallel training corpus with a single supertag sequence per sentence. Then we extract phrase-pairs together with the cooccuring English supertag sequence from this corpus via the same phrase extraction method used in the baseline model. This way we directly extend the baseline model described in section 3 with supertags both in the phrase translation table and in the language model. Next we define the probabilistic model that accompanies this syntactic enrichment of the baseline model.

Let ST represent a supertag sequence of the same length as a target sentence t. Equation (2) changes as follows:

$$\arg\max_{t} \sum_{ST} P(s \mid t, ST) P_{ST}(t, ST) \approx$$

$$\arg\max_{\langle t, ST \rangle} \overbrace{P(\phi_s \mid \phi_{t,ST})}^{TM\ w.sup.tags} \overbrace{P(O_s \mid O_t)^{\lambda_o}}^{distortion}$$

$$\overbrace{P_{ST}(t, ST)}^{LM\ w.sup.tags} \overbrace{exp^{|t|\lambda_w}}^{word-penalty}$$

The approximations made in this formula are of two kinds: the standard split into components and the search for the most likely joint probability of a target hypothesis and a supertag sequence cooccuring with the source sentence (a kind of Viterbi approach to avoid the complex optimization involving the sum over supertag sequences). The distortion and word penalty models are the same as those used in the baseline PBSMT model.

Supertagged Language Model The 'language model' $P_{ST}(t, ST)$ is a supertagger assigning probabilities to sequences of word–supertag pairs. The language model is further smoothed by log-linear interpolation with the baseline language model over word sequences.

Supertags in Phrase Tables The supertagged phrase translation probability consists of a combination of supertagged components analogous to their counterparts in the baseline model (equation (3)), i.e. it consists of $P(s \mid t, ST)$, its reverse and a word-level probability. We smooth this probability by log-linear interpolation with the factored

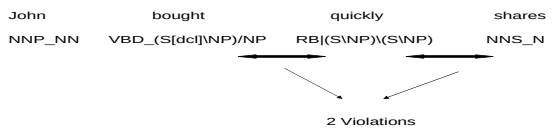

Figure 2: Example CCG operator violations: $V = 2$ and $L = 3$, and so the penalty factor is $1/3$.

backoff version $P(s \mid t)P(s \mid ST)$, where we import the baseline phrase table probability and exploit the probability of a source phrase given the target supertag sequence. A model in which we omit $P(s \mid ST)$ turns out to be slightly less optimal than this one.

As in most state-of-the-art PBSMT systems, we use GIZA++ to obtain word-level alignments in both language directions. The bidirectional word alignment is used to obtain lexical phrase translation pairs using heuristics presented in (Och & Ney, 2003) and (Koehn et al., 2003). Given the collected phrase pairs, we estimate the phrase translation probability distribution by relative frequency as follows:

$$\hat{P}_{ph}(s|t) = \frac{count(s,t)}{\sum_s count(s,t)}$$

For each extracted lexical phrase pair, we extract the corresponding supertagged phrase pairs from the supertagged target sequence in the training corpus (cf. section 5). For each lexical phrase pair, there is at least one corresponding supertagged phrase pair. The probability of the supertagged phrase pair is estimated by relative frequency as follows:

$$P_{st}(s|t, st) = \frac{count(s,t,st)}{\sum_s count(s,t,st)}$$

4.3 LMs with a Grammaticality Factor

The supertags usually encode dependency information that could be used to construct an 'almost parse' with the help of the CCG/LTAG composition operators. The *n*-gram language model over supertags applies a kind of statistical 'compositionality check' but due to smoothing effects this could mask crucial violations of the compositionality operators of the grammar formalism (CCG in this case). It is interesting to observe the effect of integrating into the language model a penalty imposed when formal compostion operators are violated. We combine the *n*-gram language model with a penalty factor that measures the number of encountered combinatory operator violations in a sequence of supertags (cf. Figure 2). For a supertag sequence of length (L) which has (V) operator violations (as measured by the CCG system), the language model P will be adjusted as $P* = P \times (1 - \frac{V}{L})$. This is of course no longer a simple smoothed maximum-likelihood estimate nor is it a true probability. Nevertheless, this mechanism provides a simple, efficient integration of a global compositionality (grammaticality) measure into the *n*-gram language model over supertags.

Decoder The decoder used in this work is Moses, a log-linear decoder similar to Pharaoh (Koehn, 2004), modified to accommodate supertag phrase probabilities and supertag language models.

5 Experiments

In this section we present a number of experiments that demonstrate the effect of lexical syntax on translation quality. We carried out experiments on the NIST open domain news translation task from Arabic into English. We performed a number of experiments to examine the effect of supertagging approaches (CCG or LTAG) with varying data sizes.

Data and Settings The experiments were conducted for Arabic to English translation and tested on the NIST 2005 evaluation set. The systems were trained on the LDC Arabic–English parallel corpus; we use the news part (130K sentences, about 5 million words) to train systems with what we call the *small* data set, and the news and a large part of the UN data (2 million sentences, about 50 million words) for experiments with *large* data sets.

The *n*-gram target language model was built using 250M words from the English GigaWord Corpus using the SRILM toolkit.[4] Taking 10% of the English GigaWord Corpus used for building our target language model, the supertag-based target language models were built from 25M words that were supertagged. For the LTAG supertags experiments, we used the LTAG English supertagger[5] (Bangalore

[4] http://www.speech.sri.com/projects/srilm/

[5] http://www.cis.upenn.edu/~xtag/gramrelease.html

& Joshi, 1999) to tag the English part of the parallel data and the supertag language model data. For the CCG supertag experiments, we used the CCG supertagger of (Clark & Curran, 2004) and the Edinburgh CCG tools[6] to tag the English part of the parallel corpus as well as the CCG supertag language model data.

The NIST MT03 test set is used for development, particularly for optimizing the interpolation weights using Minimum Error Rate training (Och, 2003).

Baseline System The baseline system is a state-of-the-art PBSMT system as described in section 3. We built two baseline systems with two different-sized training sets: 'Base-SMALL' (5 million words) and 'Base-LARGE' (50 million words) as described above. Both systems use a trigram language model built using 250 million words from the English GigaWord Corpus. Table 1 presents the BLEU scores (Papineni et al., 2002) of both systems on the NIST 2005 MT Evaluation test set.

System	BLEU Score
Base-SMALL	0.4008
Base-LARGE	0.4418

Table 1: Baseline systems' BLEU scores

5.1 Baseline vs. Supertags on Small Data Sets

We compared the translation quality of the baseline systems with the LTAG and CCG supertags systems (LTAG-SMALL and CCG-SMALL). The results are given in Table 2. All systems were trained on the same parallel data. The LTAG supertag-based system outperforms the baseline by 1.97 BLEU points absolute (or 4.9% relative), while the CCG supertag-based system scores 1.66 BLEU points over the baseline (4.1% relative). These significant improvements indicate that the rich information in supertags helps select better translation candidates.

System	BLEU Score
Base-SMALL	0.4008
LTAG-SMALL	0.4205
CCG-SMALL	0.4174

Table 2: LTAG and CCG systems on small data

POS Tags vs. Supertags A supertag is a complex tag that localizes the dependency and the syntax information from the context, whereas a normal POS tag just describes the general syntactic category of the word without further constraints. In this experiment we compared the effect of using supertags and POS tags on translation quality. As can be seen in Table 3, while the POS tags help (0.65 BLEU points, or 1.7% relative increase over the baseline), they clearly underperform compared to the supertag model (by 3.2%).

System	BLEU Score
Base-SMALL	0.4008
POS-SMALL	0.4073
LTAG-SMALL	.0.4205

Table 3: Comparing the effect of supertags and POS tags

The Usefulness of a Supertagged LM In these experiments we study the effect of the two added feature (cost) functions: supertagged translation and language models. We compare the baseline system to the supertags system with the supertag phrase-table probability but without the supertag LM. Table 4 lists the baseline system (Base-SMALL), the LTAG system without supertagged language model (LTAG-TM-ONLY) and the LTAG-SMALL system with both supertagged translation and language models. The results presented in Table 4 indicate that the improvement is a shared contribution between the supertagged translation and language models: adding the LTAG TM improves BLEU score by 1.38 points (3.4% relative) over the baseline, with the LTAG LM improving BLEU score by

System	BLEU Score
Base-SMALL	0.4008
LTAG-TM-ONLY	0.4146
LTAG-SMALL	.0.4205

Table 4: The effect of supertagged components

[6] http://groups.inf.ed.ac.uk/ccg/software.html

a further 0.59 points (a further 1.4% increase).

5.2 Scalability: Larger Training Corpora

Outperforming a PBSMT system on small amounts of training data is less impressive than doing so on really large sets. The issue here is scalability as well as whether the PBSMT system is able to bridge the performance gap with the supertagged system when reasonably large sizes of training data are used. To this end, we trained the systems on 2 million sentences of parallel data, deploying LTAG supertags and CCG supertags. Table 5 presents the comparison between these systems and the baseline trained on the same data. The LTAG system improves by 1.17 BLEU points (2.6% relative), but the CCG system gives an even larger increase: 1.91 BLEU points (4.3% relative). While this is slightly lower than the 4.9% relative improvement with the smaller data sets, the sustained increase is probably due to observing more data with different supertag contexts, which enables the model to select better target language phrases.

System	BLEU Score
Base-LARGE	0.4418
LTAG-LARGE	0.4535
CCG-LARGE	**0.4609**

Table 5: The effect of more training data

Adding a grammaticality factor As described in section 4.3, we integrate an impoverished grammaticality factor based on two standard CCG combination operations, namely Forward and Backward Application. Table 6 compares the results of the baseline, the CCG with an n-gram LM-only system (CCG-LARGE) and CCG-LARGE with this 'grammaticalized' LM system (CCG-LARGE-GRAM). We see that bringing the grammaticality tests to bear onto the supertagged system gives a further improvement of 0.79 BLEU points, a 1.7% relative increase, culminating in an overall increase of 2.7 BLEU points, or a 6.1% relative improvement over the baseline system.

System	BLEU Score
Base-LARGE	0.4418
CCG-LARGE	0.4609
CCG-LARGE-GRAM	**0.4688**

Table 6: Comparing the effect of CCG-GRAM

5.3 Discussion

A natural question to ask is whether LTAG and CCG supertags are playing similar (overlapping, or conflicting) roles in practice. Using an oracle to choose the best output of the two systems gives a BLEU score of 0.441, indicating that the combination provides significant room for improvement (cf. Table 2). However, our efforts to build a system that benefits from the combination using a simple log-linear combination of the two models did not give any significant performance change relative to the baseline CCG system. Obviously, more informed ways of combining the two could result in better performance than a simple log-linear interpolation of the components.

Figure 3 shows some example system output. While the baseline system omits the verb giving "the authorities that it had...", both the LTAG and CCG found a formulation "authorities reported that" with a closer meaning to the reference translation "The authorities said that". Omitting verbs turns out to be a problem for the baseline system when translating the notorious verbless Arabic sentences (see Figure 4). The supertagged systems have a more grammatically strict language model than a standard word-level Markov model, thereby exhibiting a preference (in the CCG system especially) for the insertion of a verb with a similar meaning to that contained in the reference sentence.

6 Conclusions

SMT practitioners have on the whole found it difficult to integrate syntax into their systems. In this work, we have presented a novel model of PBSMT which integrates supertags into the target language model and the target side of the translation model.

Using LTAG supertags gives the best improvement over a state-of-the-art PBSMT system for a smaller data set, while CCG supertags work best on a large 2 million-sentence pair training set. Adding grammaticality factors based on algebraic compositional operators gives the best result, namely 0.4688 BLEU, or a 6.1% relative increase over the baseline.

Figure 4: Verbless Arabic sentence and sample output from different systems

This result compares favourably with the best systems on the NIST 2005 Arabic–English task. We expect more work on system integration to improve results still further, and anticipate that similar increases are to be seen for other language pairs.

Regression for Sentence-Level MT Evaluation with Pseudo References

Joshua S. Albrecht and Rebecca Hwa
Department of Computer Science
University of Pittsburgh
{jsa8,hwa}@cs.pitt.edu

Abstract

Many automatic evaluation metrics for machine translation (MT) rely on making comparisons to human translations, a resource that may not always be available. We present a method for developing sentence-level MT evaluation metrics that do not directly rely on human reference translations. Our metrics are developed using regression learning and are based on a set of weaker indicators of fluency and adequacy (*pseudo references*). Experimental results suggest that they rival standard reference-based metrics in terms of correlations with human judgments on new test instances.

1 Introduction

Automatic assessment of translation quality is a challenging problem because the evaluation task, at its core, is based on subjective human judgments. Reference-based metrics such as BLEU (Papineni et al., 2002) have rephrased this subjective task as a somewhat more objective question: how closely does the translation resemble sentences that are known to be good translations for the same source? This approach requires the participation of human translators, who provide the "gold standard" reference sentences. However, keeping humans in the evaluation loop represents a significant expenditure both in terms of time and resources; therefore it is worthwhile to explore ways of reducing the degree of human involvement.

To this end, Gamon et al. (2005) proposed a learning-based evaluation metric that does not compare against reference translations. Under a learning framework, the input (i.e., the sentence to be evaluated) is represented as a set of *features*. These are measurements that can be extracted from the input sentence (and may be individual metrics themselves). The learning algorithm combines the features to form a model (a composite evaluation metric) that produces the final score for the input. Without human references, the features in the model proposed by Gamon et al. were primarily language model features and linguistic indicators that could be directly derived from the input sentence alone. Although their initial results were not competitive with standard reference-based metrics, their studies suggested that a referenceless metric may still provide useful information about translation fluency. However, a potential pitfall is that systems might "game the metric" by producing fluent outputs that are not adequate translations of the source.

This paper proposes an alternative approach to evaluate MT outputs without comparing against human references. While our metrics are also trained, our model consists of different features and is trained under a different learning regime. Crucially, our model includes features that capture some notions of adequacy by comparing the input against *pseudo references*: sentences from other MT systems (such as commercial off-the-shelf systems or open sourced research systems). To improve fluency judgments, the model also includes features that compare the input against target-language "references" such as large text corpora and treebanks.

Unlike human translations used by standard reference-based metrics, pseudo references are not

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 296–303,
Prague, Czech Republic, June 2007.

"gold standards" and can be worse than the sentences being evaluated; therefore, these "references" in-and-of themselves are not necessarily informative enough for MT evaluation. The main insight of our approach is that through regression, the trained metrics can make more nuanced comparisons between the input and pseudo references. More specifically, our regression objective is to infer a function that maps a feature vector (which measures an input's similarity to the pseudo references) to a score that indicates the quality of the input. This is achieved by optimizing the model's output to correlate against a set of training examples, which are translation sentences labeled with quantitative assessments of their quality by human judges. Although this approach does incur some human effort, it is primarily for the development of training data, which, ideally, can be amortized over a long period of time.

To determine the feasibility of the proposed approach, we conducted empirical studies that compare our trained metrics against standard reference-based metrics. We report three main findings. First, pseudo references are informative comparison points. Experimental results suggest that a regression-trained metric that compares against pseudo references can have higher correlations with human judgments than applying standard metrics with multiple human references. Second, the learning model that uses both adequacy and fluency features performed the best, with adequacy being the more important factor. Third, when the pseudo references are multiple MT systems, the regression-trained metric is predictive even when the input is from a better MT system than those providing the references. We conjecture that comparing MT outputs against other imperfect translations allows for a more nuanced discrimination of quality.

2 Background and Related Work

For a formally organized event, such as the annual MT Evaluation sponsored by National Institute of Standard and Technology (NIST MT Eval), it may be worthwhile to recruit multiple human translators to translate a few hundred sentences for evaluation references. However, there are situations in which multiple human references are not practically available (e.g., the source may be of a large quantity, and no human translation exists). One such instance is translation quality assurance, in which one wishes to identify poor outputs in a large body of machine translated text automatically for human to post-edit. Another instance is in day-to-day MT research and development, where new test set with multiple references are also hard to come by. One could work with previous datasets from events such as the NIST MT Evals, but there is a danger of over-fitting. One also could extract a single reference from parallel corpora, although it is known that automatic metrics are more reliable when comparing against multiple references.

The aim of this work is to develop a trainable automatic metric for evaluation without human references. This can be seen as a form of confidence estimation on MT outputs (Blatz et al., 2003; Ueffing et al., 2003; Quirk, 2004). The main distinction is that confidence estimation is typically performed with a particular system in mind, and may rely on system-internal information in estimation. In this study, we draw on only system-independent indicators so that the resulting metric may be more generally applied. This allows us to have a clearer picture of the contributing factors as they interact with different types of MT systems.

Also relevant is previous work that applied machine learning approaches to MT evaluation, both with human references (Corston-Oliver et al., 2001; Kulesza and Shieber, 2004; Albrecht and Hwa, 2007; Liu and Gildea, 2007) and without (Gamon et al., 2005). One motivation for the learning approach is the ease of combining multiple criteria. Literature in translation evaluation reports a myriad of criteria that people use in their judgments, but it is not clear how these factors should be combined mathematically. Machine learning offers a principled and unified framework to induce a computational model of human's decision process. Disparate indicators can be encoded as one or more input features, and the learning algorithm tries to find a mapping from input features to a score that quantifies the input's quality by optimizing the model to match human judgments on training examples. The framework is attractive because its objective directly captures the goal of MT evaluation: how would a user rate the quality of these translations?

This work differs from previous approaches in

two aspects. One is the representation of the model; our model treats the metric as a distance measure even though there are no human references. Another is the training of the model. More so than when human references are available, regression is central to the success of the approach, as it determines how much we can trust the distance measures against each pseudo reference system.

While our model does not use human references directly, its features are adapted from the following distance-based metrics. The well-known BLEU (Papineni et al., 2002) is based on the number of common n-grams between the translation hypothesis and human reference translations of the same sentence. Metrics such as ROUGE, Head Word Chain (HWC), METEOR, and other recently proposed methods all offer different ways of comparing machine and human translations. ROUGE utilizes 'skip n-grams', which allow for matches of sequences of words that are not necessarily adjacent (Lin and Och, 2004a). METEOR uses the Porter stemmer and synonym-matching via WordNet to calculate recall and precision more accurately (Banerjee and Lavie, 2005). The HWC metrics compare dependency and constituency trees for both reference and machine translations (Liu and Gildea, 2005).

3 MT Evaluation with Pseudo References using Regression

Reference-based metrics are typically thought of as measurements of "similarity to good translations" because human translations are used as references, but in more general terms, they are distance measurements between two sentences. The distance between a translation hypothesis and an imperfect reference is still somewhat informative. As a toy example, consider a one-dimensional line segment. A distance from the end-point uniquely determines the position of a point. When the reference location is anywhere else on the line segment, a relative distance to the reference does not uniquely specify a location on the line segment. However, the position of a point can be uniquely determined if we are given its relative distances to two reference locations.

The problem space for MT evaluation, though more complex, is not dissimilar to the toy scenario. There are two main differences. First, we do not know the actual distance function – this is what we are trying to learn. The distance functions we have at our disposal are all heuristic approximations to the true translational distance function. Second, unlike human references, whose quality value is assumed to be maximum, the quality of a pseudo reference sentence is not known. In fact, prior to training, we do not even know the quality of the reference systems. Although the direct way to calibrate a reference system is to evaluate *its* outputs, this is not practically ideal, since human judgments would be needed each time we wish to incorporate a new reference system. Our proposed alternative is to calibrate the reference systems against an existing set of human judgments for a range of outputs from different MT systems. That is, if many of the reference system's outputs are similar to those MT outputs that received low assessments, we conclude this reference system may not be of high quality. Thus, if a new translation is found to be similar with this reference system's output, it is more likely for the new translation to also be bad.

Both issues of combining evidences from heuristic distances and calibrating the quality of pseudo reference systems can be addressed by a probabilistic learning model. In particular, we use regression because its problem formulation fits naturally with the objective of MT evaluations. In regression learning, we are interested in approximating a function f that maps a multi-dimensional input vector, $\mathbf{x}$, to a continuous real value, y, such that the error over a set of m training examples, $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_m, y_m)\}$, is minimized according to a loss function.

In the context of MT evaluation, y is the "true" quantitative measure of translation quality for an input sentence[1]. The function f represents a mathematical model of human judgments of translations; an input sentence is represented as a feature vector, $\mathbf{x}$, which contains the information that can be extracted from the input sentence (possibly including comparisons against some reference sentences) that are relevant to computing y. Determining the set of relevant features for this modeling is on-going re-

[1] Perhaps even more so than grammaticality judgments, there is variability in people's judgments of translation quality. However, like grammaticality judgments, people do share some similarities in their judgments at a coarse-grained level. Ideally, what we refer to as the true value of translational quality should reflect the consensus judgments of all people.

search. In this work, we consider some of the more widely used metrics as features. Our full feature vector consists of $r \times 18$ adequacy features, where r is the number of reference systems used, and 26 fluency features:

Adequacy features: These include features derived from BLEU (e.g., n-gram precision, where $1 \leq n \leq 5$, length ratios), PER, WER, features derived from METEOR (precision, recall, fragmentation), and ROUGE-related features (non-consecutive bigrams with a gap size of g, where $1 \leq g \leq 5$ and longest common subsequence).

Fluency features: We consider both string-level features such as computing n-gram precision against a target-language corpus as well as several syntax-based features. We parse each input sentence into a dependency tree and compared aspects of it against a large target-language dependency treebank. In addition to adapting the idea of Head Word Chains (Liu and Gildea, 2005), we also compared the input sentence's argument structures against the treebank for certain syntactic categories.

Due to the large feature space to explore, we chose to work with support vector regression as the learning algorithm. As its loss function, support vector regression uses an ϵ-insensitive error function, which allows for errors within a margin of a small positive value, ϵ, to be considered as having zero error (cf. Bishop (2006), pp.339-344). Like its classification counterpart, this is a kernel-based algorithm that finds sparse solutions so that scores for new test instances are efficiently computed based on a subset of the most informative training examples. In this work, Gaussian kernels are used.

The cost of regression learning is that it requires training examples that are manually assessed by human judges. However, compared to the cost of creating new references whenever new (test) sentences are evaluated, the effort of creating human assessment training data is a limited (ideally, one-time) cost. Moreover, there is already a sizable collection of human assessed data for a range of MT systems through multiple years of the NIST MT Eval efforts. Our experiments suggest that there is enough assessed data to train the proposed regression model.

Aside from reducing the cost of developing human reference translations, the proposed metric also provides an alternative perspective on automatic MT evaluation that may be informative in its own right. We conjecture that a metric that compares inputs against a diverse population of differently imperfect sentences may be more discriminative in judging translation systems than solely comparing against gold standards. That is, two sentences may be considered equally bad from the perspective of a gold standard, but subtle differences between them may become more prominent if they are compared against sentences in their peer group.

4 Experiments

We conducted experiments to determine the feasibility of the proposed approach and to address the following questions: (1) How informative are pseudo references in-and-of themselves? Does varying the number and/or the quality of the references have an impact on the metrics? (2) What are the contributions of the adequacy features versus the fluency features to the learning-based metric? (3) How do the quality and distribution of the training examples, together with the quality of the pseudo references, impact the metric training? (4) Do these factors impact the metric's ability in assessing sentences produced within a single MT system? How does that system's quality affect metric performance?

4.1 Data preparation and Experimental Setup

The implementation of support vector regression used for these experiments is SVM-Light (Joachims, 1999). We performed all experiments using the 2004 NIST Chinese MT Eval dataset. It consists of 447 source sentences that were translated by four human translators as well as ten MT systems. Each machine translated sentence was evaluated by two human judges for their fluency and adequacy on a 5-point scale[2]. To remove the bias in the distributions of scores between different judges, we follow the normalization procedure described by Blatz et al. (2003). The two judge's total scores (i.e., sum of the normalized fluency and adequacy scores) are then averaged.

[2]The NIST human judges use human reference translations when making assessments; however, our approach is generally applicable when the judges are bilingual speakers who compare source sentences with translation outputs.

We chose to work with this NIST dataset because it contains numerous systems that span over a range of performance levels (see Table 1 for a ranking of the systems and their averaged human assessment scores). This allows us to have control over the variability of the experiments while answering the questions we posed above (such as the quality of the systems providing the pseudo references, the quality of MT systems being evaluated, and the diversity over the distribution of training examples).

Specifically, we reserved four systems (MT2, MT5, MT6, and MT9) for the role of pseudo references. Sentences produced by the remaining six systems are used as evaluative data. This set includes the best and worst systems so that we can see how well the metrics performs on sentences that are better (or worse) than the pseudo references. Metrics that require no learning are directly applied onto all sentences of the evaluative set. For the learning-based metrics, we perform six-fold cross validation on the evaluative dataset. Each fold consists of sentences from one MT system. In a round robin fashion, each fold serves as the test set while the other five are used for training and heldout. Thus, the trained models have seen neither the test instances nor other instances from the MT system that produced them.

A metric is evaluated based on its Spearman rank correlation coefficient between the scores it gave to the evaluative dataset and human assessments for the same data. The correlation coefficient is a real number between -1, indicating perfect negative correlations, and +1, indicating perfect positive correlations. To compare the relative quality of different metrics, we apply bootstrapping re-sampling on the data, and then use paired t-test to determine the statistical significance of the correlation differences (Koehn, 2004). For the results we report, unless explicitly mentioned, all stated comparisons are statistically significant with 99.8% confidence. We include two standard reference-based metrics, BLEU and METEOR, as baseline comparisons. BLEU is smoothed (Lin and Och, 2004b), and it considers only matching up to bigrams because this has higher correlations with human judgments than when higher-ordered n-grams are included.

SysID	Human-assessment score
MT1	0.661
MT2	**0.626**
MT3	0.586
MT4	0.578
MT5	**0.537**
MT6	**0.530**
MT7	0.530
MT8	0.375
MT9	**0.332**
MT10	0.243

Table 1: The human-judged quality of ten participating systems in the NIST 2004 Chinese MT Evaluation. We used four systems as references (highlighted in boldface) and the data from the remaining six for training and evaluation.

4.2 Pseudo Reference Variations vs. Metrics

We first compare different metrics' performance on the six-system evaluative dataset under different configurations of human and/or pseudo references. For the case when only one human reference is used, the reference was chosen at random from the 2004 NIST Eval dataset[3]. The correlation results on the evaluative dataset are summarized in Table 2.

Some trends are as expected: comparing within a metric, having four references is better than having just one; having human references is better than an equal number of system references; having a high quality system as reference is better than one with low quality. Perhaps more surprising is the consistent trend that metrics do significantly better with four MT references than with one human reference, and they do almost as well as using four human references. The results show that pseudo references are informative, as standard metrics were able to make use of the pseudo references and achieve higher correlations than judging from fluency alone. However, higher correlations are achieved when learning with regression, suggesting that the trained metrics are better at interpreting comparisons against pseudo references.

Comparing within each reference configuration, the regression-trained metric that includes both ad-

[3]One reviewer asked about the quality this human's translations. Although we were not given official rankings of the human references, we compared each person against the other three using MT evaluation metrics and found this particular translator to rank third, though the quality of all four are significantly higher than even the best MT systems.

equacy and fluency features always has the highest correlations. If the metric consists of only adequacy features, its performance degrades with the decreasing quality of the references. At another extreme, a metric based only on fluency features has an overall correlation rate of 0.459, which is lower than most correlations reported in Table 2. This confirms the importance of modeling adequacy; even a single mid-quality MT system may be an informative pseudo reference. Finally, we note that a regression-trained metric with the full features set that compares against 4 pseudo references has a higher correlation than BLEU with four human references. These results suggest that the feedback from the human assessed training examples was able to help the learning algorithm to combine different features to form a better composite metric.

4.3 Sentence-Level Evaluation on Single Systems

To explore the interaction between the quality of the reference MT systems and that of the test MT systems, we further study the following pseudo reference configurations: all four systems, a high-quality system with a medium quality system, two systems of medium-quality, one medium with one poor system, and only the high-quality system. For each pseudo reference configuration, we consider three metrics: BLEU, METEOR, and the regression-trained metric (using the full feature set). Each metric evaluates sentences from four test systems of varying quality: the best system in the dataset (MT1), the worst in the set (MT10), and two mid-ranged systems (MT4 and MT7). The correlation coefficients are summarized in Table 3. Each row specifies a metric/reference-type combination; each column specifies an MT system being evaluated (using sentences from all other systems as training examples). The fluency-only metric and standard metrics using four human references are baselines.

The overall trends at the dataset level generally also hold for the per-system comparisons. With the exception of the evaluation of MT10, regression-based metrics always has higher correlations than standard metrics that use the same reference configuration (comparing correlation coefficients within each cell). When the best MT reference system (MT2) is included as pseudo references, regression-based metrics are typically better than or not statistically different from standard applications of BLEU and METEOR with 4 human references. Using the two mid-quality MT systems as references (MT5 and MT6), regression metrics yield correlations that are only slightly lower than standard metrics with human references. These results support our conjecture that comparing against multiple systems is informative.

The poorer performances of the regression-based metrics on MT10 point out an asymmetry in the learning approach. The regression model aims to learn a function that approximates human judgments of translated sentences through training examples. In the space of all possible MT outputs, the neighborhood of good translations is much smaller than that of bad translations. Thus, as long as the regression models sees some examples of sentences with high assessment scores during training, it should have a much better estimation of the characteristics of good translations. This idea is supported by the experimental data. Consider the scenario of evaluating MT1 while using two mid-quality MT systems as references. Although the reference systems are not as high quality as the system under evaluation, and although the training examples shown to the regression model were also generated by systems whose overall quality was rated lower, the trained metric was reasonably good at ranking sentences produced by MT1. In contrast, the task of evaluating sentences from MT10 is more difficult for the learning approach, perhaps because it is sufficiently different from all training and reference systems. Correlations might be improved with additional reference systems.

4.4 Discussions

The design of these experiments aims to simulate practical situations to use our proposed metrics. For the more frequently encountered language pairs, it should be possible to find at least two mid-quality (or better) MT systems to serve as pseudo references. For example, one might use commercial off-the-shelf systems, some of which are free over the web. For less commonly used languages, one might use open source research systems (Al-Onaizan et al., 1999; Burbank et al., 2005).

Datasets from formal evaluation events such as

Ref type and #	Ref Sys.	BLEU-S(2)	METEOR	Regr (adq. only)	Regr (full)

Table 3: Correlation comparisons of metrics by test systems. For each test system (columns) the overall highest correlations is distinguished by an asterisk (*); correlations higher than *standard metrics using human-references* are highlighted in boldface; those that are statistically comparable to them are italicized.

NIST MT Evals, which contains human assessed MT outputs for a variety of systems, can be used for training examples. Alternatively, one might directly recruit human judges to assess sample sentences from the system(s) to be evaluated. This should result in better correlations than what we reported here, since the human assessed training examples will be more similar to the test instances than the setup in our experiments.

In developing new MT systems, pseudo references may supplement the single human reference translations that could be extracted from a parallel text. Using the same setup as Exp. 1 (see Table 2), adding pseudo references does improve correlations. Adding four pseudo references to the single human reference raises the correlation coefficient to 0.650 (from 0.597) for the regression metric. Adding them to four human references results in a correlation coefficient of 0.660 (from 0.644)[4].

5 Conclusion

In this paper, we have presented a method for developing sentence-level MT evaluation metrics without using human references. We showed that by learning from human assessed training examples,

[4]BLEU with four human references has a correlation of 0.628. Adding four pseudo references increases BLEU to 0.650.

the regression-trained metric can evaluate an input sentence by comparing it against multiple machine-generated pseudo references and other target language resources. Our experimental results suggest that the resulting metrics are robust even when the sentences under evaluation are from a system of higher quality than the systems serving as references. We observe that regression metrics that use multiple pseudo references often have comparable or higher correlation rates with human judgments than standard reference-based metrics. Our study suggests that in conjunction with regression training, multiple imperfect references may be as informative as gold-standard references.

Bootstrapping Word Alignment via Word Packing

Yanjun Ma, Nicolas Stroppa, Andy Way

Abstract

We introduce a simple method to pack words for statistical word alignment. Our goal is to simplify the task of automatic word alignment by packing several consecutive words together when we believe they correspond to a single word in the opposite language. This is done using the word aligner itself, i.e. by bootstrapping on its output. We evaluate the performance of our approach on a Chinese-to-English machine translation task, and report a 12.2% relative increase in BLEU score over a state-of-the art phrase-based SMT system.

1 Introduction

Automatic word alignment can be defined as the problem of determining a translational correspondence at word level given a parallel corpus of aligned sentences. Most current statistical models (Brown et al., 1993; Vogel et al., 1996; Deng and Byrne, 2005) treat the aligned sentences in the corpus as sequences of tokens that are meant to be words; the goal of the alignment process is to find links between source and target words. Before applying such aligners, we thus need to segment the sentences into words – a task which can be quite hard for languages such as Chinese for which word boundaries are not orthographically marked. More importantly, however, this segmentation is often performed in a *monolingual* context, which makes the word alignment task more difficult since different languages may realize the same concept using varying numbers of words (see e.g. (Wu, 1997)). Moreover, a segmentation considered to be "good" from a monolingual point of view may be unadapted for training alignment models.

Although some statistical alignment models allow for 1-to-n word alignments for those reasons, they rarely question the monolingual tokenization and the basic unit of the alignment process remains the word. In this paper, we focus on 1-to-n alignments with the goal of simplifying the task of automatic word aligners by *packing* several consecutive words together when we believe they correspond to a single word in the opposite language; by identifying enough such cases, we reduce the number of 1-to-n alignments, thus making the task of word alignment both easier and more natural.

Our approach consists of using the output from an existing statistical word aligner to obtain a set of candidates for word packing. We evaluate the reliability of these candidates, using simple metrics based on co-occurence frequencies, similar to those used in associative approaches to word alignment (Kitamura and Matsumoto, 1996; Melamed, 2000; Tiedemann, 2003). We then modify the segmentation of the sentences in the parallel corpus according to this packing of words; these modified sentences are then given back to the word aligner, which produces new alignments. We evaluate the validity of our approach by measuring the influence of the alignment process on a Chinese-to-English Machine Translation (MT) task.

The remainder of this paper is organized as follows. In Section 2, we study the case of 1-to-n word alignment. Section 3 introduces an automatic method to pack together groups of consecutive

words based on the output from a word aligner. In Section 4, the experimental setting is described. In Section 5, we evaluate the influence of our method on the alignment process on a Chinese to English MT task, and experimental results are presented. Section 6 concludes the paper and gives avenues for future work.

2 The Case of 1-to-n Alignment

The same concept can be expressed in different languages using varying numbers of words; for example, a single Chinese word may surface as a compound or a collocation in English. This is frequent for languages as different as Chinese and English. To quickly (and approximately) evaluate this phenomenon, we trained the statistical IBM word-alignment model 4 (Brown et al., 1993),[1] using the GIZA++ software (Och and Ney, 2003) for the following language pairs: Chinese–English, Italian–English, and Dutch–English, using the IWSLT-2006 corpus (Takezawa et al., 2002; Paul, 2006) for the first two language pairs, and the Europarl corpus (Koehn, 2005) for the last one. These asymmetric models produce 1-to-n alignments, with $n \geq 0$, in both directions. Here, it is important to mention that the segmentation of sentences is performed totally independently of the bilingual alignment process, i.e. it is done in a *monolingual* context. For European languages, we apply the maximum-entropy based tokenizer of OpenNLP[2]; the Chinese sentences were human segmented (Paul, 2006).

In Table 1, we report the frequencies of the different types of alignments for the various languages and directions. As expected, the number of 1:n alignments with $n \neq 1$ is high for Chinese–English ($\simeq 40\%$), and significantly higher than for the European languages. The case of 1-to-n alignments is, therefore, obviously an important issue when dealing with Chinese–English word alignment.[3]

2.1 The Treatment of 1-to-n Alignments

Fertility-based models such as IBM models 3, 4, and 5 allow for alignments between one word and several words (1-to-n or 1:n alignments in what follows), in particular for the reasons specified above. They can be seen as extensions of the simpler IBM models 1 and 2 (Brown et al., 1993). Similarly, Deng and Byrne (2005) propose an HMM framework capable of dealing with 1-to-n alignment, which is an extension of the original model of (Vogel et al., 1996).

However, these models rarely question the monolingual tokenization, i.e. the basic unit of the alignment process is the word.[4] One alternative to extending the expressivity of one model (and usually its complexity) is to focus on the *input representation*; in particular, we argue that the alignment process can benefit from a simplification of the input, which consists of trying to reduce the number of 1-to-n alignments to consider. Note that the need to consider segmentation and alignment at the same time is also mentioned in (Tiedemann, 2003), and related issues are reported in (Wu, 1997).

2.2 Notation

While in this paper, we focus on Chinese–English, the method proposed is applicable to any language

[1] More specifically, we performed 5 iterations of Model 1, 5 iterations of HMM, 5 iterations of Model 3, and 5 iterations of Model 4.

[2] `http://opennlp.sourceforge.net/`.

[3] Note that a 1:0 alignment may denote a failure to capture a 1:n alignment with $n > 1$.

[4] Interestingly, this is actually even the case for approaches that directly model alignments between phrases (Marcu and Wong, 2002; Birch et al., 2006).

pair – even for closely related languages, we expect improvements to be seen. The notation however assume Chinese–English MT. Given a Chinese sentence c_1^J consisting of J words $\{c_1, \ldots, c_J\}$ and an English sentence e_1^I consisting of I words $\{e_1, \ldots, e_I\}$, $A_{C \to E}$ (resp. $A_{E \to C}$) will denote a Chinese-to-English (resp. an English-to-Chinese) word alignment between c_1^J and e_1^I. Since we are primarily interested in 1-to-n alignments, $A_{C \to E}$ can be represented as a set of pairs $a_j = \langle c_j, E_j \rangle$ denoting a link between one single Chinese word c_j and a few English words E_j (and similarly for $A_{E \to C}$). The set E_j is empty if the word c_j is not aligned to any word in e_1^I.

3 Automatic Word Repacking

Our approach consists of packing consecutive words together when we believe they correspond to a single word in the other language. This bilingually motivated packing of words changes the basic unit of the alignment process, and simplifies the task of automatic word alignment. We thus minimize the number of 1-to-n alignments in order to obtain more comparable segmentations in the two languages. In this section, we present an automatic method that builds upon the output from an existing automatic word aligner. More specifically, we (i) use a word aligner to obtain 1-to-n alignments, (ii) extract candidates for word packing, (iii) estimate the reliability of these candidates, (iv) replace the groups of words to pack by a single token in the parallel corpus, and (v) re-iterate the alignment process using the updated corpus. The first three steps are performed in both directions, and produce two *bilingual dictionaries* (source-target and target-source) of groups of words to pack.

3.1 Candidate Extraction

In the following, we assume the availability of an automatic word aligner that can output alignments $A_{C \to E}$ and $A_{E \to C}$ for any sentence pair (c_1^J, e_1^I) in a parallel corpus. We also assume that $A_{C \to E}$ and $A_{E \to C}$ contain $1{:}\,n$ alignments. Our method for repacking words is very simple: whenever a single word is aligned with several consecutive words, they are considered candidates for repacking. Formally, given an alignment $A_{C \to E}$ between c_1^J and e_1^I, if $a_j = \langle c_j, E_j \rangle \in A_{C \to E}$, with $E_j = \{e_{j_1}, \ldots, e_{j_m}\}$ and $\forall k \in [\![1, m-1]\!]$, $j_{k+1} - j_k = 1$, then the alignment a_j between c_j and the sequence of words E_j is considered a candidate for word repacking. The same goes for $A_{E \to C}$. Some examples of such 1-to-n alignments between Chinese and English (in both directions) we can derive automatically are displayed in Figure 1.

白葡萄酒: white wine	closest: 最 近
百货公司: department store	fifteen: 十 五
抱歉: excuse me	fine: 很 好
报警: call the police	flight: 次 航班
杯: cup of	get: 拿 到
必须: have to	here: 在 这里

Figure 1: Example of 1-to-n word alignments between Chinese and English

3.2 Candidate Reliability Estimation

Of course, the process described above is error-prone and if we want to change the input to give to the word aligner, we need to make sure that we are not making harmful modifications.[5] We thus additionally evaluate the reliability of the candidates we extract and filter them before inclusion in our bilingual dictionary. To perform this filtering, we use two simple statistical measures. In the following, $a_j = \langle c_j, E_j \rangle$ denotes a candidate.

The first measure we consider is co-occurrence frequency ($COOC(c_j, E_j)$), i.e. the number of times c_j and E_j co-occur in the bilingual corpus. This very simple measure is frequently used in associative approaches (Melamed, 1997; Tiedemann, 2003). The second measure is the alignment confidence, defined as

$$AC(a_j) = \frac{C(a_j)}{COOC(c_j, E_j)},$$

where $C(a_j)$ denotes the number of alignments proposed by the word aligner that are identical to a_j. In other words, $AC(a_j)$ measures how often the

[5] Consequently, if we compare our approach to the problem of collocation identification, we may say that we are more interested in precision than recall (Smadja et al., 1996). However, note that our goal is not recognizing specific sequences of words such as compounds or collocations; it is making (bilingually motivated) changes that simplify the alignment process.

aligner aligns c_j and E_j when they co-occur. We also impose that $|E_j| \leq k$, where k is a fixed integer that may depend on the language pair (between 3 and 5 in practice). The rationale behind this is that it is very rare to get reliable alignment between one word and k consecutive words when k is high.

The candidates are included in our bilingual dictionary if and only if their measures are above some fixed thresholds t_{cooc} and t_{ac}, which allow for the control of the size of the dictionary and the quality of its contents. Some other measures (including the Dice coefficient) could be considered; however, it has to be noted that we are more interested here in the filtering than in the discovery of alignment, since our method builds upon an existing aligner. Moreover, we will see that even these simple measures can lead to an improvement of the alignment process in a MT context (cf. Section 5).

3.3 Bootstrapped Word Repacking

Once the candidates are extracted, we repack the words in the bilingual dictionaries constructed using the method described above; this provides us with an updated training corpus, in which some word sequences have been replaced by a single token. This update is totally naive: if an entry $a_j = \langle c_j, E_j \rangle$ is present in the dictionary and matches one sentence pair (c_1^J, e_1^I) (i.e. c_j and E_j are respectively contained in c_1^J and e_1^I), then we replace the sequence of words E_j with a single token which becomes a new lexical unit.[6] Note that this replacement occurs even if no alignment was found between c_j and E_j for the pair (c_1^J, e_1^I). This is motivated by the fact that the filtering described above is quite conservative; we trust the entry a_i to be correct. This update is performed in both directions. It is then possible to run the word aligner using the updated (simplified) parallel corpus, in order to get new alignments. By performing a deterministic word packing, we avoid the computation of the fertility parameters associated with fertility-based models.

Word packing can be applied several times: once we have grouped some words together, they become the new basic unit to consider, and we can re-run the same method to get additional groupings. However, we have not seen in practice much benefit from running it more than twice (few new candidates are extracted after two iterations).

It is also important to note that this process is bilingually motivated and strongly depends on the language pair. For example, *white wine*, *excuse me*, *call the police*, and *cup of* (cf. Figure 1) translate respectively as *vin blanc*, *excusez-moi*, *appellez la police*, and *tasse de* in French. Those groupings would not be found for a language pair such as French–English, which is consistent with the fact that they are less useful for French–English than for Chinese–English in a MT perspective.

3.4 Using Manually Developed Dictionaries

We wanted to compare this automatic approach to manually developed resources. For this purpose, we used a dictionary built by the MT group of Harbin Institute of Technology, as a preprocessing step to Chinese–English word alignment, and motivated by several years of Chinese–English MT practice. Some examples extracted from this resource are displayed in Figure 2.

有: there is
想要: want to
不必: need not
前面: in front of
一: as soon as
看: look at

Figure 2: Examples of entries from the manually developed dictionary

4 Experimental Setting

4.1 Evaluation

The intrinsic quality of word alignment can be assessed using the Alignment Error Rate (AER) metric (Och and Ney, 2003), that compares a system's alignment output to a set of gold-standard alignment. While this method gives a direct evaluation of the quality of word alignment, it is faced with several limitations. First, it is really difficult to build a reliable and objective gold-standard set, especially for languages as different as Chinese and English. Second, an increase in AER does not necessarily imply an improvement in translation quality (Liang et al., 2006) and vice-versa (Vilar et al., 2006). The

[6] In case of overlap between several groups of words to replace, we select the one with highest confidence (according to t_{ac}).

relationship between word alignments and their impact on MT is also investigated in (Ayan and Dorr, 2006; Lopez and Resnik, 2006; Fraser and Marcu, 2006). Consequently, we chose to extrinsically evaluate the performance of our approach via the translation task, i.e. we measure the influence of the alignment process on the final translation output. The quality of the translation output is evaluated using BLEU (Papineni et al., 2002).

4.2 Data

The experiments were carried out using the Chinese–English datasets provided within the IWSLT 2006 evaluation campaign (Paul, 2006), extracted from the Basic Travel Expression Corpus (BTEC) (Takezawa et al., 2002). This multilingual speech corpus contains sentences similar to those that are usually found in phrase-books for tourists going abroad. Training was performed using the default training set, to which we added the sets devset1, devset2, and devset3.[7] The English side of the test set was not available at the time we conducted our experiments, so we split the development set (devset 4) into two parts: one was kept for testing (200 aligned sentences) with the rest (289 aligned sentences) used for development purposes.

As a pre-processing step, the English sentences were tokenized using the maximum-entropy based tokenizer of the OpenNLP toolkit, and case information was removed. For Chinese, the data provided were tokenized according to the output format of ASR systems, and human-corrected (Paul, 2006). Since segmentations are human-corrected, we are sure that they are good from a monolingual point of view. Table 2 contains the various corpus statistics.

4.3 Baseline

We use a standard log-linear phrase-based statistical machine translation system as a baseline: GIZA++ implementation of IBM word alignment model 4 (Brown et al., 1993; Och and Ney, 2003),[8] the refinement and phrase-extraction heuristics described in (Koehn et al., 2003), minimum-error-rate training (Och, 2003) using Phramer (Olteanu et al., 2006), a 3-gram language model with Kneser-Ney smoothing trained with SRILM (Stolcke, 2002) on the English side of the training data and Pharaoh (Koehn, 2004) with default settings to decode. The log-linear model is also based on standard features: conditional probabilities and lexical smoothing of phrases in both directions, and phrase penalty (Zens and Ney, 2004).

		Chinese	English

	Vocabulary size	569	1,081

Table 2: Chinese–English corpus statistics

5 Experimental Results

5.1 Results

The initial word alignments are obtained using the baseline configuration described above. From these, we build two bilingual 1-to-n dictionaries (one for each direction), and the training corpus is updated by repacking the words in the dictionaries, using the method presented in Section 2. As previously mentioned, this process can be repeated several times; at each step, we can also choose to exploit only one of the two available dictionaries, if so desired. We then extract aligned phrases using the same procedure as for the baseline system; the only difference is the basic unit we are considering. Once the phrases are extracted, we perform the estimation of the features of the log-linear model and unpack the grouped words to recover the initial words. Finally, minimum-error-rate training and decoding are performed.

The various parameters of the method (k, t_{cooc}, t_{ac}, cf. Section 2) have been optimized on the development set. We found out that it was enough to perform two iterations of repacking: the optimal set of values was found to be $k = 3$, $t_{ac} = 0.5$, $t_{cooc} = 20$ for the first iteration, and $t_{cooc} = 10$ for the second

[7] More specifically, we choose the first English reference from the 7 references and the Chinese sentence to construct new sentence pairs.

[8] Training is performed using the same number of iterations as in Section 2.

	BLEU[%]
Baseline	15.14
n=1. with C-E dict.	15.92
n=1. with E-C dict.	15.77
n=1. with both	**16.59**
n=2. with C-E dict.	**16.99**
n=2. with E-C dict.	16.59
n=2. with both	16.88

Table 3: Influence of word repacking on Chinese-to-English MT

iteration, for both directions.[9] In Table 3, we report the results obtained on the test set, where n denotes the iteration. We first considered the inclusion of only the Chinese–English dictionary, then only the English–Chinese dictionary, and then both.

After the first step, we can already see an improvement over the baseline when considering one of the two dictionaries. When using both, we observe an increase of 1.45 BLEU points, which corresponds to a 9.6% relative increase. Moreover, we can gain from performing another step. However, the inclusion of the English–Chinese dictionary is harmful in this case, probably because 1-to-n alignments are less frequent for this direction, and have been captured during the first step. By including the Chinese–English dictionary only, we can achieve an increase of 1.85 absolute BLEU points (12.2% relative) over the initial baseline.[10]

Quality of the Dictionaries To assess the quality of the extraction procedure, we simply manually evaluated the ratio of incorrect entries in the dictionaries. After one step of word packing, the Chinese–English and the English–Chinese dictionaries respectively contain 7.4% and 13.5% incorrect entries. After two steps of packing, they only contain 5.9% and 10.3% incorrect entries.

5.2 Alignment Types

Intuitively, the word alignments obtained after word packing are more likely to be 1-to-1 than before. Indeed, the word sequences in one language that usually align to one single word in the other language have been grouped together to form one single token. Table 4 shows the detail of the distribution of alignment types after one and two steps of automatic repacking. In particular, we can observe that the $1\!:\!1$ alignments are more frequent after the application of repacking: the ratio of this type of alignment has increased by 7.81% for Chinese–English and 5.26% for English–Chinese.

		$1\!:\!0$	$1\!:\!1$	$1\!:\!2$	$1\!:\!3$	$1\!:\!n$ $(n>3)$
C-E	Base.	21.64	**63.76**	9.49	3.36	1.75
	n=1	19.69	69.43	6.32	2.79	1.78
	n=2	19.67	**71.57**	4.87	2.12	1.76
E-C	Base.	29.77	**57.47**	10.03	1.65	1.08
	n=1	26.59	61.95	8.82	1.55	1.09
	n=2	25.10	**62.73**	9.38	1.68	1.12

Table 4: Distribution of alignment types ($\%$)

5.3 Influence of Word Segmentation

To test the influence of the initial word segmentation on the process of word packing, we considered an additional segmentation configuration, based on an automatic segmenter combining rule-based and statistical techniques (Zhao et al., 2001).

	BLEU[%]
Original segmentation	15.14
Original segmentation + Word packing	**16.99**
Automatic segmentation	14.91
Automatic segmentation + Word packing	**17.51**

Table 5: Influence of Chinese segmentation

The results obtained are displayed in Table 5. As expected, the automatic segmenter leads to slightly lower results than the human-corrected segmentation. However, the proposed method seems to be beneficial irrespective of the choice of segmentation. Indeed, we can also observe an improvement in the new setting: 2.6 points absolute increase in BLEU (17.4% relative).[11]

[9] The parameters k, t_{ac}, and t_{cooc} are optimized for each step, and the alignment obtained using the best set of parameters for a given step are used as input for the following step.

[10] Note that this setting (using both dictionaries for the first step and only the Chinese dictionary for the second step) is also the best setting on the development set.

[11] We could actually consider an extreme case, which would consist of splitting the sentences into characters, i.e. each character would be blindly treated as one word. The segmentation

5.4 Exploiting Manually Developed Resources

We also compared our technique for automatic packing of words with the exploitation of manually developed resources. More specifically, we used a 1-to-n Chinese–English bilingual dictionary, described in Section 3.4, and used it in place of the automatically acquired dictionary. Words are thus grouped according to this dictionary, and we then apply the same word aligner as for previous experiments. In this case, since we are not bootstrapping from the output of a word aligner, this can actually be seen as a pre-processing step prior to alignment. These resources follow more or less the same format as the output of the word segmenter mentioned in Section 5.1.2 (Zhao et al., 2001), so the experiments are carried out using this segmentation.

	BLEU[%]
Baseline	14.91
Automatic word packing	**17.51**
Packing with "manual" dictionary	16.15

Table 6: Exploiting manually developed resources

The results obtained are displayed in Table 6.We can observe that the use of the manually developed dictionary provides us with an improvement in translation quality: 1.24 BLEU points absolute (8.3% relative). However, there does not seem to be a clear gain when compared with the automatic method. Even if those manual resources were extended, we do not believe the improvement is sufficient enough to justify this additional effort.

6 Conclusion and Future Work

In this paper, we have introduced a simple yet effective method to pack words together in order to give a different and simplified input to automatic word aligners. We use a bootstrap approach in which we first extract 1-to-n word alignments using an existing word aligner, and then estimate the confidence of those alignments to decide whether or not the n words have to be grouped; if so, this group is considered a new basic unit to consider. We can finally re-apply the word aligner to the updated sentences.

We have evaluated the performance of our approach by measuring the influence of this process on a Chinese-to-English MT task, based on the IWSLT 2006 evaluation campaign. We report a 12.2% relative increase in BLEU score over a standard phrase-based SMT system. We have verified that this process actually reduces the number of $1{:}\,n$ alignments with $n \neq 1$, and that it is rather independent from the (Chinese) segmentation strategy.

As for future work, we first plan to consider different confidence measures for the filtering of the alignment candidates. We also want to bootstrap on different word aligners; in particular, one possibility is to use the flexible HMM word-to-phrase model of Deng and Byrne (2005) in place of IBM model 4. Finally, we would like to apply this method to other corpora and language pairs.

Acknowledgment

This work is supported by Science Foundation Ireland (grant number OS/IN/1732). Prof. Tiejun Zhao and Dr. Muyun Yang from the MT group of Harbin Institute of Technology, and Yajuan Lv from the Institute of Computing Technology, Chinese Academy of Sciences, are kindly acknowledged for providing us with the Chinese segmenter and the manually developed bilingual dictionary used in our experiments.

Abstract

Recently, confusion network decoding has been applied in machine translation system combination. Due to errors in the hypothesis alignment, decoding may result in ungrammatical combination outputs. This paper describes an improved confusion network based method to combine outputs from multiple MT systems. In this approach, arbitrary features may be added log-linearly into the objective function, thus allowing language model expansion and re-scoring. Also, a novel method to automatically select the hypothesis which other hypotheses are aligned against is proposed. A generic weight tuning algorithm may be used to optimize various automatic evaluation metrics including TER, BLEU and METEOR. The experiments using the 2005 Arabic to English and Chinese to English NIST MT evaluation tasks show significant improvements in BLEU scores compared to earlier confusion network decoding based methods.

1 Introduction

System combination has been shown to improve classification performance in various tasks. There are several approaches for combining classifiers. In ensemble learning, a collection of simple classifiers is used to yield better performance than any single classifier; for example boosting (Schapire, 1990). Another approach is to combine outputs from a few highly specialized classifiers. The classifiers may be based on the same basic modeling techniques but differ by, for example, alternative feature representations. Combination of speech recognition outputs is an example of this approach (Fiscus, 1997). In speech recognition, confusion network decoding (Mangu et al., 2000) has become widely used in system combination.

Unlike speech recognition, current statistical machine translation (MT) systems are based on various different paradigms; for example phrasal, hierarchical and syntax-based systems. The idea of combining outputs from different MT systems to produce consensus translations in the hope of generating better translations has been around for a while (Frederking and Nirenburg, 1994). Recently, confusion network decoding for MT system combination has been proposed (Bangalore et al., 2001). To generate confusion networks, hypotheses have to be aligned against each other. In (Bangalore et al., 2001), Levenshtein alignment was used to generate the network. As opposed to speech recognition, the word order between two correct MT outputs may be different and the Levenshtein alignment may not be able to align shifted words in the hypotheses. In (Matusov et al., 2006), different word orderings are taken into account by training alignment models by considering all hypothesis pairs as a parallel corpus using GIZA++ (Och and Ney, 2003). The size of the test set may influence the quality of these alignments. Thus, system outputs from development sets may have to be added to improve the GIZA++ alignments. A modified Levenshtein alignment allowing shifts as in computation of the translation edit rate (TER) (Snover et al., 2006) was used to align hy-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 312–319,
Prague, Czech Republic, June 2007.

potheses in (Sim et al., 2007). The alignments from TER are consistent as they do not depend on the test set size. Also, a more heuristic alignment method has been proposed in a different system combination approach (Jayaraman and Lavie, 2005). A full comparison of different alignment methods would be difficult as many approaches require a significant amount of engineering.

Confusion networks are generated by choosing one hypothesis as the "skeleton", and other hypotheses are aligned against it. The skeleton defines the word order of the combination output. Minimum Bayes risk (MBR) was used to choose the skeleton in (Sim et al., 2007). The average TER score was computed between each system's 1-best hypothesis and all other hypotheses. The MBR hypothesis is the one with the minimum average TER and thus, may be viewed as the closest to all other hypotheses in terms of TER. This work was extended in (Rosti et al., 2007) by introducing system weights for word confidences. However, the system weights did not influence the skeleton selection, so a hypothesis from a system with zero weight might have been chosen as the skeleton. In this work, confusion networks are generated by using the 1-best output from each system as the skeleton, and prior probabilities for each network are estimated from the average TER scores between the skeleton and other hypotheses. All resulting confusion networks are connected in parallel into a joint lattice where the prior probabilities are also multiplied by the system weights.

The combination outputs from confusion network decoding may be ungrammatical due to alignment errors. Also the word-level decoding may break coherent phrases produced by the individual systems. In this work, log-posterior probabilities are estimated for each confusion network arc instead of using votes or simple word confidences. This allows a log-linear addition of arbitrary features such as language model (LM) scores. The LM scores should increase the total log-posterior of more grammatical hypotheses. Powell's method (Brent, 1973) is used to tune the system and feature weights simultaneously so as to optimize various automatic evaluation metrics on a development set. Tuning is fully automatic, as opposed to (Matusov et al., 2006) where global system weights were set manually.

This paper is organized as follows. Three evaluation metrics used in weights tuning and reporting the test set results are reviewed in Section 2. Section 3 describes confusion network decoding for MT system combination. The extensions to add features log-linearly and improve the skeleton selection are presented in Sections 4 and 5, respectively. Section 6 details the weights optimization algorithm and the experimental results are reported in Section 7. Conclusions and future work are discussed in Section 8.

2 Evaluation Metrics

Currently, the most widely used automatic MT evaluation metric is the NIST BLEU-4 (Papineni et al., 2002). It is computed as the geometric mean of n-gram precisions up to 4-grams between the hypothesis E and reference E_r as follows

$$\mathrm{BLEU}(E, E_r) = \exp\Big(\frac{1}{4}\sum_{n=1}^{4}\log p_n(E, E_r)\Big)\gamma(E, E_r) \quad (1)$$

where $\gamma(E, E_r) \leq 1$ is the brevity penalty and $p_n(E, E_r)$ are the n-gram precisions. When multiple references are provided, the n-gram counts against all references are accumulated to compute the precisions. Similarly, full test set scores are obtained by accumulating counts over all hypothesis and reference pairs. The BLEU scores are between 0 and 1, higher being better. Often BLEU scores are reported as percentages and "one BLEU point gain" usually means a BLEU increase of 0.01.

Other evaluation metrics have been proposed to replace BLEU. It has been argued that METEOR correlates better with human judgment due to higher weight on recall than precision (Banerjee and Lavie, 2005). METEOR is based on the weighted harmonic mean of the precision and recall measured on unigram matches as follows

$$\mathrm{MTR}(E, E_r) = \frac{10m}{N_h + 9N_r}\Big(1 - 0.5(c/m)^3\Big) \quad (2)$$

where m is the total number of unigram matches, N_h is the hypothesis length, N_r is the reference length and c is the minimum number of n-gram matches that covers the alignment. The second term is a fragmentation penalty which penalizes the harmonic mean by a factor of up to 0.5 when $c = m$; i.e.,

there are no matching n-grams higher than $n = 1$. By default, METEOR script counts the words that match exactly, and words that match after a simple Porter stemmer. Additional matching modules including WordNet stemming and synonymy may also be used. When multiple references are provided, the lowest score is reported. Full test set scores are obtained by accumulating statistics over all test sentences. The METEOR scores are also between 0 and 1, higher being better. The scores in the results section are reported as percentages.

Translation edit rate (TER) (Snover et al., 2006) has been proposed as more intuitive evaluation metric since it is based on the rate of edits required to transform the hypothesis into the reference. The TER score is computed as follows

$$\mathrm{TER}(E, E_r) = \frac{\mathrm{Ins} + \mathrm{Del} + \mathrm{Sub} + \mathrm{Shft}}{N_r} \quad (3)$$

where N_r is the reference length. The only difference to word error rate is that the TER allows shifts. A shift of a sequence of words is counted as a single edit. The minimum translation edit alignment is usually found through a beam search. When multiple references are provided, the edits from the closest reference are divided by the average reference length. Full test set scores are obtained by accumulating the edits and the average reference lengths. The perfect TER score is 0, and otherwise higher than zero. The TER score may also be higher than 1 due to insertions. Also TER is reported as a percentage in the results section.

3 Confusion Network Decoding

Confusion network decoding in MT has to pick one hypothesis as the skeleton which determines the word order of the combination. The other hypotheses are aligned against the skeleton. Either votes or some form of confidences are assigned to each word in the network. For example using "cat sat the mat" as the skeleton, aligning "cat sitting on the mat" and "hat on a mat" against it might yield the following alignments:

cat	sat	ε	the	mat
cat	sitting	on	the	mat
hat	ε	on	a	mat

where ε represents a NULL word. In graphical form, the resulting confusion network is shown in Figure 1. Each arc represents an alternative word at that position in the sentence and the number of votes for each word is marked in parentheses. Confusion network decoding usually requires finding the path with the highest confidence in the network. Based on vote counts, there are three alternatives in the example: "cat sat on the mat", "cat on the mat" and "cat sitting on the mat", each having accumulated 10 votes. The alignment procedure plays an important role, as by switching the position of the word 'sat' and the following NULL in the skeleton, there would be a single highest scoring path through the network; that is, "cat on the mat".

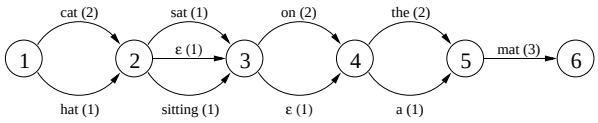

Figure 1: Example consensus network with votes on word arcs.

Different alignment methods yield different confusion networks. The modified Levenshtein alignment as used in TER is more natural than simple edit distance such as word error rate since machine translation hypotheses may have different word orders while having the same meaning. As the skeleton determines the word order, the quality of the combination output also depends on which hypothesis is chosen as the skeleton. Since the modified Levenshtein alignment produces TER scores between the skeleton and the other hypotheses, a natural choice for selecting the skeleton is the minimum average TER score. The hypothesis resulting in the lowest average TER score when aligned against all other hypotheses is chosen as the skeleton E_s as follows

$$E_s = \arg\min_{E \in E_i} \sum_{j=1}^{N_s} \mathrm{TER}(E_j, E_i) \quad (4)$$

where N_s is the number of systems. This is equivalent to minimum Bayes risk decoding with uniform posterior probabilities (Sim et al., 2007). Other evaluation metrics may also be used as the MBR loss function. For BLEU and METEOR, the loss function would be $1 - \mathrm{BLEU}(E_j, E_i)$ and $1 - \mathrm{MTR}(E_j, E_i)$.

It has been found that multiple hypotheses from each system may be used to improve the quality of

the combination output (Sim et al., 2007). When using N-best lists from each system, the words may be assigned a different score based on the rank of the hypothesis. In (Rosti et al., 2007), simple $1/(1+k)$ score was assigned to the word coming from the kth-best hypothesis. Due to the computational burden of the TER alignment, only 1-best hypotheses were considered as possible skeletons, and $n = 10$ hypotheses per system were aligned. Similar approach to estimate word posteriors is adopted in this work.

System weights may be used to assign a system specific confidence on each word in the network. The weights may be based on the systems' relative performance on a separate development set or they may be automatically tuned to optimize some evaluation metric on the development set. In (Rosti et al., 2007), the total confidence of the nth best confusion network hypothesis $E_{j,n}$, including NULL words, given the jth source sentence F_j was given by

$$c(E_{j,n}|F_j) = \sum_{i=1}^{N_j-1} \sum_{l=1}^{N_s} \lambda_l c_{wli} + \mu N_{nulls}(E_{j,n}) \quad (5)$$

where N_j is the number of nodes in the confusion network for the source sentence F_j, N_s is the number of translation systems, λ_l is the lth system weight, c_{wli} is the accumulated confidence for word w produced by system l between nodes i and $i+1$, and μ is a weight for the number of NULL links along the hypothesis $N_{nulls}(E_{j,n})$. The word confidences c_{wli} were increased by $1/(1+k)$ if the word w aligns between nodes i and $i+1$ in the network. If no word aligns between nodes i and $i+1$, the NULL word confidence at that position was increased by $1/(1+k)$. The last term controls the number of NULL words generated in the output and may be viewed as an insertion penalty. Each arc in the confusion network carries the word label w and N_s scores c_{wli}. The decoder outputs the hypothesis with the highest $c(E_{j,n}|F_j)$ given the current set of weights.

3.1 Discussion

There are several problems with the previous confusion network decoding approaches. First, the decoding can generate ungrammatical hypotheses due to alignment errors and phrases broken by the word-level decoding. For example, two synonymous words may be aligned to other words not already aligned, which may result in repetitive output. Second, the additive confidence scores in Equation 5 have no probabilistic meaning and cannot therefore be combined with language model scores. Language model expansion and re-scoring may help by increasing the probability of more grammatical hypotheses in decoding. Third, the system weights are independent of the skeleton selection. Therefore, a hypothesis from a system with a low or zero weight may be chosen as the skeleton.

4 Log-Linear Combination with Arbitrary Features

To address the issue with ungrammatical hypotheses and allow language model expansion and re-scoring, the hypothesis confidence computation is modified. Instead of summing arbitrary confidence scores as in Equation 5, word posterior probabilities are used as follows

$$\log p(E_{j,n}|F_j) = \sum_{i=1}^{N_j-1} \log \Big(\sum_{l=1}^{N_s} \lambda_l p(w|l,i) \Big) + \nu L(E_{j,n}) + \mu N_{nulls}(E_{j,n}) + \xi N_{words}(E_{j,n}) \quad (6)$$

where ν is the language model weight, $L(E_{j,n})$ is the LM log-probability and $N_{words}(E_{j,n})$ is the number of words in the hypothesis $E_{j,n}$. The word posteriors $p(w|l,i)$ are estimated by scaling the confidences c_{wli} to sum to one for each system l over all words w in between nodes i and $i+1$. The system weights are also constrained to sum to one. Equation 6 may be viewed as a log-linear sum of sentence-level features. The first feature is the sum of word log-posteriors, the second is the LM log-probability, the third is the log-NULL score and the last is the log-length score. The last two terms are not completely independent but seem to help based on experimental results.

The number of paths through a confusion network grows exponentially with the number of nodes. Therefore expanding a network with an n-gram language model may result in huge lattices if n is high. Instead of high order n-grams with heavy pruning, a bi-gram may first be used to expand the lattice. After optimizing one set of weights for the expanded

confusion network, a second set of weights for N-best list re-scoring with a higher order n-gram model may be optimized. On a test set, the first set of weights is used to generate an N-best list from the bi-gram expanded lattice. This N-best list is then re-scored with the higher order n-gram. The second set of weights is used to find the final 1-best from the re-scored N-best list.

5 Multiple Confusion Network Decoding

As discussed in Section 3, there is a disconnect between the skeleton selection and confidence estimation. To prevent the 1-best from a system with a low or zero weight being selected as the skeleton, confusion networks are generated for each system and the average TER score in Equation 4 is used to estimate a prior probability for the corresponding network. All N_s confusion networks are connected to a single start node with NULL arcs which contain the prior probability from the system used as the skeleton for that network. All confusion network are connected to a common end node with NULL arcs. The final arcs have a probability of one. The prior probabilities in the arcs leaving the first node will be multiplied by the corresponding system weights which guarantees that a path through a network generated around a 1-best from a system with a zero weight will not be chosen.

The prior probabilities are estimated by viewing the negative average TER scores between the skeleton and other hypotheses as log-probabilities. These log-probabilities are scaled so that the priors sum to one. There is a concern that the prior probabilities estimated this way may be inaccurate. Therefore, the priors may have to be smoothed by a tunable exponent. However, the optimization experiments showed that the best performance was obtained by having a smoothing factor of 1 which is equivalent to the original priors. Thus, no smoothing was used in the experiments presented later in this paper.

An example joint network with the priors is shown in Figure 2. This example has three confusion networks with priors 0.5, 0.2 and 0.3. The total number of nodes in the network is represented by N_a. Similar combination of multiple confusion networks was presented in (Matusov et al., 2006). However, this approach did not include sentence specific prior estimates, word posterior estimates, and did not allow joint optimization of the system and feature weights.

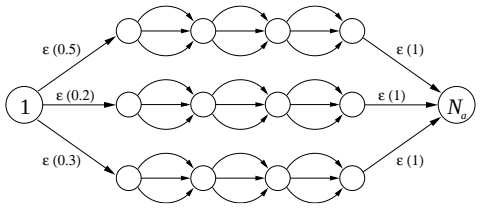

Figure 2: Three confusion networks with prior probabilities.

6 Weights Optimization

The optimization of the system and feature weights may be carried out using N-best lists as in (Ostendorf et al., 1991). A confusion network may be represented by a word lattice and standard tools may be used to generate N-best hypothesis lists including word confidence scores, language model scores and other features. The N-best list may be re-ordered using the sentence-level posteriors $p(E_{j,n}|F_j)$ from Equation 6 for the jth source sentence F_j and the corresponding nth hypothesis $E_{j,n}$. The current 1-best hypothesis $\hat{E}_j$ given a set of weights $\theta = \{\lambda_1, \ldots, \lambda_{N_s}, \nu, \mu, \xi\}$ may be represented as follows

$$\hat{E}_j(F_j|\theta) = \arg\max_{E \in E_{j,n}} p(E_{j,n}|F_j) \qquad (7)$$

The objective is to optimize the 1-best score on a development set given a set of reference translations. For example, estimating weights which minimize TER between a set of 1-best hypothesis $\hat{S}$ and reference translations S_r can be written as

$$\hat{\theta} = \arg\min_{\theta} \mathrm{TER}(\hat{S}, S_r) \qquad (8)$$

This objective function is very complicated, so gradient-based optimization methods may not be used. In this work, modified Powell's method as proposed by (Brent, 1973) is used. The algorithm explores better weights iteratively starting from a set of initial weights. First, each dimension is optimized using a grid-based line minimization algorithm. Then, a new direction based on the changes in the objective function is estimated to speed up the search. To improve the chances of finding a

global optimum, 19 random perturbations of the initial weights are used in parallel optimization runs. Since the N-best list represents only a small portion of all hypotheses in the confusion network, the optimized weights from one iteration may be used to generate a new N-best list from the lattice for the next iteration. Similarly, weights which maximize BLEU or METEOR may be optimized.

The same Powell's method has been used to estimate feature weights of a standard feature-based phrasal MT decoder in (Och, 2003). A more efficient algorithm for log-linear models was also proposed. In this work, both the system and feature weights are jointly optimized, so the efficient algorithm for the log-linear models cannot be used.

7 Results

The improved system combination method was compared to a simple confusion network decoding without system weights and the method proposed in (Rosti et al., 2007) on the Arabic to English and Chinese to English NIST MT05 tasks. Six MT systems were combined: three (A,C,E) were phrase-based similar to (Koehn, 2004), two (B,D) were hierarchical similar to (Chiang, 2005) and one (F) was syntax-based similar to (Galley et al., 2006). All systems were trained on the same data and the outputs used the same tokenization. The decoder weights for systems A and B were tuned to optimize TER, and others were tuned to optimize BLEU. All decoder weight tuning was done on the NIST MT02 task.

The joint confusion network was expanded with a bi-gram language model and a 300-best list was generated from the lattice for each tuning iteration. The system and feature weights were tuned on the union of NIST MT03 and MT04 tasks. All four reference translations available for the tuning and test sets were used. A first set of weights with the bi-gram LM was optimized with three iterations. A second set of weights was tuned for 5-gram N-best list re-scoring. The bi-gram and 5-gram English language models were trained on about 7 billion words. The final combination outputs were detokenized and cased before scoring.

The tuning set results on the Arabic to English NIST MT03+MT04 task are shown in Table 1. The best score on each metric is shown in bold face fonts. The row labeled as `no weights` corresponds to Equation 5 with uniform system weights λ_l and zero NULL weight. The `baseline` corresponds to Equation 5 with TER tuned weights. The following three rows correspond to the improved confusion network decoding with different optimization metrics. As expected, the scores on the metric used in tuning are the best on that metric. Also, the combination results are better than any single system on all metrics in the case of TER and BLEU tuning. However, the METEOR tuning yields extremely high TER and low BLEU scores. This must be due to the higher weight on the recall compared to precision in the harmonic mean used to compute the METEOR

Arabic tuning	TER	BLEU	MTR

Table 4: Mixed-case TER and BLEU, and lower-case METEOR scores on Chinese NIST MT05.

score. Even though METEOR has been shown to be a good metric on a given MT output, tuning to optimize METEOR results in a high insertion rate and low precision. The Arabic test set results are shown in Table 2. The TER and BLEU optimized combination results beat all single system scores on all metrics. The best results on a given metric are again obtained by the combination optimized for the corresponding metric. It should be noted that the TER optimized combination has significantly higher BLEU score than the TER optimized baseline. Compared to the baseline system which is also optimized for TER, the BLEU score is improved by 0.97 points. Also, the METEOR score using the METEOR optimized weights is very high. However, the other scores are worse in common with the tuning set results.

The tuning set results on the Chinese to English NIST MT03+MT04 task are shown in Table 3. The baseline combination weights were tuned to optimize BLEU. Again, the best scores on each metric are obtained by the combination tuned for that metric. Only the METEOR score of the TER tuned combination is worse than the METEOR scores of systems E and F - other combinations are better than any single system on all metrics apart from the METEOR tuned combinations. The test set results follow clearly the tuning results again - the TER tuned combination is the best in terms of TER, the BLEU tuned in terms of BLEU, and the METEOR tuned in terms of METEOR. Compared to the baseline, the BLEU score of the BLEU tuned combination is improved by 1.47 points. Again, the METEOR tuned weights hurt the other metrics significantly.

8 Conclusions

An improved confusion network decoding method combining the word posteriors with arbitrary features was presented. This allows the addition of language model scores by expanding the lattices or re-scoring N-best lists. The LM integration should result in more grammatical combination outputs. Also, confusion networks generated by using the 1-best hypothesis from all systems as the skeleton were used with prior probabilities derived from the average TER scores. This guarantees that the best path will not be found from a network generated for a system with zero weight. Compared to the earlier system combination approaches, this method is fully automatic and requires very little additional information on top of the development set outputs from the individual systems to tune the weights.

The new method was evaluated on the Arabic to English and Chinese to English NIST MT05 tasks. Compared to the baseline from (Rosti et al., 2007), the new method improves the BLEU scores significantly. The combination weights were tuned to optimize three automatic evaluation metrics: TER, BLEU and METEOR. The TER tuning seems to yield very good results on Arabic - the BLEU tuning seems to be better on Chinese. It also seems like

METEOR should not be used in tuning due to high insertion rate and low precision. It would be interesting to know which tuning metric results in the best translations in terms of human judgment. However, this would require time consuming evaluations such as human mediated TER post-editing (Snover et al., 2006).

The improved confusion network decoding approach allows arbitrary features to be used in the combination. New features may be added in the future. Hypothesis alignment is also very important in confusion network generation. Better alignment methods which take synonymy into account should be investigated. This method could also benefit from more sophisticated word posterior estimation.

Generating Constituent Order in German Clauses

Katja Filippova and **Michael Strube**
EML Research gGmbH
Schloss-Wolfsbrunnenweg 33

http://www.eml-research.de/nlp

Abstract

We investigate the factors which determine constituent order in German clauses and propose an algorithm which performs the task in two steps: First, the best candidate for the initial sentence position is chosen. Then, the order for the remaining constituents is determined. The first task is more difficult than the second one because of properties of the German sentence-initial position. Experiments show a significant improvement over competing approaches. Our algorithm is also more efficient than these.

1 Introduction

Many natural languages allow variation in the word order. This is a challenge for natural language generation and machine translation systems, or for text summarizers. E.g., in text-to-text generation (Barzilay & McKeown, 2005; Marsi & Krahmer, 2005; Wan et al., 2005), new sentences are fused from dependency structures of input sentences. The last step of sentence fusion is linearization of the resulting parse. Even for English, which is a language with fixed word order, this is not a trivial task.

German has a relatively free word order. This concerns the order of *constituents*[1] within sentences while the order of words within constituents is relatively rigid. The grammar only partially prescribes how constituents dependent on the verb should be ordered, and for many clauses each of the $n!$ possible permutations of n constituents is grammatical.

[1]Henceforth, we will use this term to refer to constituents dependent on the clausal top node, i.e. a verb, only.

In spite of the permanent interest in German word order in the linguistics community, most studies have limited their scope to the order of verb arguments and few researchers have implemented – and even less evaluated – a generation algorithm. In this paper, we present an algorithm, which orders not only verb arguments but all kinds of constituents, and evaluate it on a corpus of biographies. For each parsed sentence in the test set, our maximum-entropy-based algorithm aims at reproducing the order found in the original text. We investigate the importance of different linguistic factors and suggest an algorithm to constituent ordering which first determines the sentence initial constituent and then orders the remaining ones. We provide evidence that the task requires language-specific knowledge to achieve better results and point to the most difficult part of it. Similar to Langkilde & Knight (1998) we utilize statistical methods. Unlike overgeneration approaches (Varges & Mellish, 2001, inter alia) which select the best of *all* possible outputs ours is more efficient, because we do not need to generate every permutation.

2 Theoretical Premises

2.1 Background

It has been suggested that several factors have an influence on German constituent order. Apart from the constraints posed by the grammar, information structure, surface form, and discourse status have also been shown to play a role. It has also been observed that there are preferences for a particular order. The preferences summarized below have mo-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 320–327,
Prague, Czech Republic, June 2007.

tivated our choice of features:

- constituents in the nominative case precede those in other cases, and dative constituents often precede those in the accusative case (Uszkoreit, 1987; Keller, 2000);
- the verb arguments' order depends on the verb's subcategorization properties (Kurz, 2000);
- constituents with a definite article precede those with an indefinite one (Weber & Müller, 2004);
- pronominalized constituents precede non-pronominalized ones (Kempen & Harbusch, 2004);
- animate referents precede inanimate ones (Pappert et al., 2007);
- short constituents precede longer ones (Kimball, 1973);
- the preferred topic position is right after the verb (Frey, 2004);
- the initial position is usually occupied by scene-setting elements and topics (Speyer, 2005).
- there is a default order based on semantic properties of constituents (Sgall et al., 1986):
  Actor < Temporal < SpaceLocative < Means < Addressee < Patient < Source < Destination < Purpose

Note that most of these preferences were identified in corpus studies and experiments with native speakers and concern the order of verb arguments only. Little has been said so far about how non-arguments should be ordered.

German is a verb second language, i.e., the position of the verb in the main clause is determined exclusively by the grammar and is insensitive to other factors. Thus, the German main clause is divided into two parts by the finite verb: *Vorfeld (VF)*, which contains exactly one constituent, and *Mittelfeld (MF)*, where the remaining constituents are located. The subordinate clause normally has only MF. The VF and MF are marked with brackets in Example 1:

(1) [Außerdem] entwickelte [Lummer eine Quecksilberdampflampe, um monochromatisches Licht herzustellen].
Apart from that developed Lummer a Mercury-vapor lamp to monochrome light produce.

'Apart from that, Lummer developed a Mercury-vapor lamp to produce monochrome light'.

2.2 Our Hypothesis

The essential contribution of our study is that we treat preverbal and postverbal parts of the sentence differently. The sentence-initial position, which in German is the VF, has been shown to be cognitively more prominent than other positions (Gernsbacher & Hargreaves, 1988). Motivated by the theoretical work by Chafe (1976) and Jacobs (2001), we view the VF as the place for elements which modify the situation described in the sentence, i.e. for so called frame-setting topics (Jacobs, 2001). For example, temporal or locational constituents, or anaphoric adverbs are good candidates for the VF. We hypothesize that the reasons which bring a constituent to the VF are different from those which place it, say, to the beginning of the MF, for the order in the MF has been shown to be relatively rigid (Keller, 2000; Kempen & Harbusch, 2004). Speakers have the freedom of selecting the outgoing point for a sentence. Once they have selected it, the remaining constituents are arranged in the MF, mainly according to their grammatical properties.

This last observation motivates another hypothesis we make: The cumulation of the properties of a constituent determines its *salience*. This salience can be calculated and used for ordering with a simple rule stating that more salient constituents should precede less salient ones. In this case there is no need to generate all possible orders and rank them. The best order can be obtained from a random one by sorting. Our experiments support this view. A two-step approach, which first selects the best candidate for the VF and then arranges the remaining constituents in the MF with respect to their salience performs better than algorithms which generate the order for a sentence as a whole.

3 Related Work

Uszkoreit (1987) addresses the problem from a mostly grammar-based perspective and suggests weighted constraints, such as [+NOM] $\prec$ [+DAT], [+PRO] $\prec$ [–PRO], [–FOCUS] $\prec$ [+FOCUS], etc.

Kruijff et al. (2001) describe an architecture which supports generating the appropriate word order for different languages. Inspired by the findings of the Prague School (Sgall et al., 1986) and Systemic Functional Linguistics (Halliday, 1985), they focus on the role that information structure plays in constituent ordering. Kruijff-Korbayová et al. (2002) address the task of word order generation in the same vein. Similar to ours, their algorithm recognizes the special role of the sentence-initial position which they reserve for the *theme* – the point of departure of the message. Unfortunately, they did not implement their algorithm, and it is hard to judge how well the system would perform on real data.

Harbusch et al. (2006) present a generation workbench, which has the goal of producing not the most appropriate order, but all grammatical ones. They also do not provide experimental results.

The work of Uchimoto et al. (2000) is done on the free word order language Japanese. They determine the order of phrasal units dependent on the same modifiee. Their approach is similar to ours in that they aim at regenerating the original order from a dependency parse, but differs in the scope of the problem as they regenerate the order of modifers for all and not only for the top clausal node. Using a maximum entropy framework, they choose the most probable order from the set of all permutations of n words by the following formula:

$$\begin{aligned} P(1|h) &= P(\{W_{i,i+j} = 1 | 1 \leq i \leq n-1, 1 \leq j \leq n-i\}|h) \\ &\approx \prod_{i=1}^{n-1} \prod_{j=1}^{n-i} P(W_{i,i+j} = 1 | h_{i,i+j}) \\ &= \prod_{i=1}^{n-1} \prod_{j=1}^{n-i} P_{ME}(1 | h_{i,i+j}) \end{aligned} \quad (1)$$

For each permutation, for every pair of words , they multiply the probability of their being in the correct[2] order given the history h. Random variable $W_{i,i+j}$ is 1 if word w_i precedes w_{i+j} in the reference sentence, 0 otherwise. The features they use are akin to those which play a role in determining German word order. We use their approach as a non-trivial baseline in our study.

Ringger et al. (2004) aim at regenerating the order of constituents as well as the order within them for German and French technical manuals. Utilizing syntactic, semantic, sub-categorization and length features, they test several statistical models to find the order which maximizes the probability of an ordered tree. Using "Markov grammars" as the starting point and conditioning on the syntactic category only, they expand a non-terminal node C by predicting its daughters from left to right:

$$P(C|h) = \prod_{i=1}^{n} P(d_i | d_{i-1}, ..., d_{i-j}, c, h) \quad (2)$$

Here, c is the syntactic category of C, d and h are the syntactic categories of C's daughters and the daughter which is the head of C respectively.

In their simplest system, whose performance is only 2.5% worse than the performance of the best one, they condition on both syntactic categories and semantic relations (ψ) according to the formula:

$$P(C|h) = \prod_{i=1}^{n} \left[\begin{array}{l} P(\psi_i | d_{i-1}, \psi_{i-1}, ...d_{i-j}, \psi_{i-j}, c, h) \\ \times P(d_i | \psi_i, d_{i-1}, \psi_{i-1}..., d_{i-j}, \psi_{i-j}, c, h) \end{array} \right] \quad (3)$$

Although they test their system on German data, it is hard to compare their results to ours directly. First, the metric they use does not describe the performance appropriately (see Section 6.1). Second, while the word order within NPs and PPs as well as the verb position are prescribed by the grammar to a large extent, the constituents can theoretically be ordered in any way. Thus, by generating the order for every non-terminal node, they combine two tasks of different complexity and mix the results of the more difficult task with those of the easier one.

4 Data

The data we work with is a collection of biographies from the German version of Wikipedia[3]. Fully automatic preprocessing in our system comprises the following steps: First, a list of people of a certain Wikipedia category is taken and an article is extracted for every person. Second, sentence

[2] Only reference orders are assumed to be correct.

[3] http://de.wikipedia.org

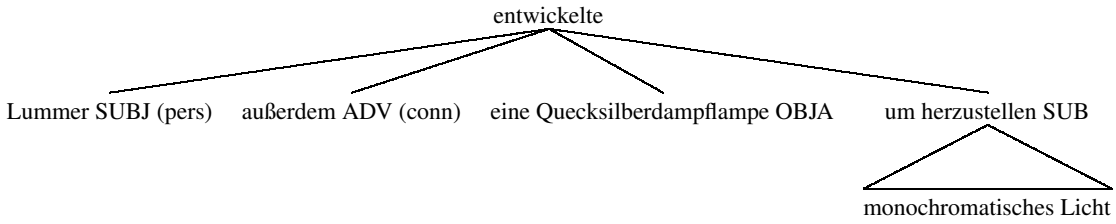

Figure 1: The representation of the sentence in Example 1

boundaries are identified with a Perl CPAN module[4] whose performance we improved by extending the list of abbreviations. Next, the sentences are split into tokens. The TnT tagger (Brants, 2000) and the TreeTagger (Schmid, 1997) are used for tagging and lemmatization. Finally, the articles are parsed with the CDG dependency parser (Foth & Menzel, 2006). Named entities are classified according to their semantic type using lists and category information from Wikipedia: person (*pers*), location (*loc*), organization (*org*), or undefined named entity (*undef_ne*). Temporal expressions (*Oktober 1915*, *danach (after that)* etc.) are identified automatically by a set of patterns. Inevitable during automatic annotation, errors at one of the preprocessing stages cause errors at the ordering stage.

Distinguishing between main and subordinate clauses, we split the total of about 19 000 sentences into training, development and test sets (Table 1). Clauses with one constituent are sorted out as trivial. The distribution of both types of clauses according to their length in constituents is given in Table 2.

	train	dev	test
main	14324	3344	1683
sub	3304	777	408
total	17628	4121	2091

Table 1: Size of the data sets in clauses

	2	3	4	5	6+
main	20%	35%	27%	12%	6%
sub	49%	35%	11%	2%	3%

Table 2: Proportion of clauses with certain lengths

[4]http://search.cpan.org/~holsten/Lingua-DE-Sentence-0.07/Sentence.pm

Given the sentence in Example 1, we first transform its dependency parse into a more general representation (Figure 1[5]) and then, based on the predictions of our learner, arrange the four constituents. For evaluation, we compare the arranged order against the original one.

Note that we predict neither the position of the verb, nor the order within constituents as the former is explicitly determined by the grammar, and the latter is much more rigid than the order of constituents.

5 Baselines and Algorithms

We compare the performance of two our algorithms with four baselines.

5.1 Random

We improve a trivial random baseline (RAND) by two syntax-oriented rules: the first position is reserved for the subject and the second for the direct object if there is any; the order of the remaining constituents is generated randomly (RAND_IMP).

5.2 Statistical Bigram Model

Similar to Ringger et al. (2004), we find the order with the highest probability conditioned on syntactic and semantic categories. Unlike them we use dependency parses and compute the probability of the top node only, which is modified by all constituents. With these adjustments the probability of an order O given the history h, if conditioned on syntactic functions of constituents $(s_1 ... s_n)$, is simply:

$$P(O|h) = \prod_{i=1}^{n} P(s_i|s_{i-1}, h) \qquad (4)$$

Ringger et al. (2004) do not make explicit, what their set of semantic relations consists of. From the

[5]OBJA stands for the accusative object.

example in the paper, it seems that these are a mixture of lexical and syntactic information[6]. Our annotation does not specify semantic relations. Instead, some of the constituents are categorized as *pers, loc, temp, org* or *undef_ne* if their heads bear one of these labels. By joining these with possible syntactic functions, we obtain a larger set of syntactic-semantic tags as, e.g., *subj-pers, pp-loc, adv-temp*. We transform each clause in the training set into a sequence of such tags, plus three tags for the verb position (*v*), the beginning (*b*) and the end (*e*) of the clause. Then we compute the bigram probabilities[7].

For our third baseline (BIGRAM), we select from all possible orders the one with the highest probability as calculated by the following formula:

$$P(O|h) = \prod_{i=1}^{n} P(t_i|t_{i-1}, h) \quad (5)$$

where t_i is from the set of joined tags. For Example 1, possible tag sequences (i.e. orders) are *'b subj-pers v adv obja sub e', 'b adv v subj-pers obja sub e', 'b obja v adv sub subj-pers e'*, etc.

5.3 Uchimoto

For the fourth baseline (UCHIMOTO), we utilized a maximum entropy learner (OpenNLP[8]) and reimplemented the algorithm of Uchimoto et al. (2000). For every possible permutation, its probability is estimated according to Formula (1). The binary classifier, whose task was to predict the probability that the order of a pair of constituents is correct, was trained on the following features describing the verb or h_c – the head of a constituent c[9]:

vlex, vpass, vmod the lemma of the root of the clause (non-auxiliary verb), the voice of the verb and the number of constituents to order;

lex the lemma of h_c or, if h_c is a functional word, the lemma of the word which depends on it;

pos part-of-speech tag of h_c;

sem if defined, the semantic class of *c*; e.g. *im April 1900* and *mit Albert Einstein (with Albert Einstein)* are classified *temp* and *pers* respectively;

syn, same the syntactic function of h_c and whether it is the same for the two constituents;

mod number of modifiers of h_c;

rep whether h_c appears in the preceding sentence;

pro whether *c* contains a (anaphoric) pronoun.

5.4 Maximum Entropy

The first configuration of our system is an extended version of the UCHIMOTO baseline (MAXENT). To the features describing c we added the following ones:

det the kind of determiner modifying h_c (*def, indef, non-appl*);

rel whether h_c is modified by a relative clause (*yes, no, non-appl*);

dep the depth of *c*;

len the length of *c* in words.

The first two features describe the discourse status of a constituent; the other two provide information on its "weight". Since our learner treats all values as nominal, we discretized the values of **dep** and **len** with a C4.5 classifier (Kohavi & Sahami, 1996).

Another modification concerns the efficiency of the algorithm. Instead of calculating probabilities for all pairs, we obtain the right order from a random one by *sorting*. We compare adjacent elements by consulting the learner as if we would sort an array of numbers. Given two adjacent constituents, $c_i < c_j$, we check the probability of their being in the right order, i.e. that c_i precedes c_j: $P_{pre}(c_i, c_j)$. If it is less than 0.5, we transpose the two and compare c_i with the next one.

Since the sorting method presupposes that the predicted relation is transitive, we checked whether this is really so on the development and test data sets. We looked for three constituents c_i, c_j, c_k from a sentence S, such that $P_{pre}(c_i, c_j) > 0.5, P_{pre}(c_j, c_k) > 0.5, P_{pre}(c_i, c_k) < 0.5$ and found none. Therefore, unlike UCHIMOTO, where one needs to make exactly $N! * N(N-1)/2$ comparisons, we have to make $N(N-1)/2$ comparisons at most.

[6] E.g. *DefDet, Coords, Possr, werden*

[7] We use the CMU Toolkit (Clarkson & Rosenfeld, 1997).

[8] http://opennlp.sourceforge.net

[9] We disregarded features which use information specific to Japanese and non-applicable to German (e.g. on postpositional particles).

5.5 The Two-Step Approach

The main difference between our first algorithm (MAXENT) and the second one (TWO-STEP) is that we generate the order in two steps[10] (both classifiers are trained on the same features):

1. For the VF, using the OpenNLP maximum entropy learner for a binary classification (VF vs. MF), we select the constituent c with the highest probability of being in the VF.

2. For the MF, the remaining constituents are put into a random order and then *sorted* the way it is done for MAXENT. The training data for the second task was generated only from the MF of clauses.

6 Results

6.1 Evaluation Metrics

We use several metrics to evaluate our systems and the baselines. The first is per-sentence *accuracy* (*acc*) which is the proportion of correctly regenerated sentences. Kendall's τ, which has been used for evaluating sentence ordering tasks (Lapata, 2006), is the second metric we use. τ is calculated as $1 - 4\frac{t}{N(N-1)}$, where t is the number of interchanges of consecutive elements to arrange N elements in the right order. τ is sensitive to near misses and assigns *abdc* (almost correct order) a score of 0.66 while *dcba* (inverse order) gets -1. Note that it is questionable whether this metric is as appropriate for word ordering tasks as for sentence ordering ones because a near miss might turn out to be ungrammatical whereas a more different order stays acceptable.

Apart from *acc* and τ, we also adopt the metrics used by Uchimoto et al. (2000) and Ringger et al. (2004). The former use *agreement rate* (*agr*) calculated as $\frac{2p}{N(N-1)}$: the number of correctly ordered pairs of constituents over the total number of all possible pairs, as well as *complete agreement* which is basically per-sentence accuracy. Unlike τ, which has -1 as the lowest score, *agr* ranges from 0 to 1. Ringger et al. (2004) evaluate the performance only in terms of *per-constituent edit distance* calculated as $\frac{m}{N}$, where m is the minimum number of moves[11] needed to arrange N constituents in the right order. This measure seems less appropriate than τ or *agr* because it does not take the distance of the move into account and scores *abced* and *eabcd* equally (0.2).

Since τ and *agr*, unlike *edit distance*, give higher scores to better orders, we compute *inverse distance*: *inv = 1 – edit_distance* instead. Thus, all three metrics (τ, *agr, inv*) give the maximum of 1 if constituents are ordered correctly. However, like τ, *agr* and *inv* can give a positive score to an ungrammatical order. Hence, none of the evaluation metrics describes the performance perfectly. Human evaluation which reliably distinguishes between appropriate, acceptable, grammatical and ingrammatical orders was out of choice because of its high cost.

6.2 Results

The results on the test data are presented in Table 3. The performance of TWO-STEP is significantly better than any other method (χ^2, $p < 0.01$). The performance of MAXENT does not significantly differ from UCHIMOTO. BIGRAM performed about as good as UCHIMOTO and MAXENT. We also checked how well TWO-STEP performs on each of the two sub-tasks (Table 4) and found that the VF selection is considerably more difficult than the sorting part.

	acc	τ	agr	inv
RAND	15%	0.02	0.51	0.64
RAND_IMP	23%	0.24	0.62	0.71
BIGRAM	51%	0.60	0.80	0.83
UCHIMOTO	50%	0.65	0.82	0.83
MAXENT	52%	0.67	0.84	0.84
TWO-STEP	61%	0.72	0.86	0.87

Table 3: Per-clause mean of the results

The most important conclusion we draw from the results is that the gain of 9% accuracy is due to the VF selection only, because the feature sets are identical for MAXENT and TWO-STEP. From this follows that doing feature selection without splitting the task in two is ineffective, because the importance of a feature depends on whether the VF or the MF is considered. For the MF, feature selection has shown **syn** and **pos** to be the most relevant features. They alone bring the performance in the MF up to 75%. In contrast, these two features explain only 56% of the

[10] Since subordinate clauses do not have a VF, the first step is not needed.

[11] A move is a deletion combined with an insertion.

cases in the VF. This implies that the order in the MF mainly depends on grammatical features, while for the VF all features are important because removal of any feature caused a loss in accuracy.

	acc	τ	agr	inv
TWO-STEP VF	68%	-	-	-
TWO-STEP MF	80%	0.92	0.96	0.95

Table 4: Mean of the results for the VF and the MF

Another important finding is that there is no need to overgenerate to find the right order. Insignificant for clauses with two or three constituents, for clauses with 10 constituents, the number of comparisons is reduced drastically from 163,296,000 to 45.

According to the *inv* metric, our results are considerably worse than those reported by Ringger et al. (2004). As mentioned in Section 3, the fact that they generate the order for every non-terminal node seriously inflates their numbers. Apart from that, they do not report accuracy, and it is unknown, how many sentences they actually reproduced correctly.

6.3 Error Analysis

To reveal the main error sources, we analyzed incorrect predictions concerning the VF and the MF, one hundred for each. Most errors in the VF did not lead to unacceptability or ungrammaticality. From lexical and semantic features, the classifier learned that some expressions are often used in the beginning of a sentence. These are temporal or locational PPs, anaphoric adverbials, some connectives or phrases starting with *unlike X, together with X, as X*, etc. Such elements were placed in the VF instead of the subject and caused an error although both variants were equally acceptable. In other cases the classifier could not find a better candidate but the subject because it could not conclude from the provided features that another constituent would nicely introduce the sentence into the discourse. Mainly this concerns recognizing information familiar to the reader not by an already mentioned entity, but one which is inferrable from what has been read.

In the MF, many orders had a PP transposed with the direct object. In some cases the predicted order seemed as good as the correct one. Often the algorithm failed at identifying verb-specific preferences: E.g., some verbs take PPs with the locational meaning as an argument and normally have them right next to them, whereas others do not. Another frequent error was the wrong placement of superficially identical constituents, e.g. two PPs of the same size. To handle this error, the system needs more specific semantic information. Some errors were caused by the parser, which created extra constituents (e.g. false PP or adverb attachment) or confused the subject with the direct verb.

We retrained our system on a corpus of newspaper articles (Telljohann et al., 2003, TüBa-D/Z) which is manually annotated but encodes no semantic knowledge. The results for the MF were the same as on the data from Wikipedia. The results for the VF were much worse (45%) because of the lack of semantic information.

7 Conclusion

We presented a novel approach to ordering constituents in German. The results indicate that a linguistically-motivated two-step system, which first selects a constituent for the initial position and then orders the remaining ones, works significantly better than approaches which do not make this separation. Our results also confirm the hypothesis – which has been attested in several corpus studies – that the order in the MF is rather rigid and dependent on grammatical properties.

We have also demonstrated that there is no need to overgenerate to find the best order. On a practical side, this finding reduces the amount of work considerably. Theoretically, it lets us conclude that the relatively fixed order in the MF depends on the salience which can be predicted mainly from grammatical features. It is much harder to predict which element should be placed in the VF. We suppose that this difficulty comes from the double function of the initial position which can either introduce the addressation topic, or be the scene- or frame-setting position (Jacobs, 2001).

Abstract

Surface realisers divide into those used in generation (NLG geared realisers) and those mirroring the parsing process (Reversible realisers). While the first rely on grammars not easily usable for parsing, it is unclear how the second type of realisers could be parameterised to yield from among the set of possible paraphrases, the paraphrase appropriate to a given generation context. In this paper, we present a surface realiser which combines a reversible grammar (used for parsing and doing semantic construction) with a symbolic means of selecting paraphrases.

1 Introduction

In generation, the *surface realisation* task consists in mapping a semantic representation into a grammatical sentence.

Depending on their use, on their degree of non-determinism and on the type of grammar they assume, existing surface realisers can be divided into two main categories namely, *NLG (Natural Language Generation) geared realisers* and *reversible realisers*.

NLG geared realisers are meant as modules in a full-blown generation system and as such, they are constrained to be deterministic: a generation system must output exactly one text, no less, no more. In order to ensure this determinism, NLG geared realisers generally rely on theories of grammar which systematically link form to function such as systemic functional grammar (SFG, (Matthiessen and Bateman, 1991)) and, to a lesser extent, Meaning Text Theory (MTT, (Mel'cuk, 1988)). In these theories, a sentence is associated not just with a semantic representation but with a semantic representation enriched with additional syntactic, pragmatic and/or discourse information. This additional information is then used to constrain the realiser output.[1] One drawback of these NLG geared realisers however, is that the grammar used is not usually reversible i.e., cannot be used both for parsing and for generation. Given the time and expertise involved in developing a grammar, this is a non-trivial drawback.

Reversible realisers on the other hand, are meant to mirror the parsing process. They are used on a grammar developed for parsing and equipped with a compositional semantics. Given a string and such a grammar, a parser will assign the input string all the semantic representations associated with that string by the grammar. Conversely, given a semantic representation and the same grammar, a realiser will assign the input semantics all the strings associated with that semantics by the grammar. In such approaches, non-determinism is usually handled by statistical filtering: treebank induced probabilities are used to select from among the possible paraphrases, the most probable one. Since the most probable paraphrase is not necessarily the most appropriate one in a given context, it is unclear however, how such realisers could be integrated into a generation system.

In this paper, we present a surface realiser which

[1] On the other hand, one of our reviewers noted that "determinism" often comes more from defaults when input constraints are not supplied. One might see these realisers as being less deterministic than advertised; however, the point is that it is possible to supply the constraints that ensure determinism.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 328–335,
Prague, Czech Republic, June 2007.

combines reversibility with a symbolic approach to determinism. The grammar used is fully reversible (it is used for parsing) and the realisation algorithm can be constrained by the input so as to ensure a unique output conforming to the requirement of a given (generation) context. We show both that the grammar used has a good paraphrastic power (it is designed in such a way that grammatical paraphrases are assigned the same semantic representations) and that the realisation algorithm can be used either to generate all the grammatical paraphrases of a given input or just one provided the input is adequately constrained.

The paper is structured as follows. Section 2 introduces the grammar used namely, a Feature Based Lexicalised Tree Adjoining Grammar enriched with a compositional semantics. Importantly, this grammar is compiled from a more abstract specification (a so-called "meta-grammar") and as we shall see, it is this feature which permits a natural and systematic coupling of semantic literals with syntactic annotations. Section 3 defines the surface realisation algorithm used to generate sentences from semantic formulae. This algorithm is non-deterministic and produces all paraphrases associated by the grammar with the input semantics. We then go on to show (section 4) how this algorithm can be used on a semantic input enriched with syntactic or more abstract control annotations and further, how these annotations can be used to select from among the set of admissible paraphrases precisely these which obey the constraints expressed in the added annotations. Section 5 reports on a quantitative evaluation based on the use of a core tree adjoining grammar for French. The evaluation gives an indication of the paraphrasing power of the grammar used as well as some evidence of the deterministic nature of the realiser. Section 6 relates the proposed approach to existing work and section 7 concludes with pointers for further research.

2 The grammar

We use a unification based version of LTAG namely, Feature-based TAG. A Feature-based TAG (FTAG, (Vijay-Shanker and Joshi, 1988)) consists of a set of (auxiliary or initial) elementary trees and of two tree composition operations: substitution and adjunction. Initial trees are trees whose leaves are labelled with substitution nodes (marked with a downarrow) or terminal categories. Auxiliary trees are distinguished by a foot node (marked with a star) whose category must be the same as that of the root node. Substitution inserts a tree onto a substitution node of some other tree while adjunction inserts an auxiliary tree into a tree. In an FTAG, the tree nodes are furthermore decorated with two feature structures (called **top** and **bottom**) which are unified during derivation as follows. On substitution, the top of the substitution node is unified with the top of the root node of the tree being substituted in. On adjunction, the top of the root of the auxiliary tree is unified with the top of the node where adjunction takes place; and the bottom features of the foot node are unified with the bottom features of this node. At the end of a derivation, the top and bottom of all nodes in the derived tree are unified.

To associate semantic representations with natural language expressions, the FTAG is modified as proposed in (Gardent and Kallmeyer, 2003).

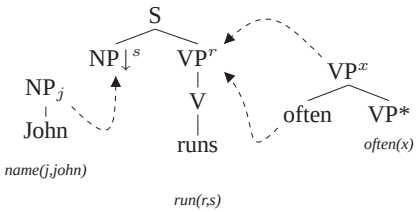

Figure 1: Flat Semantics for "John often runs"

Each elementary tree is associated with a flat semantic representation. For instance, in Figure 1,[2] the trees for *John*, *runs* and *often* are associated with the semantics *name(j,john)*, *run(r,s)* and *often(x)* respectively.

Importantly, the arguments of a semantic functor are represented by unification variables which occur both in the semantic representation of this functor and on some nodes of the associated syntactic tree. For instance in Figure 1, the semantic index s occurring in the semantic representation of *runs* also occurs on the subject substitution node of the associated elementary tree.

[2] C^x/C_x abbreviate a node with category C and a top/bottom feature structure including the feature-value pair { **index :** x}.

The value of semantic arguments is determined by the unifications resulting from adjunction and substitution. For instance, the semantic index s in the tree for *runs* is unified during substitution with the semantic indices labelling the root nodes of the tree for *John*. As a result, the semantics of *John often runs* is

(1) `{name(j,john),run(r,j),often(r)}`

The grammar used describes a core fragment of French and contains around 6 000 elementary trees. It covers some 35 basic subcategorisation frames and for each of these frames, the set of argument redistributions (active, passive, middle, neuter, reflexivisation, impersonal, passive impersonal) and of argument realisations (cliticisation, extraction, omission, permutations, etc.) possible for this frame. As a result, it captures most grammatical paraphrases that is, paraphrases due to diverging argument realisations or to different meaning preserving alternation (e.g., active/passive or clefted/non-clefted sentence).

3 The surface realiser, GenI

The basic surface realisation algorithm used is a bottom up, tabular realisation algorithm (Kay, 1996) optimised for TAGs. It follows a three step strategy which can be summarised as follows. Given an empty agenda, an empty chart and an input semantics ϕ:

Lexical selection. Select all elementary trees whose semantics subsumes (part of) ϕ. Store these trees in the agenda. Auxiliary trees devoid of substitution nodes are stored in a separate agenda called the auxiliary agenda.

Substitution phase. Retrieve a tree from the agenda, add it to the chart and try to combine it by substitution with trees present in the chart. Add any resulting derived tree to the agenda. Stop when the agenda is empty.

Adjunction phase. Move the chart trees to the agenda and the auxiliary agenda trees to the chart. Retrieve a tree from the agenda, add it to the chart and try to combine it by adjunction with trees present in the chart. Add any resulting derived tree to the agenda. Stop when the agenda is empty.

When processing stops, the yield of any syntactically complete tree whose semantics is ϕ yields an output i.e., a sentence.

The workings of this algorithm can be illustrated by the following example. Suppose that the input semantics is (1). In a first step (**lexical selection**), the elementary trees selected are the ones for *John*, *runs*, *often*. Their semantics subsumes part of the input semantics. The trees for *John* and *runs* are placed on the agenda, the one for *often* is placed on the auxiliary agenda.

The second step (the **substitution phase**) consists in systematically exploring the possibility of combining two trees by substitution. Here, the tree for *John* is substituted into the one for *runs*, and the resulting derived tree for *John runs* is placed on the agenda. Trees on the agenda are processed one by one in this fashion. When the agenda is empty, indicating that all combinations have been tried, we prepare for the next phase.

All items containing an empty substitution node are erased from the chart (here, the tree anchored by *runs*). The agenda is then reinitialised to the content of the chart and the chart to the content of the auxiliary agenda (here *often*). The **adjunction phase** proceeds much like the previous phase, except that now all possible adjunctions are performed. When the agenda is empty once more, the items in the chart whose semantics matches the input semantics are selected, and their strings printed out, yielding in this case the sentence *John often runs*.

4 Paraphrase selection

The surface realisation algorithm just sketched is non-deterministic. Given a semantic formula, it might produce several outputs. For instance, given the appropriate grammar for French, the input in (2a) will generate the set of paraphrases partly given in (2b-2k).

(2) a. l_j*:jean(j)* l_a*:aime(e,j,m)* l_m*:marie(m)*

h. C'est Jean dont Marie est aimée
i. C'est Marie qui est aimée par Jean

j. C'est Marie qu'aime Jean

k. C'est Marie que Jean aime

To select from among all possible paraphrases of a given input, exactly one paraphrase, NLG geared realisers use symbolic information to encode syntactic, stylistic or pragmatic constraints on the output. Thus for instance, both REALPRO (Lavoie and Rambow, 1997) and SURGE (Elhadad and Robin, 1999) assume that the input associates semantic literals with low level syntactic and lexical information mostly leaving the realiser to just handle inflection, word order, insertion of grammatical words and agreement. Similarly, KPML (Matthiessen and Bateman, 1991) assumes access to ideational, interpersonal and textual information which roughly corresponds to semantic, mood/voice, theme/rheme and focus/ground information.

In what follows, we first show that the semantic input assumed by the realiser sketched in the previous section can be systematically enriched with syntactic information so as to ensure determinism. We then indicate how the satisfiability of this enriched input could be controlled.

4.1 At most one realisation

In the realisation algorithm sketched in Section 3, non-determinism stems from lexical ambiguity:[3] for each (combination of) literal(s) l in the input there usually is more than one TAG elementary tree whose semantics subsumes l. Thus each (combination of) literal(s) in the input selects a set of elementary trees and the realiser output is the set of combinations of selected lexical trees which are licensed by the grammar operations (substitution and adjunction) and whose semantics is the input.

One way to enforce determinism consists in ensuring that each literal in the input selects exactly one elementary tree. For instance, suppose we want to generate (2b), repeated here as (3a), rather than any of the paraphrases listed in (2c-2k). Intuitively, the syntactic constraints to be expressed are those given in (3b).

(3) a. Jean aime Marie

b. Canonical Nominal Subject, Active verb form, Canonical Nominal Object

c. l_j*:jean(j)* l_a*:aime(e,j,m)* l_m*:marie(m)*

The question is how precisely to formulate these constraints, how to associate them with the semantic input assumed in Section 3 and how to ensure that the constraints used do enforce uniqueness of selection (i.e., that for each input literal, exactly one elementary tree is selected)? To answer this, we rely on a feature of the grammar used, namely that *each elementary tree is associated with a linguistically meaningful unique identifier.*

The reason for this is that the grammar is compiled from a higher level description where tree fragments are first encapsulated into so-called classes and then explicitly combined (by inheritance, conjunction and disjunction) to produce the grammar elementary trees (cf. (Crabbé and Duchier, 2004)).

More generally, each elementary tree in the grammar is associated with the set of classes used to produce that tree and importantly, this set of classes (we will call this the *tree identifier*) provides a distinguishing description (a unique identifier) for that tree: a tree is defined by a specific combination of classes and conversely, a specific combination of classes yields a unique tree.[4] Thus the set of classes associated by the compilation process with a given elementary tree can be used to uniquely identify that tree.

Given this, surface realisation is constrained as follows.

1. Each tree identifier *Id(tree)* is mapped into a simplified set of tree properties TP_t. There are two reasons for this simplification. First, some classes are irrelevant. For instance, the class used to enforce subject-verb agreement is needed to ensure this agreement but does not help in selecting among competing trees. Second, a given class C can be defined to be

[3] Given two TAG trees, there might also be several ways of combining them thereby inducing more non-determinism. However in practice we found that most of this non-determinism is due either to over-generation (cases where the grammar is not sufficiently constrained and allows for one tree to adjoin to another tree in several places) or to spurious derivation (distinct derivations with identical semantics). The few remaining cases that are linguistically correct are due to varying modifier positions and could be constrained by a sophisticated feature decorations in the elementary tree.

[4] This is not absolutely true as a tree identifier only reflects part of the compilation process. In practice, they are few exceptions though so that distinct trees whose tree identifiers are identical can be manually distinguished.

equivalent to the combination of other classes $C_1 \ldots C_n$ and consequently a tree identifier containing $C, C_1 \ldots C_n$ can be reduced to include either C or $C_1 \ldots C_n$.

2. Each literal l_i in the input is associated with a tree property set TP_i (i.e., the input we generate from is enriched with syntactic information)

3. During realisation, for each literal/tree property pair $\langle l_i : TP_i \rangle$ in the enriched input semantics, lexical selection is constrained to retrieve only those trees (i) whose semantics subsumes l_i and (ii) whose tree properties are TP_i

Since each literal is associated with a (simplified) tree identifier and each tree identifier uniquely identifies an elementary tree, realisation produces at most one realisation.

Examples 4a-4c illustrates the kind of constraints used by the realiser.

4.2 At least one realisation

For a realiser to be usable by a generation system, there must be some means to ensure that its input is satisfiable i.e., that it can be realised. How can this be done without actually carrying out realisation i.e., without checking that the input is satisfiable? Existing realisers indicate two types of answers to that dilemma.

A first possibility would be to draw on (Yang et al., 1991)'s proposal and compute the enriched input based on the traversal of a systemic network. More specifically, one possibility would be to consider a systemic network such as NIGEL, precompile all the functional features associated with each possible traversal of the network, map them onto the corresponding tree properties and use the resulting set of tree properties to ensure the satisfiability of the enriched input.

Another option would be to check the well formedness of the input at some level of the linguistic theory on which the realiser is based. Thus for instance, REALPRO assumes as input a well formed deep syntactic structure (DSyntS) as defined by Meaning Text Theory (MTT) and similarly, SURGE takes as input a functional description (FD) which in essence is an underspecified grammatical structure within the SURGE grammar. In both cases, there is no guarantee that the input be satisfiable since all the other levels of the linguistic theory must be verified for this to be true. In MTT, the DSyntS must first be mapped onto a surface syntactic structure and then successively onto the other levels of the theory while in SURGE, the input FD can be realised only if it provides consistent information for a complete top-down traversal of the grammar right down to the lexical level. In short, in both cases, the well formedness of the input can be checked with respect to some criteria (e.g., well formedness of a deep syntactic structure in MTT, well formedness of a FD in SURGE) but this well formedness does not guarantee satisfiability. Nonetheless this basic well formedness check is important as it provides some guidance as to what an acceptable input to the realiser should look like.

We adopt a similar strategy and resort to the notion of *polarity neutral input* to control the well formedness of the enriched input. The proposal draws on ideas from (Koller and Striegnitz, 2002; Gardent and Kow, 2005) and aims to determine whether for a given input (a set of TAG elementary trees whose semantics equate the input semantics), syntactic requirements and resources cancel out. More specifically, the aim is to determine whether given the input set of elementary trees, each substitution and each adjunction requirement is satisfied by exactly one elementary tree of the appropriate syntactic category and semantic index.

Roughly,[5] the technique consists in (automatically) associating with each elementary tree a polarity signature reflecting its substitution/adjunction requirements and resources and in computing the grand polarity of each possible combination of trees covering the input semantics. Each such combination whose total polarity is non-null is then filtered out (not considered for realisation) as it cannot possibly lead to a valid derivation (either a requirement cannot be satisfied or a resource cannot be used).

In the context of a generation system, polarity checking can be used to check the satisfiability of the input or more interestingly, to correct an ill formed input i.e., an input which can be detected as being unsatisfiable.

To check a given input, it suffices to compute its polarity count. If it is non-null, the input is unsatisfiable and should be revised. This is not very useful however, as the enriched input ensures determinism and thereby make realisation very easy, indeed almost as easy as polarity checking.

More interestingly, polarity checking can be used to suggest ways of fixing an ill formed input. In such a case, the enriched input is stripped of its control annotations, realisation proceeds on the basis of this simplified input and polarity checking is used to preselect all polarity neutral combinations of elementary trees. A closest match (i.e. the polarity neutral combination with the greatest number of control annotations in common with the ill formed input) to the ill formed input is then proposed as a probably satisfiable alternative.

5 Evaluation

To evaluate both the paraphrastic power of the realiser and the impact of the control annotations on non-determinism, we used a graduated test-suite which was built by (i) parsing a set of sentences, (ii) selecting the correct meaning representations from the parser output and (iii) generating from these meaning representations. The gradation in the test suite complexity was obtained by partitioning the input into sentences containing one, two or three finite verbs and by choosing cases allowing for different paraphrasing patterns. More specifically, the test suite includes cases involving the following types of paraphrases:

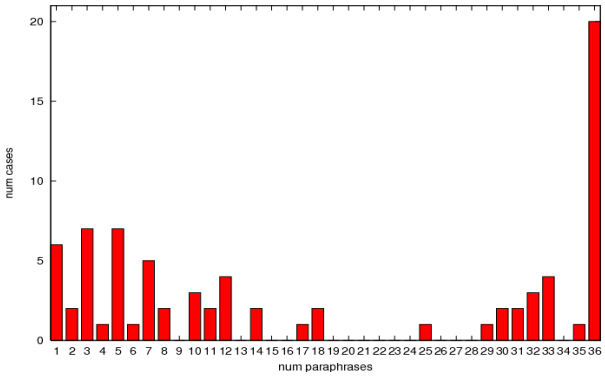
- Grammatical variations in the realisations of the arguments (cleft, cliticisation, question, relativisation, subject-inversion, etc.) or of the verb (active/passive, impersonal)
- Variations in the realisation of modifiers (e.g., relative clause vs adjective, predicative vs non-predicative adjective)
- Variations in the position of modifiers (e.g., pre- vs post-nominal adjective)
- Variations licensed by a morpho-derivational link (e.g., to arrive/arrival)

On a test set of 80 cases, the paraphrastic level varies between 1 and over 50 with an average of 18 paraphrases per input (taking 36 as upper cut off point in the paraphrases count). Figure 5 gives a more detailed description of the distribution of the paraphrastic variation. In essence, 42% of the sentences with one finite verb accept 1 to 3 paraphrases (cases of intransitive verbs), 44% accept 4 to 28 paraphrases (verbs of arity 2) and 13% yield more than 29 paraphrases (ditransitives). For sentences containing two finite verbs, the ratio is 5% for 1 to 3 paraphrases, 36% for 4 to 14 paraphrases and 59% for more than 14 paraphrases. Finally, sentences containing 3 finite verbs all accept more than 29 paraphrases.

Two things are worth noting here. First, the paraphrase figures might seem low wrt to e.g., work by (Velldal and Oepen, 2006) which mentions several thousand outputs for one given input and an average number of realisations per input varying between 85.7 and 102.2. Admittedly, the French grammar we are using has a much more limited coverage than the ERG (the grammar used by (Velldal and Oepen, 2006)) and it is possible that its paraphrastic power is lower. However, the counts we give only take into account *valid paraphrases of the input*. In other words, overgeneration and spurious derivations are excluded from the toll. This does not seem to be the case in (Velldal and Oepen, 2006)'s approach where the count seems to include *all* sentences associated by the grammar with the input semantics.

Second, although the test set may seem small it is important to keep in mind that it represents 80 inputs

[5] Lack of space prevents us from giving much details here. We refer the reader to (Koller and Striegnitz, 2002; Gardent and Kow, 2005) for more details.



with distinct grammatical and paraphrastic properties. In effect, these 80 test cases yields 1 528 distinct well-formed sentences. This figure compares favourably with the size of the largest regression test suite used by a symbolic NLG realiser namely, the SURGE test suite which contains 500 input each corresponding to a single sentence. It also compares reasonably with other more recent evaluations (Callaway, 2003; Langkilde-Geary, 2002) which derive their input data from the Penn Treebank by transforming each sentence tree into a format suitable for the realiser (Callaway, 2003). For these approaches, the test set size varies between roughly 1 000 and almost 3 000 sentences. But again, it is worth stressing that these evaluations aim at assessing coverage and correctness (does the realiser find the sentence used to derive the input by parsing it?) rather than the paraphrastic power of the grammar. They fail to provide a systematic assessment of how many distinct grammatical paraphrases are associated with each given input.

To verify the claim that tree properties can be used to ensure determinism (cf. footnote 4), we started by eliminating from the output all ill-formed sentences. We then automatically associated each well-formed output with its set of tree properties. Finally, for each input semantics, we did a systematic pairwise comparison of the tree property sets associated with the input realisations and we checked whether for any given input, there were two (or more) distinct paraphrases whose tree properties were the same. We found that such cases represented slightly over 2% of the total number of (input,realisations) pairs. Closer investigation of the faulty data indicates two main reasons for non-determinism namely, trees with alternating order of arguments and derivations with distinct modifier adjunctions. Both cases can be handled by modifying the grammar in such a way that those differences are reflected in the tree properties.

6 Related work

The approach presented here combines a reversible grammar realiser with a symbolic approach to paraphrase selection. We now compare it to existing surfaces realisers.

NLG geared realisers. Prominent general purpose NLG geared realisers include REALPRO, SURGE, KPML, NITROGEN and HALOGEN. Furthermore, HALOGEN has been shown to achieve broad coverage and high quality output on a set of 2 400 input automatically derived from the Penn treebank.

The main difference between these and the present approach is that our approach is based on a reversible grammar whilst NLG geared realisers are not. This has several important consequences.

First, it means that one and *the same grammar and lexicon can be used both for parsing and for generation*. Given the complexity involved in developing such resources, this is an important feature.

Second, as demonstrated in the Redwood Lingo Treebank, reversibility makes it easy to *rapidly create very large evaluation suites*: it suffices to parse a set of sentences and select from the parser output the correct semantics. In contrast, NLG geared realisers either work on evaluation sets of restricted size (500 input for SURGE, 210 for KPML) or require the time expensive implementation of a preprocessor transforming e.g., Penn Treebank trees into a format suitable for the realisers. For instance, (Callaway, 2003) reports that the implementation of such a processor for SURGE was the most time consuming part of the evaluation with the resulting component containing 4000 lines of code and 900 rules.

Third, a reversible grammar can be exploited to *support not only realisation but also its reverse, namely semantic construction*. Indeed, reversibility is ensured through a compositional semantics that is, through a tight coupling between syntax and semantics. In contrast, NLG geared realisers often have to reconstruct this association in rather ad hoc ways. Thus for instance, (Yang et al., 1991) resorts to ad

hoc "mapping tables" to associate substitution nodes with semantic indices and "fr-nodes" to constrain adjunction to the correct nodes. More generally, the lack of a clearly defined compositional semantics in NLG geared realisers makes it difficult to see how the grammar they use could be exploited to also support semantic construction.

Fourth, the *grammar can be used both to generate and to detect paraphrases*. It could be used for instance, in combination with the parser and the semantic construction module described in (Gardent and Parmentier, 2005), to support textual entailment recognition or answer detection in question answering.

Reversible realisers. The realiser presented here differs in mainly two ways from existing reversible realisers such as (White, 2004)'s CCG system or the HPSG ERG based realiser (Carroll and Oepen, 2005).

First, it permits a symbolic selection of the output paraphrase. In contrast, existing reversible realisers use statistical information to select from the produced output the most plausible paraphrase.

Second, particular attention has been paid to the treatment of paraphrases in the grammar. Recall that TAG elementary trees are grouped into families and further, that the specific TAG we use is compiled from a highly factorised description. We rely on these features to associate one and the same semantic to large sets of trees denoting semantically equivalent but syntactically distinct configurations (cf. (Gardent, 2006)).

7 Conclusion

The realiser presented here, GENI, exploits a grammar which is produced semi-automatically by compiling a high level grammar description into a Tree Adjoining Grammar. We have argued that a side-effect of this compilation process – namely, the association with each elementary tree of a set of tree properties – can be used to constrain the realiser output. The resulting system combines the advantages of two orthogonal approaches. From the reversible approach, it takes the reusability, the ability to rapidly create very large test suites and the capacity to both generate and detect paraphrases. From the NLG geared paradigm, it takes the ability to symbolically constrain the realiser output to a given generation context.

GENI is free (GPL) software and is available at `http://trac.loria.fr/~geni`.

Abstract

We translate sentence generation from TAG grammars with semantic and pragmatic information into a planning problem by encoding the contribution of each word declaratively and explicitly. This allows us to exploit the performance of off-the-shelf planners. It also opens up new perspectives on referring expression generation and the relationship between language and action.

1 Introduction

Systems that produce natural language must synthesize the primitives of linguistic structure into well-formed utterances that make desired contributions to discourse. This is fundamentally a planning problem: Each linguistic primitive makes certain contributions while potentially introducing new goals. In this paper, we make this perspective explicit by translating the sentence generation problem of TAG grammars with semantic and pragmatic information into a planning problem stated in the widely used Planning Domain Definition Language (PDDL, McDermott (2000)). The encoding provides a clean separation between computation and linguistic modelling and is open to future extensions. It also allows us to benefit from the past and ongoing advances in the performance of off-the-shelf planners (Blum and Furst, 1997; Kautz and Selman, 1998; Hoffmann and Nebel, 2001).

While there have been previous systems that encode generation as planning (Cohen and Perrault, 1979; Appelt, 1985; Heeman and Hirst, 1995), our approach is distinguished from these systems by its focus on the grammatically specified contributions of each individual word (and the TAG tree it anchors) to syntax, semantics, and local pragmatics (Hobbs et al., 1993). For example, words directly achieve content goals by adding a corresponding semantic primitive to the conversational record. We deliberately avoid reasoning about utterances as coordinated rational behavior, as earlier systems did; this allows us to get by with a much simpler logic.

The problem we solve encompasses the generation of referring expressions (REs) as a special case. Unlike some approaches (Dale and Reiter, 1995; Heeman and Hirst, 1995), we do not have to distinguish between generating NPs and expressions of other syntactic categories. We develop a new perspective on the lifecycle of a distractor, which allows us to generate more succinct REs by taking the rest of the utterance into account. More generally, we do not split the process of sentence generation into two separate steps of sentence planning and realization, as most other systems do, but solve the joint problem in a single integrated step. This can potentially allow us to generate higher-quality sentences. We share these advantages with systems such as SPUD (Stone et al., 2003).

Crucially, however, our approach describes the dynamics of interpretation explicitly and declaratively. We do not need to assume extra machinery beyond the encoding of words as PDDL planning operators; for example, our planning operators give a self-contained description of how each individual word contributes to resolving references. This makes our encoding more direct and transparent than those in work like Thomason and Hobbs (1997) and Stone et al. (2003).

We present our encoding in a sequence of steps, each of which adds more linguistic information to

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 336–343,
Prague, Czech Republic, June 2007.

the planning operators. After a brief review of LTAG and PDDL, we first focus on syntax alone and show how to cast the problem of generating grammatically well-formed LTAG trees as a planning problem in Section 2. In Section 3, we add semantics to the elementary trees and add goals to communicate specific content (this corresponds to surface realization). We complete the account by modeling referring expressions and go through an example. Finally, we assess the practical efficiency of our approach and discuss future work in Section 4.

2 Grammaticality as planning

We start by reviewing the LTAG grammar formalism and giving an intuition of how LTAG generation is planning. We then add semantic roles to the LTAG elementary trees in order to distinguish different substitution nodes. Finally, we review the PDDL planning specification language and show how LTAG grammaticality can be encoded as a PDDL problem and how we can reconstruct an LTAG derivation from the plan.

2.1 Tree-adjoining grammars

The grammar formalism we use here is that of *lexicalized tree-adjoining grammars* (LTAG; Joshi and Schabes (1997)). An LTAG grammar consists of a finite set of lexicalized *elementary trees* as shown in Fig. 1a. Each elementary tree contains exactly one *anchor* node, which is labelled by a word. Elementary trees can contain *substitution nodes*, which are marked by down arrows (↓). Those elementary trees that are *auxiliary trees* also contain exactly one *foot node*, which is marked with an asterisk (∗). Trees that are not auxiliary trees are called *initial trees*.

Elementary trees can be combined by *substitution* and *adjunction* to form larger trees. Substitution is the operation of replacing a substitution node of some tree by another initial tree with the same root label. Adjunction is the operation of splicing an auxiliary tree into some node v of a tree, in such a way that the root of the auxiliary tree becomes the child of v's parent, and the foot node becomes the parent of v's children. If a node carries a *null adjunction constraint* (indicated by no-adjoin), no adjunction is allowed at this node; if it carries an *obligatory adjunction constraint* (indicated by adjoin!), an auxiliary tree *must* be adjoined there.

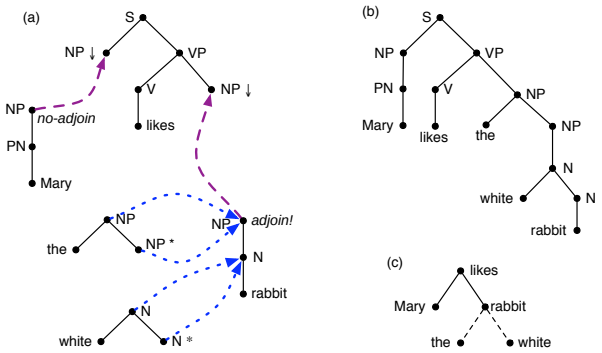

Figure 1: Building a derived (b) and a derivation tree (c) by combining elementary trees (a).

In Fig. 1a, we have combined some elementary trees by substitution (indicated by the dashed/magenta arrows) and adjunction (dotted/blue arrows). The result of these operations is the *derived tree* in Fig. 1b. The *derivation tree* in Fig. 1c represents the tree combination operations we used by having one node per elementary tree and drawing a solid edge if we combined the two trees by substitution, and a dashed edge for adjunctions.

2.2 The basic idea

Consider the process of constructing a derivation tree top-down. To build the tree in Fig. 1c, say, we start with the empty derivation tree and an obligation to generate an expression of category S. We satisfy this obligation by adding the tree for "likes" as the root of the derivation; but in doing so, we have introduced new unfilled substitution nodes of category NP, i.e. the derivation tree is not complete. We use the NP tree for "Mary" to fill one substitution node and the NP tree for "rabbit" to fill the other. This fills both substitution nodes, but the "rabbit" tree introduces an obligatory adjunction constraint, which we must satisfy by adjoining the auxiliary tree for "the". We now have a grammatical derivation tree, but we are free to continue by adding more auxiliary trees, such as the one for "white".

As we have just presented it, the generation of derivation trees is essentially a planning problem. A planning problem involves *states* and *actions* that can move from one state to another. The task is to find a sequence of actions that moves us from the

initial state to a state that satisfies all the *goals*. In our case, the states are defined by the unfilled substitution nodes, the unsatisfied obligatory adjunction constraints, and the nodes that are available for adjunction in some (possibly incomplete) derivation tree. Each action adds a single elementary tree to the derivation, removing some of these "open nodes" while introducing new ones. The initial state is associated with the empty derivation tree and a requirement to generate an expression for the given root category. The goal is for the current derivation tree to be grammatically complete.

2.3 Semantic roles

Formalizing this intuition requires unique names for each node in the derived tree. Such names are necessary to distinguish the different open substitution nodes that still need to be filled, or the different available adjunction sites; in the example, the planner needed to be aware that "likes" introduces *two* separate NP substitution nodes to fill.

There are many ways to assign these names. One that works particularly well in the context of PDDL (as we will see below) is to assume that each node in an elementary tree, except for ones with null adjunction constraints, is marked with a *semantic role*, and that all substitution nodes are marked with different roles. Nothing hinges on the particular role inventory; here we assume an inventory including the roles ag for "agent" and pat for "patient". We also assume one special role self, which must be used for the root of each elementary tree and must never be used for substitution nodes.

We can now assign a unique name to every substitution node in a derived tree by assigning arbitrary but distinct *indices* to each use of an elementary tree, and giving the substitution node with role r in the elementary tree with index i the *identity* $i.r$. In the example, let's say the "likes" tree has index 1 and the semantic roles for the substitution nodes were ag and pat, respectively. The planner action that adds this tree would then require substitution of one NP with identity 1.ag and another NP with identity 1.pat; the "Mary" tree would satisfy the first requirement and the "rabbit" tree the second. If we assume that no elementary tree contains two internal nodes with the same category and role, we can refer to adjunction opportunities in a similar way.

Action `S-likes-1`(u). Precond: $\mathsf{subst}(\mathrm{S},u),\mathsf{step}(1)$
Effect: $\neg\mathsf{subst}(\mathrm{S},u),\mathsf{subst}(\mathrm{NP},1.\mathsf{ag}),$
$\mathsf{subst}(\mathrm{NP},1.\mathsf{pat}),\neg\mathsf{step}(1),\mathsf{step}(2)$

Action `NP-Mary-2`(u). Precond: $\mathsf{subst}(\mathrm{NP},u),\mathsf{step}(2)$
Effect: $\neg\mathsf{subst}(\mathrm{NP},u),\neg\mathsf{step}(2),\mathsf{step}(3)$

Action `NP-rabbit-3`(u). Precond: $\mathsf{subst}(\mathrm{NP},u),\mathsf{step}(3)$
Effect: $\neg\mathsf{subst}(\mathrm{NP},u),\mathsf{canadjoin}(\mathrm{NP},u),$
$\mathsf{mustadjoin}(\mathrm{NP},u),\neg\mathsf{step}(3),\mathsf{step}(4)$

Action `NP-the-4`(u). Precond: $\mathsf{canadjoin}(\mathrm{NP},u),\mathsf{step}(4)$
Effect: $\neg\mathsf{mustadjoin}(\mathrm{NP},u),\neg\mathsf{step}(4),\mathsf{step}(5)$

Figure 2: Some actions for the grammar in Fig. 1.

2.4 Encoding in PDDL

Now we are ready to encode the problem of generating grammatical LTAG derivation trees into PDDL. PDDL (McDermott, 2000) is the standard input language for modern planning systems. It is based on the well-known STRIPS language (Fikes and Nilsson, 1971). In this paradigm, a planning state is defined as a finite set of ground atoms of predicate logic that are true in this state; all other atoms are assumed to be false. Actions have a number of *parameters*, as well as a *precondition* and *effect*, both of which are logical formulas. When a planner tries to apply an action, it will first create an action *instance* by binding all parameters to constants from the domain. It must then verify that the precondition of the action instance is satisfied in the current state. If so, the action can be applied, in which case the effect is processed in order to change the state. In STRIPS, the precondition and effect both had to be conjunctions of atoms or negated atoms; positive effects are interpreted as making the atom true in the new state, and negative ones as making it false. PDDL permits numerous extensions to the formulas that can be used as preconditions and effects.

Each action in our planning problem encodes the effect of adding some elementary tree to the derivation tree. An initial tree with root category A translates to an action with a parameter u for the identity of the node that the current tree is substituted into. The action carries the precondition $\mathsf{subst}(A,u)$, and so can only be applied if u is an open substitution node in the current derivation with the correct category A. Auxiliary trees are analogous, but carry the precondition $\mathsf{canadjoin}(A,u)$. The effect of an initial tree is to remove the subst condition from the planning state (to record that the substitu-

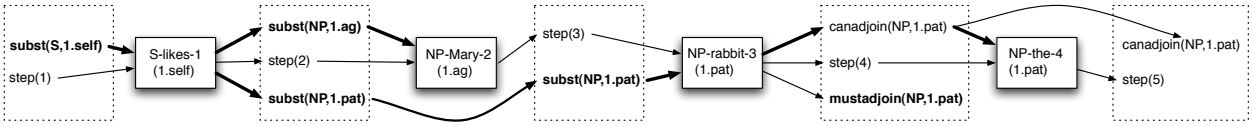

Figure 3: A plan for the actions in Fig. 2.

tion node u is now filled); an auxiliary tree has an effect $\neg\mathsf{mustadjoin}(A,u)$ to indicate that any obligatory adjunction constraint is satisfied but leaves the canadjoin condition in place to allow multiple adjunctions into the same node. In both cases, effects add subst, canadjoin and mustadjoin atoms representing the substitution nodes and adjunction sites that are introduced by the new elementary tree.

One remaining complication is that an action must assign new identities to the nodes it introduces; thus it must have access to a tree index that was not used in the derivation tree so far. We use the number of the current plan step as the index. We add an atom $\mathsf{step}(1)$ to the initial state of the planning problem, and we introduce k different copies of the actions for each elementary tree, where k is some upper limit on the plan size. These actions are identical, except that the i-th copy has an extra precondition $\mathsf{step}(i)$ and effects $\neg\mathsf{step}(i)$ and $\mathsf{step}(i+1)$. It is no restriction to assume an upper limit on the plan size, as most modern planners search for plans smaller than a given maximum length anyway.

Fig. 2 shows some of the actions into which the grammar in Fig. 1 translates. We display only one copy of each action and have left out most of the canadjoin effects. In addition, we use an initial state containing the atoms $\mathsf{subst}(S,1.\mathsf{self})$ and $\mathsf{step}(1)$ and a final state consisting of the following goal:

$$\forall A,u.\neg\mathsf{subst}(A,u) \wedge \forall A,u.\neg\mathsf{mustadjoin}(A,u).$$

We can then send the actions and the initial state and goal specifications to any off-the-shelf planner and obtain the plan in Fig. 3. The straight arrows in the picture link the actions to their preconditions and (positive) effects; the curved arrows indicate atoms that carry over from one state to the next without being changed by the action. Atoms are printed in boldface iff they contradict the goal.

This plan can be read as a derivation tree that has one node for each action instance in the plan, and an edge from node u to node v if u establishes a subst or canadjoin fact that is a precondition of v. These causal links are drawn as bold edges in Fig. 3. The mapping is unique for substitution edges because subst atoms are removed by every action that has them as their precondition. There may be multiple action instances in the plan that introduce the same atom $\mathsf{canadjoin}(A,u)$. In this case, we can freely choose one of these instances as the parent.

3 Sentence generation as planning

Now we extend this encoding to deal with semantics and referring expressions.

3.1 Communicative goals

In order to use the planner as a *surface realization* algorithm for TAG along the lines of Koller and Striegnitz (2002), we attach *semantic content* to each elementary tree and require that the sentence achieves a certain *communicative goal*. We also use a *knowledge base* that specifies the speaker's knowledge, and require that we can only use trees that express information in this knowledge base.

We follow Stone et al. (2003) in formalizing the semantic content of a lexicalized elementary tree t as a finite set of atoms; but unlike in earlier approaches, we use the semantic roles in t as the arguments of these atoms. For instance, the semantic content of the "likes" tree in Fig. 1 is $\{\mathsf{like}(\mathsf{self},\mathsf{ag},\mathsf{pat})\}$ (see also the semcon entries in Fig. 4). The knowledge base is some finite set of ground atoms; in the example, it could contain such entries as $\mathsf{like}(e,m,r)$ and $\mathsf{rabbit}(r)$. Finally, the communicative goal is some subset of the knowledge base, such as $\{\mathsf{like}(e,m,r)\}$.

We implement unsatisfied communicative goals as flaws that the plan must remedy. To this end, we add an atom $\mathsf{cg}(P,a_1,\ldots,a_n)$ for each element $P(a_1,\ldots,a_n)$ of the communicative goal to the initial state, and we add a corresponding conjunct $\forall P,x_1,\ldots,x_n.\neg\mathsf{cg}(P,x_1,\ldots,x_n)$ to the goal. In addition, we add an atom $\mathsf{skb}(P,a_1,\ldots,a_n)$ to the initial state for each element $P(a_1,\ldots,a_n)$ of the (speaker's) knowledge base.

We then add parameters $x_1, \ldots, x_n$ to each action with n semantic roles (including self). These new parameters are intended to be bound to individual constants in the knowledge base by the planner. For each elementary tree t and possible step index i, we establish the relationship between these parameters and the roles in two steps. First we fix a function id that maps the semantic roles of t to node identities. It maps self to u and each other role r to $i.r$. Second, we fix a function ref that maps the outputs of id bijectively to the parameters $x_1, \ldots, x_n$, in such a way that $\mathsf{ref}(u) = x_1$.

We can then capture the contribution of the i-th action for t to the communicative goal by giving it an effect $\neg\mathsf{cg}(P, \mathsf{ref}(\mathsf{id}(r_1)), \ldots, \mathsf{ref}(\mathsf{id}(r_n)))$ for each element $P(r_1, \ldots, r_n)$ of the elementary tree's semantic content. We restrict ourselves to only expressing true statements by giving the action a precondition $\mathsf{skb}(P, \mathsf{ref}(\mathsf{id}(r_1)), \ldots, \mathsf{ref}(\mathsf{id}(r_n)))$ for each element of the semantic content.

In order to keep track of the connection between node identities and individuals for future reference, each action gets an effect $\mathsf{referent}(\mathsf{id}(r), \mathsf{ref}(\mathsf{id}(r)))$ for each semantic role r except self. We enforce the connection between u and x_1 by adding a precondition $\mathsf{referent}(u, x_1)$.

In the example, the most interesting action in this respect is the one for the elementary tree for "likes". This action looks as follows:

Action `S-likes-1`(u, x_1, x_2, x_3)**.**

Precond: $\mathsf{subst}(\mathrm{S}, u), \mathsf{step}(1), \mathsf{referent}(u, x_1),$
$\mathsf{skb}(\mathsf{like}, x_1, x_2, x_3)$
Effect: $\neg\mathsf{subst}(\mathrm{S}, u), \mathsf{subst}(\mathrm{NP}, 1.\mathsf{ag}), \mathsf{subst}(\mathrm{NP}, 1.\mathsf{pat}),$
$\neg\mathsf{step}(1), \mathsf{step}(2),$
$\mathsf{referent}(1.\mathsf{ag}, x_2), \mathsf{referent}(1.\mathsf{pat}, x_3),$
$\neg\mathsf{cg}(\mathsf{like}, x_1, x_2, x_3)$

We can run a planner and interpret the plan as above; the main difference is that complete plans not only correspond to grammatical derivation trees, but also express all communicative goals. Notice that this encoding models some aspects of lexical choice: The semantic content sets of the elementary trees need not be singletons, and so there may be multiple ways of partitioning the communicative goal into the content sets of various elementary trees.

3.2 Referring expressions

Finally, we extend the system to deal with the generation of referring expressions. While this problem is typically taken to require the generation of a noun phrase that refers uniquely to some individual, we don't need to make any assumptions about the syntactic category here. Moreover, we consider the problem in the wider context of generating referring expressions within a sentence, which can allow us to generate more succinct expressions.

Because a referring expression must allow the *hearer* to identify the intended referent uniquely, we keep track of the hearer's knowledge base separately. We use atoms $\mathsf{hkb}(P, a_1, \ldots, a_n)$, as with skb above. In addition, we assume *pragmatic* information of the form $\mathsf{pkb}(P, a_1, \ldots, a_n)$. The three pragmatic predicates that we will use here are hearer-new, indicating that the hearer does not know about the existence of an individual and can't infer it (Stone et al., 2003), hearer-old for the opposite, and contextset. The *context set* of an intended referent is the set of all individuals that the hearer might possibly confuse it with (DeVault et al., 2004). It is empty for hearer-new individuals. To say that b is in a's context set, we put the atom $\mathsf{pkb}(\mathsf{contextset}, a, b)$ into the initial state.

In addition to the semantic content, we equip every elementary tree in the grammar with a *semantic requirement* and a *pragmatic condition* (Stone et al., 2003). The semantic requirement is a set of atoms spelling out presuppositions of an elementary tree that can help the hearer identify what its arguments refer to. For instance, "likes" has the selectional restriction that its agent must be animate; thus the hearer will not consider inanimate individuals as distractors for the referring expression in agent position. The pragmatic condition is a set of atoms over the predicates in the pragmatic knowledge base.

In our setting, every substitution node that is introduced during the derivation introduces a new referring expression. This means that we can distinguish the referring expressions by the identity of the substitution node that introduced them. For each referring expression u (where u is a node identity), we keep track of the *distractors* in atoms of the form $\mathsf{distractor}(u, x)$. The presence of an atom $\mathsf{distractor}(u, a)$ in some planning state represents the fact that the current derivation tree is not yet informative enough to allow the hearer to identify the intended referent for u uniquely; a is another individual that is not the intended referent,

but consistent with the partial referring expression we have constructed so far. We enforce uniqueness of all referring expressions by adding the conjunct $\forall u,x \neg \mathsf{distractor}(u,x)$ to the planning goal.

Now whenever an action introduces a new substitution node u, it will also introduce some distractor atoms to record the initial distractors for the referring expression at u. An individual a is in the initial distractor set for the substitution node with role r if (a) it is not the intended referent, (b) it is in the context set of the intended referent, and (c) there is a choice of individuals for the other parameters of the action that satisfies the semantic requirement together with a. This is expressed by adding the following effect for each substitution node; the conjunction is over the elements $P(r_1,\ldots,r_n)$ of the semantic requirement, and there is one universal quantifier for y and for each parameter x_j of the action except for $\mathsf{ref}(\mathsf{id}(r))$.

$$\begin{array}{l}\forall y,x_1,\ldots,x_n \\ \quad (y \neq \mathsf{ref}(\mathsf{id}(r)) \wedge \mathsf{pkb}(\mathsf{contextset},\mathsf{ref}(\mathsf{id}(r)),y) \wedge \\ \quad \bigwedge \mathsf{hkb}(P,\mathsf{ref}(\mathsf{id}(r_1)),\ldots,\mathsf{ref}(\mathsf{id}(r_n)))[y/\mathsf{ref}(\mathsf{id}(r))]) \\ \quad \rightarrow \mathsf{distractor}(\mathsf{id}(r),y)\end{array}$$

On the other hand, a distractor a for a referring expression introduced at u is removed when we substitute or adjoin an elementary tree into u which rules a out. For instance, the elementary tree for "rabbit" will remove all non-rabbits from the distractor set of the substitution node into which it is substituted. We achieve this by adding the following effect to each action; here the conjunction is over all elements of the semantic content.

$$\begin{array}{l}\forall y.(\neg \bigwedge \mathsf{hkb}(P,\mathsf{ref}(\mathsf{id}(r_1)),\ldots,\mathsf{ref}(\mathsf{id}(r_n))))[y/x_1] \\ \quad \rightarrow \neg \mathsf{distractor}(u,y),\end{array}$$

Finally, each action gets its pragmatic condition as a precondition.

3.3 The example

By way of example, Fig. 5 shows the full versions of the actions from Fig. 2, for the extended grammar in Fig. 4. Let's say that the hearer knows about two rabbits r (which is white) and r' (which is not), about a person m with the name Mary, and about an event e, and that the context set of r is $\{r,r',m,e\}$. Let's also say that our communicative goal is $\{\mathsf{like}(e,m,r)\}$. In this case, the first action instance in Fig. 3, `S-likes-1`$(1.\mathsf{self},e,m,r)$, introduces a substitution node with identity 1.pat. The

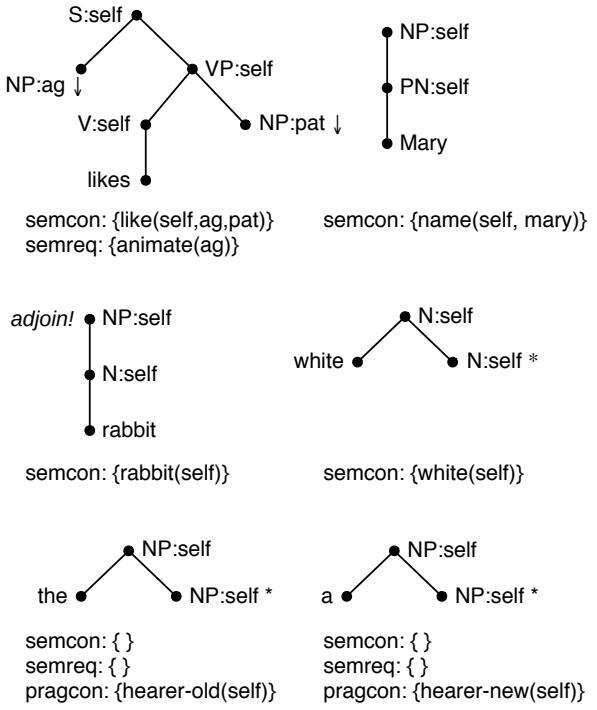

Figure 4: The extended example grammar.

initial distractor set of this node is $\{r',m\}$ – the set of all individuals in r's context set except for inanimate objects (which violate the semantic requirement) and r itself. The `NP-rabbit-3` action removes m from the distractor set, but at the end of the plan in Fig. 3, r' is still a distractor, i.e. we have not reached a goal state. We can complete the plan by performing a final action `NP-white-5`$(1.\mathsf{pat},r)$, which will remove this distractor and achieve the planning goal. We can still reconstruct a derivation tree from the complete plan literally as described in Section 2.

Now let's say that the hearer did not know about the existence of the individual r before the utterance we are generating. We model this by marking r as hearer-new in the pragmatic knowledge base and assigning it an empty context set. In this case, the referring expression 1.pat would be initialized with an empty distractor set. This entitles us to use the action `NP-a-4` and generate the four-step plan corresponding to the sentence "Mary likes a rabbit."

4 Discussion and future work

In conclusion, let's look in more detail at computational issues and the role of mutually constraining referring expressions.

Action `S-likes-1`(u,x_1,x_2,x_3)**.**
Precond: $\mathsf{referent}(u,x_1),\mathsf{skb}(\mathsf{like},x_1,x_2,x_3),\mathsf{subst}(\mathrm{S},u),\mathsf{step}(1)$
Effect: $\neg\mathsf{cg}(\mathsf{like},x_1,x_2,x_3),\neg\mathsf{subst}(\mathrm{S},u),\neg\mathsf{step}(1),\mathsf{step}(2),\mathsf{subst}(\mathrm{NP},1.\mathsf{ag}),\mathsf{subst}(\mathrm{NP},1.\mathsf{pat}),$
$\forall y.\neg\mathsf{hkb}(\mathsf{like},y,x_2,x_3)\rightarrow\neg\mathsf{distractor}(u,y),$
$\forall y,x_1,x_3.x_2\neq y\wedge\mathsf{pkb}(\mathsf{contextset},x_2,y)\wedge\mathsf{animate}(y)\rightarrow\mathsf{distractor}(1.\mathsf{ag},y),$
$\forall y,x_1,x_2.x_3\neq y\wedge\mathsf{pkb}(\mathsf{contextset},x_3,y)\rightarrow\mathsf{distractor}(1.\mathsf{pat},y)$

Action `NP-Mary-2`(u,x_1)**.**
Precond: $\mathsf{referent}(u,x_1),\mathsf{skb}(\mathsf{name},x_1,\mathsf{mary}),$
$\mathsf{subst}(\mathrm{NP},u),\mathsf{step}(2)$
Effect: $\neg\mathsf{cg}(\mathsf{name},x_1,\mathsf{mary}),\neg\mathsf{subst}(\mathrm{NP},u),$
$\neg\mathsf{step}(2),\mathsf{step}(3),$
$\forall y.\neg\mathsf{hkb}(\mathsf{name},y,\mathsf{mary})\rightarrow\neg\mathsf{distractor}(u,y)$

Action `NP-rabbit-3`(u,x_1)**.**
Precond: $\mathsf{referent}(u,x_1),\mathsf{skb}(\mathsf{rabbit},x_1),$
$\mathsf{subst}(\mathrm{N},u),\mathsf{step}(3)$
Effect: $\neg\mathsf{cg}(\mathsf{rabbit},x_1),\neg\mathsf{subst}(\mathrm{N},u),\neg\mathsf{step}(3),\mathsf{step}(4),$
$\mathsf{canadjoin}(\mathrm{NP},u),\mathsf{mustadjoin}(\mathrm{NP},u),$
$\forall y.\neg\mathsf{hkb}(\mathsf{rabbit},y)\rightarrow\neg\mathsf{distractor}(u,y)$

Action `NP-the-4`(u,x_1)**.**
Precond: $\mathsf{referent}(u,x_1),\mathsf{canadjoin}(\mathrm{NP},u),\mathsf{step}(4),$
$\mathsf{pkb}(\mathsf{hearer\text{-}old},x_1)$
Effect: $\neg\mathsf{mustadjoin}(\mathrm{NP},u),\neg\mathsf{step}(4),\mathsf{step}(5)$

Action `NP-a-4`(u,x_1)**.**
Precond: $\mathsf{referent}(u,x_1),\mathsf{canadjoin}(\mathrm{NP},u),\mathsf{step}(4),$
$\mathsf{pkb}(\mathsf{hearer\text{-}new},x_1)$
Effect: $\neg\mathsf{mustadjoin}(\mathrm{NP},u),\neg\mathsf{step}(4),\mathsf{step}(5)$

Action `NP-white-5`(u,x_1)**.**
Precond: $\mathsf{referent}(u,x_1),\mathsf{skb}(\mathsf{white},x_1),\mathsf{canadjoin}(\mathrm{NP},u),\mathsf{step}(5)$
Effect: $\neg\mathsf{cg}(\mathsf{white},x_1),\neg\mathsf{mustadjoin}(\mathrm{NP},u),\neg\mathsf{step}(5),\mathsf{step}(6),$
$\forall y.\neg\mathsf{hkb}(\mathsf{white},y)\rightarrow\neg\mathsf{distractor}(u,y)$

Figure 5: Some of the actions corresponding to the grammar in Fig. 4.

4.1 Computational issues

We lack the space to present the formal definition of the sentence generation problem we encode into PDDL. However, this problem is NP-complete, by reduction of Hamiltonian Cycle – unsurprisingly, given that it encompasses realization, and the very similar realization problem in Koller and Striegnitz (2002) is NP-hard. So any algorithm for our problem must be prepared for exponential runtimes.

We have implemented the translation described in this paper and experimented with a number of different grammars, knowledge bases, and planners. The FF planner (Hoffmann and Nebel, 2001) can compute the plans in Section 3.3 in under 100 ms using the grammar in Fig. 4. If we add 10 more lexicon entries to the grammar, the runtime grows to 190 ms; and for 20 more entries, to 360 ms. The runtime also grows with the plan length: It takes 410 ms to generate a sentence "Mary likes the Adj ... Adj rabbit" with four adjectives and 890 ms for six adjectives, corresponding to a plan length of 10. We compared these results against a planning-based reimplementation of SPUD's greedy search heuristic (Stone et al., 2003). This system is faster than FF for small inputs (360 ms for four adjectives), but becomes slower as inputs grow larger (1000 ms for six adjectives); but notice that while FF is also a heuristic planner, it is guaranteed to find a solution if one exists, unlike SPUD.

Planners have made tremendous progress in efficiency in the past decade, and by encoding sentence generation as a planning problem, we are set to profit from any future improvements; it is an advantage of the planning approach that we can compare very different search strategies like FF's and SPUD's in the same framework. However, our PDDL problems are challenging for modern planners because most planners start by computing all instances of atoms and actions. In our experiments, FF generally spent only about 10% of the runtime on search and the rest on computing the instances; that is, there is a lot of room for optimization. For larger grammars and knowledge bases, the number of instances can easily grow into the billions. In future work, we will therefore collaborate with experts on planning systems to compute action instances only by need.

4.2 Referring expressions

In our analysis of referring expressions, the tree t that introduces the new substitution nodes typically initializes the distractor sets with proper subsets of the entire domain. This allows us to generate succinct descriptions by encoding t's presuppositions as semantic requirements, and localizes the interactions between the referring expressions generated for different substitution nodes within t's action.

However, an important detail in the encoding of referring expressions above is that an individual a counts as a distractor for the role r if there is any tuple of values that satisfies the semantic requirement and has a in the r-component. This is correct, but can sometimes lead to overly complicated referring expressions. An example is the construction "X takes Y from Z", which presupposes that Y is in Z. In a scenario that involves multiple rabbits, multiple hats, and multiple individuals that are inside other individuals, but only one pair of a rabbit r inside a hat h, the expression "X takes the rabbit from the hat" is sufficient to refer uniquely to r and h (Stone and Webber, 1998). Our system would try to generate an expression for Y that suffices by itself to distinguish r from all distractors, and similarly for Z. We will explore this issue further in future work.

5 Conclusion

In this paper, we have shown how sentence generation with TAG grammars and semantic and pragmatic information can be encoded into PDDL. Our encoding is declarative in that it can be used with any correct planning algorithm, and explicit in that the actions capture the complete effect of a word on the syntactic, semantic, and local pragmatic goals. In terms of expressive power, it captures the core of SPUD, except for its inference capabilities.

This work is practically relevant because it opens up the possibility of using efficient planners to make generators faster and more flexible. Conversely, our PDDL problems are a challenge for current planners and open up NLG as an application domain that planning research itself can target.

Theoretically, our encoding provides a new framework for understanding and exploring the general relationships between language and action. It suggests new ways of going beyond SPUD's expressive power, to formulate utterances that describe and disambiguate concurrent real-world actions or exploit the dynamics of linguistic context within and across sentences.

Abstract

In evaluating the output of language technology applications—MT, natural language generation, summarisation—automatic evaluation techniques generally conflate measurement of faithfulness to source content with fluency of the resulting text. In this paper we develop an automatic evaluation metric to estimate fluency alone, by examining the use of parser outputs as metrics, and show that they correlate with human judgements of generated text fluency. We then develop a machine learner based on these, and show that this performs better than the individual parser metrics, approaching a lower bound on human performance. We finally look at different language models for generating sentences, and show that while individual parser metrics can be 'fooled' depending on generation method, the machine learner provides a consistent estimator of fluency.

1 Introduction

Intrinsic evaluation of the output of many language technologies can be characterised as having at least two aspects: how well the generated text reflects the source data, whether it be text in another language for machine translation (MT), a natural language generation (NLG) input representation, a document to be summarised, and so on; and how well it conforms to normal human language usage. These two aspects are often made explicit in approaches to creating the text. For example, in statistical MT the translation model and the language model are treated separately, characterised as faithfulness and fluency respectively (as in the treatment in Jurafsky and Martin (2000)). Similarly, the ultrasummarisation model of Witbrock and Mittal (1999) consists of a content model, modelling the probability that a word in the source text will be in the summary, and a language model.

Evaluation methods can be said to fall into two categories: a comparison to gold reference, or an appeal to human judgements. Automatic evaluation methods carrying out a comparison to gold reference tend to conflate the two aspects of faithfulness and fluency in giving a goodness score for generated output. BLEU (Papineni et al., 2002) is a canonical example: in matching n-grams in a candidate translation text with those in a reference text, the metric measures faithfulness by counting the matches, and fluency by implicitly using the reference n-grams as a language model. Often we are interested in knowing the quality of the two aspects separately; many human judgement frameworks ask specifically for separate judgements on elements of the task that correspond to faithfulness and to fluency. In addition, the need for reference texts for an evaluation metric can be problematic, and intuitively seems unnecessary for characterising an aspect of text quality that is not related to its content source but to the use of language itself. It is a goal of this paper to provide an automatic evaluation method for fluency alone, without the use of a reference text.

One might consider using a metric based on language model probabilities for sentences: in eval-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 344–351,
Prague, Czech Republic, June 2007.

uating a language model on (already existing) test data, a higher probability for a sentence (and lower perplexity over a whole test corpus) indicates better language modelling; perhaps a higher probability might indicate a better sentence. However, here we are looking at generated sentences, which have been generated using their own language model, rather than human-authored sentences already existing in a test corpus; and so it is not obvious what language model would be an objective assessment of sentence naturalness. In the case of evaluating a single system, using the language model that generated the sentence will only confirm that the sentence does fit the language model; in situations such as comparing two systems which each generate text using a different language model, it is not obvious that there is a principled way of deciding on a fair language model. Quite a different idea was suggested in Wan et al. (2005), of using the grammatical judgement of a parser to assess fluency, giving a measure independent of the language model used to generate the text. The idea is that, assuming the parser has been trained on an appropriate corpus, the poor performance of the parser on one sentence relative to another might be an indicator of some degree of ungrammaticality and possibly disfluency. In that work, however, correlation with human judgements was left uninvestigated.

The goal of this paper is to take this idea and develop it. In Section 2 we look at some related work on metrics, in particular for NLG. In Section 3, we verify whether parser outputs can be used as estimators of generated sentence fluency by correlating them with human judgements. In Section 4, we propose an SVM-based metric using parser outputs as features, and compare its correlation against human judgements with that of the individual parsers. In Section 5, we investigate the effects on the various metrics from different types of language model for the generated text. Then in Section 6 we conclude.

2 Related Work

In terms of human evaluation, there is no uniform view on what constitutes the notion of fluency, or its relationship to grammaticality or similar concepts. We mention a few examples here to illustrate the range of usage. In MT, the 2005 NIST MT Evaluation Plan uses guidelines[1] for judges to assess 'adequacy' and 'fluency' on 5 point scales, where they are asked to provide intuitive reactions rather than pondering their decisions; for fluency, the scale descriptions are fairly vague (5: flawless English; 4: good English; 3: non-native English; 2: disfluent English; 1: incomprehensible) and instructions are short, with some examples provided in appendices. Zajic et al. (2002) use similar scales for summarisation. By contrast, Pan and Shaw (2004), for their NLG system SEGUE tied the notion of fluency more tightly to grammaticality, giving two human evaluators three grade options: good, minor grammatical error, major grammatical/pragmatic error. As a further contrast, the analysis of Coch (1996) was very comprehensive and fine-grained, in a comparison of three text-production techniques: he used 14 human judges, each judging 60 letters (20 per generation system), and required them to assess the letters for correct spelling, good grammar, rhythm and flow, appropriateness of tone, and several other specific characteristics of good text.

In terms of automatic evaluation, we are not aware of any technique that measures only fluency or similar characteristics, ignoring content, apart from that of Wan et al. (2005). Even in NLG, where, given the variability of the input representations (and hence difficulty in verifying faithfulness), it might be expected that such measures would be available, the available metrics still conflate content and form. For example, the metrics proposed in Bangalore et al. (2000), such as Simple Accuracy and Generation Accuracy, measure changes with respect to a reference string based on the idea of string-edit distance. Similarly, BLEU has been used in NLG, for example by Langkilde-Geary (2002).

3 Parsers as Evaluators

There are three parts to verifying the usefulness of parsers as evaluators: choosing the parsers and the metrics derived from them; generating some texts for human and parser evaluation; and, the key part, getting human judgements on these texts and correlating them with parser metrics.

[1] http://projects.ldc.upenn.edu/TIDES/Translation/TranAssessSpec.pdf

3.1 The Parsers

In testing the idea of using parsers to judge fluency, we use three parsers, from which we derive four parser metrics, to investigate the general applicability of the idea. Those chosen were the Connexor parser,[2] the Collins parser (Collins, 1999), and the Link Grammar parser (Grinberg et al., 1995). Each produces output that can be taken as representing degree of ungrammaticality, although this output is quite different for each.

Connexor is a commercially available dependency parser that returns head–dependant relations as well as stemming information, part of speech, and so on. In the case of an ungrammatical sentence, Connexor returns tree fragments, where these fragments are defined by transitive head–dependant relations: for example, for the sentence *Everybody likes big cakes do* it returns fragments for *Everybody likes big cakes* and for *do*. We expect that the number of fragments should correlate inversely with the quality of a sentence. For a metric, we normalise this number by the largest number of fragments for a given data set. (Normalisation matters most for the machine learner in Section 4.)

The Collins parser is a statistical chart parser that aims to maximise the probability of a parse using dynamic programming. The parse tree produced is annotated with log probabilities, including one for the whole tree. In the case of ungrammatical sentences, the parser will assign a low probability to any parse, including the most likely one. We expect that the log probability (becoming more negative as the sentence is less likely) should correlate positively with the quality of a sentence. For a metric, we normalise this by the most negative value for a given data set.

Like Connexor, the Link Grammar parser returns information about word relationships, forming links, with the proviso that links cannot cross and that in a grammatical sentence all links are indirectly connected. For an ungrammatical sentence, the parser will delete words until it can produce a parse; the number it deletes is called the 'null count'. We expect that this should correlate inversely with sentence quality. For a metric, we normalise this by the sentence length. In addition, the parser produces another variable possibly of interest. In generating a parse, the parser produces many candidates and rules some out by a posteriori constraints on valid parses. In its output the parser returns the number of invalid parses. For an ungrammatical sentence, this number may be higher; however, there may also be more parses. For a metric, we normalise this by the total number of parses found for the sentence. There is no strong intuition about the direction of correlation here, but we investigate it in any case.

[2] `http://www.connexor.com`

3.2 Text Generation Method

To test whether these parsers are able to discriminate sentence-length texts of varying degrees of fluency, we need first to generate texts that we expect will be discriminable in fluency quality ranging from good to very poor. Below we describe our method for generating text, and then our preliminary check on the discriminability of the data before giving them to human judges.

Our approach to generating 'sentences' of a fixed length is to take word sequences of different lengths from a corpus and glue them together probabilistically: the intuition is that a few longer sequences glued together will be more fluent than many shorter sequences. More precisely, to generate a sentence of length n, we take sequences of length l (such that l divides n), with sequence i of the form $w_{i,1} \ldots w_{i,l}$, where $w_{i,\_}$ is a word or punctuation mark. We start by selecting sequence 1, first by randomly choosing its first word according to the unigram probability $P(w_{1,1})$, and then the sequence uniformly randomly over all sequences of length l starting with $w_{1,1}$; we select subsequent sequences j ($2 \leq j \leq n/l$) randomly according to the bigram probability $P(w_{j,1} \,|\, w_{j-1,l})$. Taking as our corpus the Reuters corpus,[3] for length $n = 24$, we generate sentences for sequence sizes $l = 1, 2, 4, 8, 24$ as in Figure 1. So, for instance, the sequence-size 8 example was constructed by stringing together the three consecutive sequences of length 8 (*There . . . to*; *be . . . have*; *to . . .*.) taken from the corpus.

These examples, and others generated, appear to be of variable quality in accordance with our intuition. However, to confirm this prior to testing them

out for discriminability in a human trial, we wanted see whether they are discriminable by some method other than our own judgement. We used the parsers described in Section 3.1, in the hope of finding a non-zero correlation between the parser outputs and the sequence lengths.

Regarding the interpretation of the absolute value of (Pearson's) correlation coefficients, both here and in the rest of the paper, we adopt Cohen's scale (Cohen, 1988) for use in human judgements, given in Table 1; we use this as most of this work is to do with human judgements of fluency. For data, we generated 1000 sentences of length 24 for each sequence length $l = 1, 2, 3, 4, 6, 8, 24$, giving 7000 sentences in total. The correlations with the four parser outputs are as in Table 2, with the medium correlations for Collins and Link Grammar (nulled tokens) indicating that the sentences are indeed discriminable to some extent, and hence the approach is likely to be useful for generating sentences for human trials.

3.3 Human Judgements

The next step is then to obtain a set of human judgements for this data. Human judges can only be expected to judge a reasonably sized amount of data,

Link Grammar Invalid Parses	0.1776
GLEU	0.4144

Table 2: Parser vs sequence size for original data set

so we first reduced the set of sequence sizes to be judged. To do this we determined for the 7000 generated sentences the scores according to the (arbitrarily chosen) Collins parser, and calculated the means for each sequence size and the 95% confidence intervals around these means. We then chose a subset of sequence sizes such that the confidence intervals did not overlap: $1, 2, 4, 8, 24$; the idea was that this would be likely to give maximally discriminable sentences. For each of these sequences sizes, we chose randomly 10 sentences from the initial set, giving a set for human judgement of size 50.

The judges consisted of twenty volunteers, all native English speakers without explicit linguistic training. We gave them general guidelines about what constituted fluency, mentioning that they should consider grammaticality but deliberately not giving detailed instructions on the manner for doing this, as we were interested in the level of agreement of intuitive understanding of fluency. We instructed them also that they should evaluate the sentence without considering its content, using *Colourless green ideas sleep furiously* as an example of a nonsensical but perfectly fluent sentence. The judges were then presented with the 50 sentences in random order, and asked to score the sentences according to their own scale, as in magnitude estimation (Bard et al., 1996); these scores were then normalised in the range [0,1].

Some judges noted that the task was difficult because of its subjectivity. Notwithstanding this subjectivity and variation in their approach to the task, the pairwise correlations between judges were high, as indicated by the maximum, minimum and mean values in Table 3, indicating that our assumption that humans had an intuitive notion of fluency and needed only minimal instruction was justified. Looking at mean scores for each sequence size, judges generally also ranked sentences by sequence size; see Figure 2. Comparing human judgement

Statistic	Corr.
Maximum correlation	0.8749
Minimum correlation	0.4710
Mean correlation	0.7040

correlations against sequence size with the same correlations for the parser metrics (as for Table 2, but on the human trial data) gives Table 4, indicating that humans can also discriminate the different generated sentence types, in fact (not surprisingly) better than the automatic metrics.

Now, having both human judgement scores of some reliability for sentences, and scoring metrics from three parsers, we give correlations in Table 5. Given Cohen's interpretation, the Collins and Link Grammar (nulled tokens) metrics show moderate correlation, the Connexor metric almost so; the Link Grammar (invalid parses) metric correlation is by far the weakest. The consistency and magnitude of the first three parser metrics, however, lends support to the idea of Wan et al. (2005) to use something like these as indicators of generated sentence fluency. The aim of the next section is to build a better predictor than the individual parser metrics alone.

4 An SVM-Based Metric

In MT, one problem with most metrics like BLEU is that they are intended to apply only to document-length texts, and any application to individual sentences is inaccurate and correlates poorly with human judgements. A neat solution to poor sentence-level evaluation proposed by Kulesza and Shieber (2004) is to use a Support Vector Machine, using features such as word error rate, to estimate sentence-level translation quality. The two main insights in applying SVMs here are, first, noting that human translations are generally good and machine translations poor, that binary training data can be created by taking the human translations as positive training instances and machine translations as negative ones; and second, that a non-binary metric of translation goodness can be derived by the distance from a test instance to the support vectors. In an empirical evaluation, Kulesza and Shieber found that their SVM gave a correlation of 0.37, which was an improvement of around half the gap between the BLEU correlations with the human judgements (0.25) and the lowest pairwise human inter-judge correlation (0.46) (Turian et al., 2003).

We take a similar approach here, using as features the four parser metrics described in Section 3. We trained an SVM,[4] taking as positive training data the 1000 instances of sentences of sequence length 24 (i.e. sentences extracted from the corpus) and as negative training data the 1000 sentences of sequence length 1. We call this learner GLEU.[5]

As a check on the ability of the GLEU SVM to distinguish these 'positive' sentences from 'negative' ones, we evaluated its classification accuracy on a (new) test set of size 300, split evenly between sentences of sequence length 24 and sequence length 1.

[4] We used the package SVM-light (Joachims, 1999).

[5] For GrammaticaLity Evaluation Utility.

This gave 81%, against a random baseline of 50%, indicating that the SVM can classify satisfactorily.

We now move from looking at classification accuracy to the main purpose of the SVM, using distance from support vector as a metric. Results are given for correlation of GLEU against sequence sizes for all data (Table 2) and for the human trial data set (Table 4); and also for correlation of GLEU against the human judges' scores (Table 5). This last indicates that GLEU correlates better with human judgements than any of the parsers individually, and is well within the 'moderate' range for correlation interpretation. In particular, for the GLEU–human correlation, the score of 0.4014 is approaching the minimum pairwise human correlation of 0.4710.

5 Different Text Generation Methods

The method used to generate text in Section 3.2 is a variation of the standard n-gram language model. A question that arises is: Are any of the metrics defined above strongly influenced by the type of language model used to generate the text? It may be the case, for example, that a parser implementation uses its own language model that predisposes it to favour a similar model in the text generation process. This is a phenomenon seen in MT, where BLEU seems to favour text that has been produced using a similar statistical n-gram language model over other symbolic models (Callison-Burch et al., 2006).

Our previous approach used only sequences of words concatenated together. To define some new methods for generating text, we introduced varying amounts of structure into the generation process.

5.1 Structural Generation Methods

PoStag In the first of these, we constructed a rough approximation of typical sentence grammar structure by taking bigrams over part-of-speech tags.[6] Then, given a string of PoS tags of length n, $t_1 \dots t_n$, we start by assigning the probabilities for the word in position 1, w_1, according to the conditional probability $P(w_1 \mid t_1)$. Then, for position j ($2 \leq j \leq n$), we assign to candidate words the value $P(w_j \mid t_j) \times P(w_j \mid w_{j-1})$ to score word sequences. So, for example, we might generate the PoS tag template **Det NN Adj Adv**, take all the words corresponding to each of these parts of speech, and combine bigram word sequence probability with the conditional probability of words with respect to these parts of speech. We then use a Viterbi-style algorithm to find the most likely word sequence.

In this model we violate the Markov assumption of independence in much the same way as Witbrock and Mittal (1999) in their combination of content and language model probabilities, by backtracking at every state in order to discourage repeated words and avoid loops.

Supertag This is a variant of the approach above, but using supertags (Bangalore and Joshi, 1999) instead of PoS tags. The idea is that the supertags might give a more fine-grained definition of structure, using partial trees rather than parts of speech.

CFG We extracted a CFG from the ∼10% of the Penn Treebank found in the NLTK-lite corpora.[7] This CFG was then augmented with productions derived from the PoS-tagged data used above. We then generated a template of length n pre-terminal categories using this CFG. To avoid loops we biased the selection towards terminals over non-terminals.

5.2 Human Judgements

We generated sentences according to a mix of the initial method of Section 3.2, for calibration, and the new methods above. We again used a sentence length of 24, and sequence lengths for the initial method of $l = 1, 8, 24$. A sample of sentences generated for each of these six types is in Figure 3.

For our data, we generated 1000 sentences per generation method, giving a corpus of 6000 sentences. For the human judgements we also again took 10 sentences per generation method, giving 60 sentences in total. The same judges were given the same instructions as previously.

Before correlating the human judges' scores and the parser outputs, it is interesting to look at how each parser treats the sentence generation methods, and how this compares with human ratings (Table 6). In particular, note that the Collins parser rates the PoStag- and Supertag-generated sentences more

highly even than real sentences (in bold). These are the two methods that use the Viterbi-style algorithm, suggesting that this probability maximisation has fooled the Collins parser. The pairwise correlation between judges was around the same on average as in Section 3.3, but with wider variation (Table 7).

The main results, determining the correlation of the various parser metrics plus GLEU against the new data, are in Table 8. This confirms the very variable performance of the Collins parser, which has dropped significantly. GLEU performs quite consistently here, this time a little behind the Link Grammar (nulled tokens) result, but still with a better correlation with human judgement than at least two

judges with each other. (Note also that the GLEU SVM was not retrained on the new sentence types.)

Looking at all the data together, however, is where GLEU particularly displays its consistency. Aggregating the old human trial data (Section 3.3) and the new data, and determining correlations against the metrics, we get the data in Table 9. Again the SVM's performance is consistent, but is now almost twice as high as its nearest alternative, Collins.

5.3 Discussion

In general, there is at least one parser that correlates quite well with the human judges for each sentence type. With well-structured sentences, the probabilistic Collins parser performs best; on sentences that are generated by a poor probabilistic model leading to poor structure, Link Grammar (nulled tokens) performs best. This supports the use of a machine learner taking as features outputs from several parser types; empirically this is confirmed by the large advantage GLEU has on overall data (Table 9).

The generated text itself from the Viterbi-based generators as implemented here is quite disappointing, given an expectation that introducing structure would make sentences more natural and hence lead to a range of sentence qualities. In hindsight, this is not so surprising; in generating the structure template, only sequences (over tags) of size 1 were used, which is perhaps why the human judges deemed them fairly close to sentences generated by the origi-

nal method using sequence size 1, the poorest of that initial data set.

6 Conclusion

In this paper we have investigated a new approach to evaluating the fluency of individual generated sentences. The notion of what constitutes fluency is an imprecise one, but trials with human judges have shown that even if it cannot be exactly defined, or even articulated by the judges, there is a high level of agreement about what is fluent and what is not. Given this data, metrics derived from parser outputs have been found useful for measuring fluency, correlating up to moderately well with these human judgements. A better approach is to combine these in a machine learner, as in our SVM GLEU, which outperforms individual parser metrics. Interestingly, we have found that the parser metrics can be fooled by the method of sentence generation; GLEU, however, gives a consistent estimate of fluency regardless of generation type; and, across all types of generated sentences examined in this paper, is superior to individual parser metrics by a large margin.

This all suggests that the approach has promise, but it needs to be developed further for pratical use. The SVM presented in this paper has only four features; more features, and in particular a wider range of parsers, should raise correlations. In terms of the data, we looked only at sentences generated with several parameters fixed, such as sentence length, due to our limited pool of judges. In future we would like to examine the space of sentence types more fully. In particular, we will look at predicting the fluency of near-human quality sentences. More generally, we would like to look also at how the approach of this paper would relate to a perplexity-based metric; how it compares against BLEU or similar measures as a predictor of fluency in a context where reference sentences are available; and whether GLEU might be useful in applications such as reranking of candidate sentences in MT.

Conditional Modality Fusion for Coreference Resolution

Abstract

Non-verbal modalities such as gesture can improve processing of spontaneous spoken language. For example, similar hand gestures tend to predict semantic similarity, so features that quantify gestural similarity can improve semantic tasks such as coreference resolution. However, not all hand movements are informative gestures; psychological research has shown that speakers are more likely to gesture meaningfully when their speech is ambiguous. Ideally, one would attend to gesture only in such circumstances, and ignore other hand movements. We present *conditional modality fusion*, which formalizes this intuition by treating the informativeness of gesture as a hidden variable to be learned jointly with the class label. Applied to coreference resolution, conditional modality fusion significantly outperforms both early and late modality fusion, which are current techniques for modality combination.

1 Introduction

Non-verbal modalities such as gesture and prosody can increase the robustness of NLP systems to the inevitable disfluency of spontaneous speech. For example, consider the following excerpt from a dialogue in which the speaker describes a mechanical device:

> "So this moves up, and it – everything moves up. And this top one clears this area here, and goes all the way up to the top."

The references in this passage are difficult to disambiguate, but the gestures shown in Figure 1 make the meaning more clear. However, non-verbal modalities are often noisy, and their interactions with speech are complex (McNeill, 1992). Gesture, for example, is sometimes communicative, but other times merely distracting. While people have little difficulty distinguishing between meaningful gestures and irrelevant hand motions (e.g., self-touching, adjusting glasses) (Goodwin and Goodwin, 1986), NLP systems may be confused by such seemingly random movements. Our goal is to include non-verbal features only in the specific cases when they are helpful and necessary.

We present a model that learns in an unsupervised fashion when non-verbal features are useful, allowing it to gate the contribution of those features. The relevance of the non-verbal features is treated as a hidden variable, which is learned jointly with the class label in a conditional model. We demonstrate that this improves performance on binary coreference resolution, the task of determining whether a noun phrases refers to a single semantic entity. Conditional modality fusion yields a relative increase of 73% in the contribution of hand-gesture features. The model is not specifically tailored to gesture-speech integration, and may also be applicable to other non-verbal modalities.

2 Related work

Most of the existing work on integrating non-verbal features relates to prosody. For example, Shriberg et al. (2000) explore the use of prosodic features for sentence and topic segmentation. The first modal-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 352–359,
Prague, Czech Republic, June 2007.

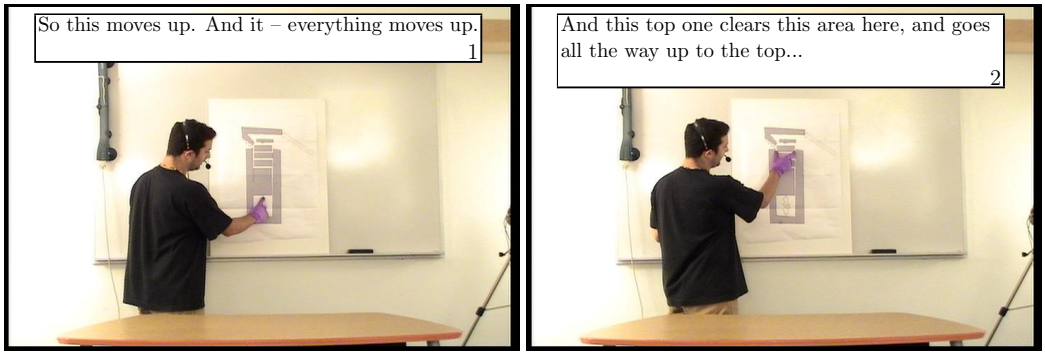

Figure 1: An example where gesture helps to disambiguate meaning.

ity combination technique that they consider trains a single classifier with all modalities combined into a single feature vector; this is sometimes called "early fusion." Shriberg et al. also consider training separate classifiers and combining their posteriors, either through weighted addition or multiplication; this is sometimes called "late fusion." Late fusion is also employed for gesture-speech combination in (Chen et al., 2004). Experiments in both (Shriberg et al., 2000) and (Kim et al., 2004) find no conclusive winner among early fusion, additive late fusion, and multiplicative late fusion.

Toyama and Horvitz (2000) introduce a Bayesian network approach to modality combination for speaker identification. As in late fusion, modality-specific classifiers are trained independently. However, the Bayesian approach also learns to predict the reliability of each modality on a given instance, and incorporates this information into the Bayes net. While more flexible than the interpolation techniques described in (Shriberg et al., 2000), training modality-specific classifiers separately is still suboptimal compared to training them jointly, because independent training of the modality-specific classifiers forces them to account for data that they cannot possibly explain. For example, if the speaker is not gesturing meaningfully, it is counterproductive to train a gesture-modality classifier on the features at this instant; doing so can lead to overfitting and poor generalization.

Our approach combines aspects of both early and late fusion. As in early fusion, classifiers for all modalities are trained jointly. But as in Toyama and Horvitz's Bayesian late fusion model, modalities can be weighted based on their predictive power for specific instances. In addition, our model is trained to maximize conditional likelihood, rather than joint likelihood.

3 Conditional modality fusion

The goal of our approach is to learn to weight the non-verbal features $\mathbf{x}_{nv}$ only when they are relevant. To do this, we introduce a hidden variable $m \in \{-1, 1\}$, which governs whether the non-verbal features are included. $p(m)$ is conditioned on a subset of features $\mathbf{x}_m$, which may belong to any modality; $p(m|\mathbf{x}_m)$ is learned jointly with the class label $p(y|\mathbf{x})$, with $y \in \{-1, 1\}$. For our coreference resolution model, y corresponds to whether a given pair of noun phrases refers to the same entity.

In a log-linear model, parameterized by weights $\mathbf{w}$, we have:

$$\begin{aligned} p(y|\mathbf{x};\mathbf{w}) &= \sum_m p(y, m|\mathbf{x};\mathbf{w}) \\ &= \frac{\sum_m exp(\psi(y, m, \mathbf{x};\mathbf{w}))}{\sum_{y',m} exp(\psi(y', m, \mathbf{x};\mathbf{w}))}. \end{aligned}$$

Here, ψ is a potential function representing the compatibility between the label y, the hidden variable m, and the observations $\mathbf{x}$; this potential is parameterized by a vector of weights, $\mathbf{w}$. The numerator expresses the compatibility of the label y and observations $\mathbf{x}$, summed over all possible values of the hidden variable m. The denominator sums over both m and all possible labels y', yielding the conditional probability $p(y|\mathbf{x};\mathbf{w})$. The use of hidden variables

in a conditionally-trained model follows (Quattoni et al., 2004).

This model can be trained by a gradient-based optimization to maximize the conditional log-likelihood of the observations. The unregularized log-likelihood and gradient are given by:

$$l(\mathbf{w}) = \sum_i \ln(p(y_i|\mathbf{x}_i; w)) \quad (1)$$

$$= \sum_i \ln \frac{\sum_m exp(\psi(y_i, m, \mathbf{x}_i; \mathbf{w}))}{\sum_{y',m} exp(\psi(y', m, \mathbf{x}_i; \mathbf{w}))} \quad (2)$$

$$\frac{\partial l_i}{\partial w_j} = \sum_m p(m|y_i, \mathbf{x}_i; \mathbf{w}) \frac{\partial}{\partial w_j} \psi(y_i, m, \mathbf{x}_i; \mathbf{w}) - \sum_{y',m} p(m, y'|\mathbf{x}_i; \mathbf{w}) \frac{\partial}{\partial w_j} \psi(y', m, \mathbf{x}_i; \mathbf{w})$$

The form of the potential function ψ is where our intuitions about the role of the hidden variable are formalized. Our goal is to include the non-verbal features $\mathbf{x}_{nv}$ only when they are relevant; consequently, the weight for these features should go to zero for some settings of the hidden variable m. In addition, *verbal* language is different when used in combination with meaningful non-verbal communication than when it is used unimodally (Kehler, 2000; Melinger and Levelt, 2004). Thus, we learn a different set of feature weights for each case: $\mathbf{w}_{v,1}$ when the non-verbal features are included, and $\mathbf{w}_{v,2}$ otherwise. The formal definition of the potential function for conditional modality fusion is:

$$\psi(y, m, \mathbf{x}; \mathbf{w}) \equiv \begin{cases} y(\mathbf{w}_{v,1}^T \mathbf{x}_v + \mathbf{w}_{nv}^T \mathbf{x}_{nv}) + \mathbf{w}_m^T \mathbf{x}_m & m = 1 \\ y\mathbf{w}_{v,2}^T \mathbf{x}_v - \mathbf{w}_m^T \mathbf{x}_m & m = -1. \end{cases} \quad (3)$$

4 Application to coreference resolution

We apply conditional modality fusion to coreference resolution – the problem of partitioning the noun phrases in a document into clusters, where all members of a cluster refer to the same semantic entity. Coreference resolution on text datasets is well-studied (e.g., (Cardie and Wagstaff, 1999)). This prior work provides the departure point for our investigation of coreference resolution on spontaneous and unconstrained speech and gesture.

4.1 Form of the model

The form of the model used in this application is slightly different from that shown in Equation 3. When determining whether two noun phrases corefer, the features at each utterance must be considered. For example, if we are to compare the similarity of the gestures that accompany the two noun phrases, it should be the case that gesture is relevant during *both* time periods.

For this reason, we create two hidden variables, m_1 and m_2; they indicate the relevance of gesture over the first (antecedent) and second (anaphor) noun phrases, respectively. Since gesture similarity is only meaningful if the gesture is relevant during *both* NPs, the gesture features are included only if $m_1 = m_2 = 1$. Similarly, the linguistic feature weights $\mathbf{w}_{v,1}$ are used when $m_1 = m_2 = 1$; otherwise the weights $\mathbf{w}_{v,2}$ are used. This yields the model shown in Equation 4.

The vector of meta features $\mathbf{x}_{m_1}$ includes all single-phrase verbal and gesture features from Table 1, computed at the antecedent noun phrase; $\mathbf{x}_{m_2}$ includes the single-phrase verbal and gesture features, computed at the anaphoric noun phrase. The label-dependent verbal features $\mathbf{x}_v$ include both pairwise and single phrase verbal features from the table, while the label-dependent non-verbal features $\mathbf{x}_{nv}$ include only the pairwise gesture features. The single-phrase non-verbal features were not included because they were not thought to be informative as to whether the associated noun-phrase would participate in coreference relations.

4.2 Verbal features

We employ a set of verbal features that is similar to the features used by state-of-the-art coreference resolution systems that operate on text (e.g., (Cardie and Wagstaff, 1999)). Pairwise verbal features include: several string-match variants; distance features, measured in terms of the number of intervening noun phrases and sentences between the candidate NPs; and some syntactic features that can be computed from part of speech tags. Single-phrase verbal features describe the type of the noun phrase (definite, indefinite, demonstrative (e.g., *this ball*), or pronoun), the number of times it appeared in the document, and whether there were any adjecti-

$$\psi(y, m_1, m_2, \mathbf{x}; \mathbf{w}) \equiv \begin{cases} y(\mathbf{w}_{v,1}^T \mathbf{x}_v + \mathbf{w}_{nv}^T \mathbf{x}_{nv}) + m_1 \mathbf{w}_m^T \mathbf{x}_{m_1} + m_2 \mathbf{w}_m^T \mathbf{x}_{m_2}, & m_1 = m_2 = 1 \\ y\mathbf{w}_{v,2}^T \mathbf{x}_v + m_1 \mathbf{w}_m^T \mathbf{x}_{m_1} + m_2 \mathbf{w}_m^T \mathbf{x}_{m_2}, & \text{otherwise.} \end{cases} \quad (4)$$

val modifiers. The continuous-valued features were binned using a supervised technique (Fayyad and Irani, 1993).

Note that some features commonly used for coreference on the MUC and ACE corpora are not applicable here. For example, gazetteers listing names of nations or corporations are not relevant to our corpus, which focuses on discussions of mechanical devices (see section 5). Because we are working from transcripts rather than text, features dependent on punctuation and capitalization, such as apposition, are also not applicable.

4.3 Non-verbal features

Our non-verbal features attempt to capture similarity between the speaker's hand gestures; similar gestures are thought to suggest semantic similarity (McNeill, 1992). For example, two noun phrases may be more likely to corefer if they are accompanied by identically-located pointing gestures. In this section, we describe features that quantify various aspects of gestural similarity.

The most straightforward measure of similarity is the Euclidean distance between the average hand position during each noun phrase – we call this the FOCUS-DISTANCE feature. Euclidean distance captures cases in which the speaker is performing a gestural "hold" in roughly the same location (McNeill, 1992).

However, Euclidean distance may not correlate directly with semantic similarity. For example, when gesturing at a detailed part of a diagram, very small changes in hand position may be semantically meaningful, while in other regions positional similarity may be defined more loosely. Ideally, we would compute a semantic feature capturing the *object* of the speaker's reference (e.g., "the red block"), but this is not possible in general, since a complete taxonomy of all possible objects of reference is usually unknown. Instead, we use a hidden Markov model (HMM) to perform a spatio-temporal clustering on hand position and velocity. The SAME-CLUSTER feature reports whether the hand positions during two noun phrases were usually grouped in the same cluster by the HMM. JS-DIV reports the Jensen-Shannon divergence, a continuous-valued feature used to measure the similarity in cluster assignment probabilities between the two gestures (Lin, 1991).

The gesture features described thus far capture the similarity between static gestures; that is, gestures in which the hand position is nearly constant. However, these features do not capture the similarity between gesture trajectories, which may also be used to communicate meaning. For example, a description of two identical motions might be expressed by very similar gesture trajectories. To measure the similarity between gesture trajectories, we use dynamic time warping (Huang et al., 2001), which gives a similarity metric for temporal data that is invariant to speed. This is reported in the DTW-DISTANCE feature.

All features are computed from hand and body pixel coordinates, which are obtained via computer vision; our vision system is similar to (Deutscher et al., 2000). The feature set currently supports only single-hand gestures, using the hand that is farthest from the body center. As with the verbal feature set, supervised binning was applied to the continuous-valued features.

4.4 Meta features

The role of the meta features is to determine whether the gesture features are relevant at a given point in time. To make this determination, both verbal and non-verbal features are applied; the only requirement is that they be computable at a single instant in time (unlike features that measure the similarity between two NPs or gestures).

Verbal meta features Meaningful gesture has been shown to be more frequent when the associated speech is ambiguous (Melinger and Levelt, 2004). Kehler finds that fully-specified noun phrases are less likely to receive multimodal support (Kehler, 2000). These findings lead us to expect that pro-

Pairwise verbal features	
edit-distance	a numerical measure of the string similarity between the two NPs
exact-match	true if the two NPs have identical surface forms
str-match	true if the NPs are identical after removing articles
nonpro-str	true if i and j are not pronouns, and str-match is true
pro-str	true if i and j are pronouns, and str-match is true
j-substring-i	true if the anaphor j is a substring of the antecedent i
i-substring-j	true if i is a substring of j
overlap	true if there are any shared words between i and j
np-dist	the number of noun phrases between i and j in the document
sent-dist	the number of sentences between i and j in the document
both-subj	true if both i and j precede the first verb of their sentences
same-verb	true if the first verb in the sentences for i and j is identical
number-match	true if i and j have the same number
Single-phrase verbal features	
pronoun	true if the NP is a pronoun
count	number of times the NP appears in the document
has-modifiers	true if the NP has adjective modifiers
indef-np	true if the NP is an indefinite NP (e.g., *a fish*)
def-np	true if the NP is a definite NP (e.g., *the scooter*)
dem-np	true if the NP begins with *this*, *that*, *these*, or *those*
lexical features	lexical features are defined for the most common pronouns: *it*, *that*, *this*, and *they*
Pairwise gesture features	
focus-distance	the Euclidean distance in pixels between the average hand position during the two NPs
DTW-agreement	a measure of the agreement of the hand-trajectories during the two NPs, computed using dynamic time warping
same-cluster	true if the hand positions during the two NPs fall in the same cluster
JS-div	the Jensen-Shannon divergence between the cluster assignment likelihoods
Single-phrase gesture features	
dist-to-rest	distance of the hand from rest position
jitter	sum of instantaneous motion across NP
speed	total displacement over NP, divided by duration
rest-cluster	true if the hand is usually in the cluster associated with rest position
movement-cluster	true if the hand is usually in the cluster associated with movement

Table 1: The feature set

nouns should be likely to co-occur with meaningful gestures, while definite NPs and noun phrases that include adjectival modifiers should be unlikely to do so. To capture these intuitions, all single-phrase verbal features are included as meta features.

Non-verbal meta features Research on gesture has shown that semantically meaningful hand motions usually take place away from "rest position," which is located at the speaker's lap or sides (McNeill, 1992). Effortful movements away from these default positions can thus be expected to predict that gesture is being used to communicate. We identify rest position as the center of the body on the x-axis, and at a fixed, predefined location on the y-axis. The DIST-TO-REST feature computes the average Euclidean distance of the hands from the rest position, over the duration of the NP.

As noted in the previous section, a spatio-temporal clustering was performed on the hand positions and velocities, using an HMM. The REST-CLUSTER feature takes the value "true" iff the most frequently occupied cluster during the NP is the cluster closest to rest position. In addition, parameter tying in the HMM forces all clusters but one to represent static hold, with the remaining cluster accounting for the transition movements between holds. Only this last cluster is permitted to have an expected non-zero speed; if the hand is most frequently in this cluster during the NP, then the MOVEMENT-CLUSTER feature takes the value "true."

4.5 Implementation

The objective function (Equation 1) is optimized using a Java implementation of L-BFGS, a quasi-Newton numerical optimization technique (Liu and Nocedal, 1989). Standard L2-norm regularization is employed to prevent overfitting, with cross-validation to select the regularization constant. Although standard logistic regression optimizes a convex objective, the inclusion of the hidden variable renders our objective non-convex. Thus, convergence to a global minimum is not guaranteed.

5 Evaluation setup

Dataset Our dataset consists of sixteen short dialogues, in which participants explained the behavior

of mechanical devices to a friend. There are nine different pairs of participants; each contributed two dialogues, with two thrown out due to recording errors. One participant, the "speaker," saw a short video describing the function of the device prior to the dialogue; the other participant was tested on comprehension of the device's behavior after the dialogue. The speaker was given a pre-printed diagram to aid in the discussion. For simplicity, only the speaker's utterances were included in these experiments.

The dialogues were limited to three minutes in duration, and most of the participants used the entire allotted time. "Markable" noun phrases – those that are permitted to participate in coreference relations – were annotated by the first author, in accordance with the MUC task definition (Hirschman and Chinchor, 1997). A total of 1141 "markable" NPs were transcribed, roughly half the size of the MUC6 development set, which includes 2072 markable NPs over 30 documents.

Evaluation metric Coreference resolution is often performed in two phases: a binary classification phase, in which the likelihood of coreference for each pair of noun phrases is assessed; and a partitioning phase, in which the clusters of mutually-coreferring NPs are formed, maximizing some global criterion (Cardie and Wagstaff, 1999). Our model does not address the formation of noun-phrase clusters, but only the question of whether each pair of noun phrases in the document corefer. Consequently, we evaluate only the binary classification phase, and report results in terms of the area under the ROC curve (AUC). As the small size of the corpus did not permit dedicated test and development sets, results are computed using leave-one-out cross-validation, with one fold for each of the sixteen documents in the corpus.

Baselines Three types of baselines were compared to our conditional modality fusion (CMF) technique:

- **Early fusion**. The early fusion baseline includes all features in a single vector, ignoring modality. This is equivalent to standard maximum-entropy classification. Early fusion is implemented with a conditionally-trained linear classifier; it uses the same code as the CMF model, but always includes all features.
- **Late fusion**. The late fusion baselines train separate classifiers for gesture and speech, and then combine their posteriors. The modality-specific classifiers are conditionally-trained linear models, and again use the same code as the CMF model. For simplicity, a parameter sweep identifies the interpolation weights that maximize performance on the test set. Thus, it is likely that these results somewhat overestimate the performance of these baseline models. We report results for both additive and multiplicative combination of posteriors.
- **No fusion**. These baselines include the features from only a single modality, and again build a conditionally-trained linear classifier. Implementation uses the same code as the CMF model, but weights on features outside the target modality are forced to zero.

Although a comparison with existing state-of-the-art coreference systems would be ideal, all such available systems use verbal features that are inapplicable to our dataset, such as punctuation, capitalization, and gazetteers. The verbal features that we have included are a representative sample from the literature (e.g., (Cardie and Wagstaff, 1999)). The "no fusion, verbal features only" baseline thus provides a reasonable representation of prior work on coreference, by applying a maximum-entropy classifier to this set of typical verbal features.

Parameter tuning Continuous features are binned separately for each cross-validation fold, using only the training data. The regularization constant is selected by cross-validation within each training subset.

6 Results

Conditional modality fusion outperforms all other approaches by a statistically significant margin (Table 2). Compared with early fusion, CMF offers an absolute improvement of 1.20% in area under the ROC curve (AUC).[1] A paired t-test shows that this

[1] AUC quantifies the ranking accuracy of a classifier. If the AUC is 1, all positively-labeled examples are ranked higher than all negative-labeled ones.

model	AUC
Conditional modality fusion	**.8226**
Early fusion	.8109
Late fusion, multiplicative	.8103
Late fusion, additive	.8068
No fusion (verbal features only)	.7945
No fusion (gesture features only)	.6732

Table 2: Results, in terms of areas under the ROC curve

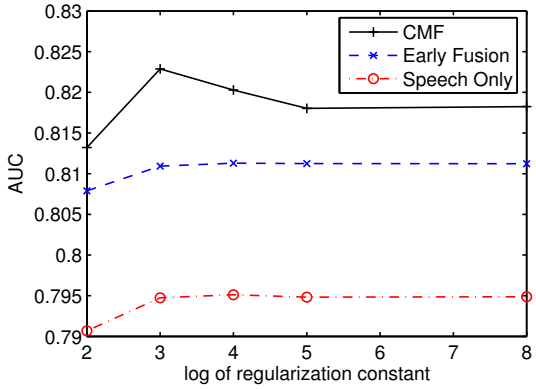

Figure 2: Conditional modality fusion is robust to variations in the regularization constant.

result is statistically significant ($p < .002, t(15) = 3.73$). CMF obtains higher performance on fourteen of the sixteen test folds. Both additive and multiplicative late fusion perform on par with early fusion.

Early fusion with gesture features is superior to unimodal verbal classification by an absolute improvement of 1.64% AUC ($p < 4 * 10^{-4}, t(15) = 4.45$). Thus, while gesture features improve coreference resolution on this dataset, their effectiveness is increased by a relative 73% when conditional modality fusion is applied. Figure 2 shows how performance varies with the regularization constant.

7 Discussion

The feature weights learned by the system to determine coreference largely confirm our linguistic intuitions. Among the textual features, a large positive weight was assigned to the string match features, while a large negative weight was assigned to features such as number incompatibility (i.e., singular versus plural). The system also learned that gestures with similar hand positions and trajectories were likely to indicate coreferring noun phrases; all of our similarity metrics were correlated positively with coreference. A chi-squared analysis found that the EDIT DISTANCE was the most informative verbal feature. The most informative gesture feature was DTW-AGREEMENT feature, which measures the similarity between gesture trajectories.

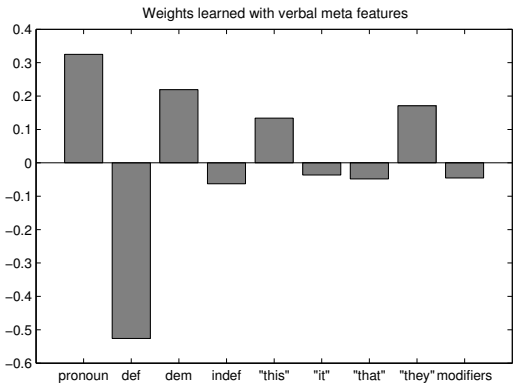

Figure 3: Weights for verbal meta features

As described in section 4, both textual and gestural features are used to determine whether the gesture is relevant. Among textual features, definite and indefinite noun phrases were assigned negative weights, suggesting gesture would not be useful to disambiguate coreference for such NPs. Pronouns were assigned positive weights, with "this" and the much less frequently used "they" receiving the strongest weights. "It" and "that" received lower weights; we observed that these pronouns were frequently used to refer to the immediately preceding noun phrase, so multimodal support was often unnecessary. Last, we note that NPs with adjectival modifiers were assigned negative weights, supporting the finding of (Kehler, 2000) that fully-specified NPs are less likely to receive multimodal support. A summary of the weights assigned to the verbal meta features is shown in Figure 3. Among gesture meta features, the weights learned by the system indicate that non-moving hand gestures away from the body are most likely to be informative in this dataset.

8 Future work

We have assumed that the relevance of gesture to semantics is dependent only on the currently available features, and not conditioned on prior history. In reality, meaningful gestures occur over contiguous blocks of time, rather than at randomly distributed instances. Indeed, the psychology literature describes a finite-state model of gesture, proceeding from "preparation," to "stroke," "hold," and then "retraction" (McNeill, 1992). These units are called *movement phases*. The relevance of various gesture features may be expected to depend on the movement phase. During strokes, the trajectory of the gesture may be the most relevant feature, while during holds, static features such as hand position and hand shape may dominate; during preparation and retraction, gesture features are likely to be irrelevant.

The identification of these movement phases should be independent of the specific problem of coreference resolution. Thus, additional labels for other linguistic phenomena (e.g., topic segmentation, disfluency) could be combined into the model. Ideally, each additional set of labels would transfer performance gains to the other labeling problems.

9 Conclusions

We have presented a new method for combining multiple modalities, which we feel is especially relevant to non-verbal modalities that are used to communicate only intermittently. Our model treats the relevance of the non-verbal modality as a hidden variable, learned jointly with the class labels. Applied to coreference resolution, this model yields a relative increase of 73% in the contribution of the gesture features. This gain is attained by identifying instances in which gesture features are especially relevant, and weighing their contribution more heavily. We next plan to investigate models with a temporal component, so that the behavior of the hidden variable is governed by a finite-state transducer.

Abstract

In this paper we explore the utility of the Navigation Map (**NM**), a graphical representation of the discourse structure. We run a user study to investigate if users perceive the NM as helpful in a tutoring spoken dialogue system. From the users' perspective, our results show that the NM presence allows them to better identify and follow the tutoring plan and to better integrate the instruction. It was also easier for users to concentrate and to learn from the system if the NM was present. Our preliminary analysis on objective metrics further strengthens these findings.

1 Introduction

With recent advances in spoken dialogue system technologies, researchers have turned their attention to more complex domains (e.g. tutoring (Litman and Silliman, 2004; Pon-Barry et al., 2006), technical support (Acomb et al., 2007), medication assistance (Allen et al., 2006)). These domains bring forward new challenges and issues that can affect the usability of such systems: increased task complexity, user's lack of or limited task knowledge, and longer system turns.

In typical information access dialogue systems, the task is relatively simple: get the information from the user and return the query results with minimal complexity added by confirmation dialogues. Moreover, in most cases, users have knowledge about the task. However, in complex domains things are different. Take for example tutoring. A tutoring dialogue system has to discuss concepts, laws and relationships and to engage in complex subdialogues to correct user misconceptions. In addition, it is very likely that users of such systems are not familiar or are only partially familiar with the tutoring topic. The length of system turns can also be affected as these systems need to make explicit the connections between parts of the underlying task.

Thus, interacting with such systems can be characterized by an increased user cognitive load associated with listening to often lengthy system turns and the need to integrate the current information to the discussion overall (Oviatt et al., 2004).

We hypothesize that one way to reduce the user's cognitive load is to make explicit two pieces of information: the purpose of the current system turn, and how the system turn relates to the overall discussion. This information is implicitly encoded in the intentional structure of a discourse as proposed in the Grosz & Sidner theory of discourse (Grosz and Sidner, 1986).

Consequently, in this paper we propose using a graphical representation of the discourse structure as a way of improving the performance of complex-domain dialogue systems (note that graphical output is required). We call it the **Navigation Map** (**NM**). The NM is a dynamic representation of the discourse segment hierarchy and the discourse segment purpose information enriched with several features (Section 3). To make a parallel with geography, as the system "navigates" with the user through the domain, the NM offers a cartographic view of the discussion. While a somewhat similar graphical representation of the discourse structure has been explored in one previous study (Rich and Sidner, 1998), to our knowledge we are the first to test its benefits (see Section 6).

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 360–367,
Prague, Czech Republic, June 2007.

As a first step towards understanding the NM effects, here we focus on investigating whether users prefer a system with the NM over a system without the NM and, if yes, what are the NM usage patterns. We test this in a speech based computer tutor (Section 2). We run a within-subjects user study in which users interacted with the system both with and without the NM (Section 4).

Our analysis of the users' subjective evaluation of the system indicates that users prefer the version of the system with the NM over the version without the NM on several dimensions. The NM presence allows the users to better identify and follow the tutoring plan and to better integrate the instruction. It was also easier for users to concentrate and to learn from the system if the NM was present. Our preliminary analysis on objective metrics further strengthens these findings.

2 ITSPOKE

ITSPOKE (Litman and Silliman, 2004) is a state-of-the-art tutoring spoken dialogue system for conceptual physics. When interacting with ITSPOKE, users first type an essay answering a qualitative physics problem using a graphical user interface. ITSPOKE then engages the user in spoken dialogue (using head-mounted microphone input and speech output) to correct misconceptions and elicit more complete explanations, after which the user revises the essay, thereby ending the tutoring or causing another round of tutoring/essay revision.

All dialogues with ITSPOKE follow a question-answer format (i.e. system initiative): ITSPOKE asks a question, users answer and then the process is repeated. Deciding what question to ask, in what order and when to stop is hand-authored beforehand in a hierarchical structure. Internally, system questions are grouped in *question segments*.

In Figure 1, we show the transcript of a sample interaction with ITSPOKE. The system is discussing the problem listed in the upper right corner of the figure and it is currently asking the question $Tutor_5$. The left side of the figure shows the interaction transcript (not available to the user at runtime). The right side of the figure shows the NM which will be discussed in the next section.

Our system behaves as follows. First, based on the analysis of the user essay, it selects a question segment to correct misconceptions or to elicit more complete explanations. Next the system asks every question from this question segment. If the user answer is correct, the system simply moves on to the next question (e.g. $Tutor_2 \rightarrow Tutor_3$). For incorrect answers there are two alternatives. For simple questions, the system will give out the correct answer accompanied by a short explanation and move on to the next question (e.g. $Tutor_1 \rightarrow Tutor_2$). For complex questions (e.g. applying physics laws), ITSPOKE will engage into a *remediation subdialogue* that attempts to remediate user's lack of knowledge or skills (e.g. $Tutor_4 \rightarrow Tutor_5$). The remediation subdialogue for each complex question is specified in another question segment.

Our system exhibits some of the issues we linked in Section 1 with complex-domain systems. Dialogues with our system can be long and complex (e.g. the question segment hierarchical structure can reach level 6) and sometimes the system's turn can be quite long (e.g. $Tutor_2$). User's reduced knowledge of the task is also inherent in tutoring.

3 The Navigation Map (NM)

We use the Grosz & Sidner theory of discourse (Grosz and Sidner, 1986) to inform our NM design. According to this theory, each discourse has a discourse purpose/intention. Satisfying the main discourse purpose is achieved by satisfying several smaller purposes/intentions organized in a hierarchical structure. As a result, the discourse is segmented into discourse segments each with an associated discourse segment purpose/intention. This theory has inspired several generic dialogue managers for spoken dialogue systems (e.g. (Rich and Sidner, 1998)).

The NM requires that we have the discourse structure information at runtime. To do that, we manually annotate the system's internal representation of the tutoring task with discourse segment purpose and hierarchy information. Based on this annotation, we can easily construct the discourse structure at runtime. In this section we describe our annotation and the NM design choices we made. Figure 1 shows the state of the NM after turn $Tutor_5$ as the user sees it on the interface (NM line numbering is for exposition only). Note that Figure 1 is not a screenshot of the actual system interface. The NM is the only part from the actual system interface. Figure 2 shows the NM after turn $Tutor_1$.

We manually annotated each system question/explanation for its intention(s)/purpose(s). Note that some system turns have multiple inten-

TUTOR$_1$: To analyze this problem we will first describe the motion of the person and his keys while he is holding them. Then we will look at the motion of the person and his keys after he lets go of them.

Let's begin by looking at the motion of the man and his keys while he is holding them.

How does his velocity compare to that of his keys?

User answer$_1$: man's velocity is bigger [incorrect]

TUTOR$_2$: Well… The problem statement says that the man is holding his keys motionless in front of his face. That means they are both falling together and are not moving with respect to each other. Hence their velocities are the same.

Now let's see what happens when he releases them.

To do so we will first find the individual forces exerted on the man and his keys, then both net forces, both accelerations, and finally we will describe and compare the velocities.

So what are the forces exerted on the man after he releases his keys? Please, specify their directions.

User answer$_2$: gravity vertically down [correct]

TUTOR$_3$: Good. Because there is just one force, gravity's, it is trivial to determine the NET force. So what is the direction of the NET force on the person?

User answer$_3$: down [correct]

TUTOR$_4$: Ok. Considering the net force, does the person have an acceleration? If yes, specify its direction.

User answer$_4$: the man has no acceleration [incorrect]

TUTOR$_5$: Well… To analyze the man's acceleration we will use Newton's second law. What is the definition of this law?

***Problem**: Suppose a man is in a free-falling elevator and is holding his keys motionless right in front of his face. He then lets go. What will be the position of the keys relative to the man's face as time passes? Explain.*

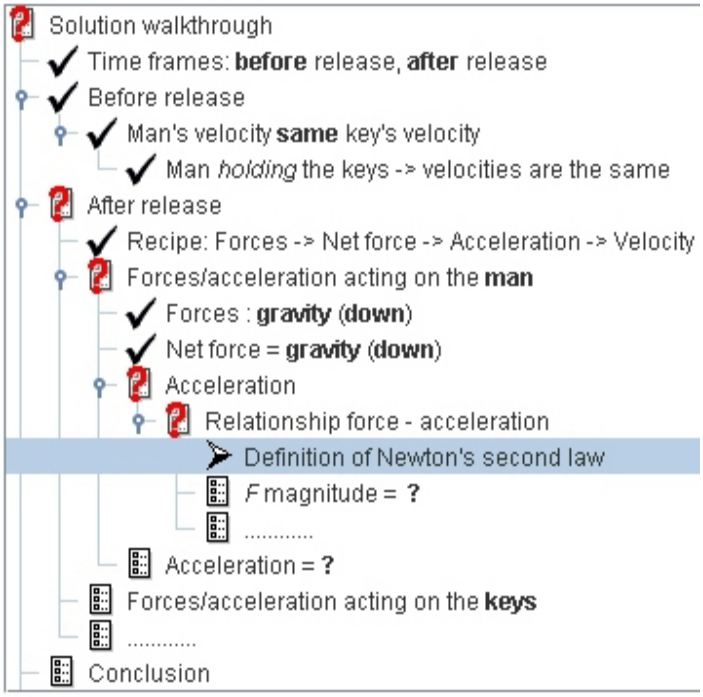

Figure 1. Transcript of a sample ITSPOKE speech interaction (left). The NM as the user sees it after turn Tutor$_5$

tions/purposes thus multiple discourse segments were created for them. For example, in Tutor$_1$ the system first identifies the time frames on which the analysis will be performed (Figure 1&2, NM$_2$). Next, the system indicates that it will discuss about the first time frame (Figure 1&2, NM$_3$) and then it asks the actual question (Figure 2, NM$_4$).

Thus, in addition to our manual annotation of the discourse segment purpose information, we manually organized all discourse segments from a question segment in a hierarchical structure that reflects the discourse structure.

At runtime, while discussing a question segment, the system has only to follow the annotated hierarchy, displaying and highlighting the discourse segment purposes associated with the uttered content. For example, while uttering Tutor$_1$, the NM will synchronously highlight NM$_2$, NM$_3$ and NM$_4$. Remediation question segments (e.g. NM$_{12}$) or explanations (e.g. NM$_5$) activated by incorrect answers are attached to the structure under the corresponding discourse segment.

3.1 NM Design Choices

In our graphical representation of the discourse structure, we used a left to right indented layout. In addition, we made several design choices to enrich the NM information content and usability.

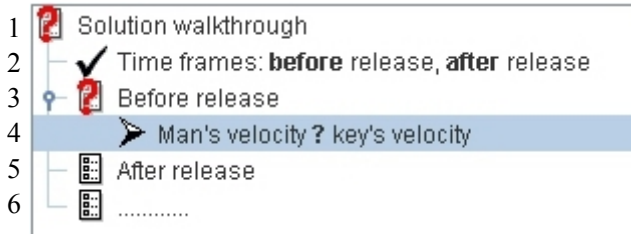

Figure 2. NM state after turn Tutor$_1$

Correct answers. In Figure 2 we show the state of the NM after uttering Tutor$_1$. The current discourse segment purpose (NM$_4$) indicates that the system is asking about the relationship between the two velocities. While we could have kept the same information after the system was done with this discourse segment, we thought that users will benefit from having the correct answer on the screen (recall NM$_4$ in Figure 1). Thus, the NM was enhanced to display the correct answer after the system is done with each question. We extracted the correct answer from the system specifications for each question and manually created a new version of the discourse segment purpose that includes this information.

Limited horizon. Since in our case the system drives the conversation (i.e. system initiative), we always know what questions would be discussed next. We hypothesized that by having access to this information, users will have a better idea of where instruction is heading, thus facilitating their understanding of the relevance of the current topic to the overall discussion. To prevent information overload, we only display the next discourse segment purpose at each level in the hierarchy (see Figure 1, NM_{14}, NM_{16}, NM_{17} and NM_{19}; Figure 2, NM_5); additional discourse segments at the same level are signaled through a dotted line. To avoid helping the students answer the current question in cases when the next discourse segment hints/describes the answer, each discourse segment has an additional purpose annotation that is displayed when the segment is part of the visible horizon.

Auto-collapse. To reduce the amount of information on the screen, discourse segments discussed in the past are automatically collapsed by the system. For example, in Figure 1, NM Line 3 is collapsed in the actual system and Lines 4 and 5 are hidden (shown in Figure1 to illustrate our discourse structure annotation.). The user can expand nodes as desired using the mouse.

Information highlight. Bold and italics font were used to highlight important information (what and when to highlight was manually annotated). For example, in Figure 1, NM_2 highlights the two time frames as they are key steps in approaching this problem. Correct answers are also highlighted.

We would like to reiterate that the goal of this study is to investigate if making certain types of discourse information explicitly available to the user provides any benefits. Thus, whether we have made the optimal design choices is of secondary importance. While, we believe that our annotation is relatively robust as the system questions follow a carefully designed tutoring plan, in the future we would like to investigate these issues.

4 User Study

We designed a user study focused primarily on user's perception of the NM presence/absence. We used a within-subject design where each user received instruction both with and without the NM.

Each user went through the same experimental procedure: 1) read a short document of background material, 2) took a pretest to measure initial physics knowledge, 3) worked through 2 problems with ITSPOKE 4) took a posttest similar to the pretest, 5) took a **NM survey**, and 6) went through a brief open-question interview with the experimenter.

In the 3rd step, the NM was enabled in *only one* problem. Note that in both problems, users did not have access to the system turn transcript. After each problem users filled in a **system questionnaire** in which they rated the system on various dimensions; these ratings were designed to cover dimensions the NM might affect (see Section 5.1). While the system questionnaire implicitly probed the NM utility, the NM survey from the 5th step explicitly asked the users whether the NM was useful and on what dimensions (see Section 5.1)

To account for the effect of the tutored problem on the user's questionnaire ratings, users were randomly assigned to one of two conditions. The users in the first condition (**F**) had the NM enabled in the first problem and disabled in the second problem, while users in the second condition (**S**) had the opposite. Thus, if the NM has any effect on the user's perception of the system, we should see a *decrease* in the questionnaire ratings from problem 1 to problem 2 for *F* users and an *increase* for *S* users.

Other factors can also influence our measurements. To reduce the effect of the text-to-speech component, we used a version of the system with human prerecorded prompts. We also had to account for the amount of instruction as in our system the top level question segment is tailored to what users write in the essay. Thus the essay analysis component was disabled; for all users, the system started with the same top level question segment which assumed no information in the essay. Note that the actual dialogue depends on the correctness of the user answers. After the dialogue, users were asked to revise their essay and then the system moved on to the next problem.

The collected corpus comes from 28 users (13 in *F* and 15 in *S*). The conditions were balanced for gender (*F*: 6 male, 7 female; *S*: 8 male, 7 female). There was no significant differences between the two conditions in terms of pretest ($p<0.63$); in both conditions users learned (significant difference between pretest and posttest, $p<0.01$).

5 Results

5.1 Subjective metrics

Our main resource for investigating the effect of the NM was the system questionnaires given after

each problem. These questionnaires are identical and include 16 questions that probed user's perception of ITSPOKE on various dimensions. Users were asked to answer the questions on a scale from 1-5 (1 – Strongly Disagree, 2 – Disagree, 3 – Somewhat Agree, 4 – Agree, 5 – Strongly Agree). If indeed the NM has any effect we should observe differences between the ratings of the NM problem and the noNM problem (i.e. the NM is disabled).

Table 1 lists the 16 questions in the questionnaire order. The table shows for every question the average rating for all condition-problem combinations (e.g. column 5: condition *F* problem 1 with the NM enabled). For all questions except Q7 and Q11 a higher rating is better. For Q7 and Q11 (italicized in Table 1) a *lower* rating is better as they gauge negative factors (high level of concentration and task disorientation). They also served as a deterrent for negligence while rating.

To test if the NM presence has a significant effect, a repeated-measure ANOVA with between-subjects factors was applied. The within-subjects factor was the NM presence (**NMPres**) and the between-subjects factor was the condition (**Cond**)[1]. The significance of the effect of each factor and their combination (NMPres*Cond) is listed in the table with significant and trend effects highlighted in bold (see columns 2-4). Post-hoc t-tests between the NM and noNM ratings were run for each condition ("s"/"t"marks significant/trend differences).

Results for Q1-6

Questions Q1-6 were inspired by previous work on spoken dialogue system evaluation (e.g. (Walker et al., 2000)) and measure user's overall perception of the system. We find that the NM presence significantly improves user's perception of the system in terms of their ability to concentrate on the instruction (Q3), in terms of their inclination to reuse the system (Q6) and in terms of the system's matching of their expectations (Q4). There is a trend that it was easier for them to learn from the NM enabled version of the system (Q2).

Results for Q7-13

Q7-13 relate directly to our hypothesis that users benefit from access to the discourse structure information. These questions probe the user's perception of ITSPOKE during the dialogue. We find that for 6 out 7 questions the NM presence has a significant/trend effect (Table 1, column 2).

Structure. Users perceive the system as having a structured tutoring plan significantly[2] more in the NM problems (Q8). Moreover, it is significantly easier for them to follow this tutoring plan if the NM is present (Q11). These effects are very clear for *F* users where their ratings differ significantly between the first (NM) and the second problem (noNM). A difference in ratings is present for *S* users but it is not significant. As with most of the *S* users' ratings, we believe that the NM presentation order is responsible for the mostly non-significant differences. More specifically, assuming that the NM has a positive effect, the *S* users are asked to rate first the poorer version of the system (noNM) and then the better version (NM). In contrast, *F* users' task is easier as they already have a high reference point (NM) and it is easier for them to criticize the second problem (noNM). Other factors that can blur the effect of the NM are domain learning and user's adaptation to the system.

Integration. Q9 and Q10 look at how well users think they integrate the system questions in both a forward-looking fashion (Q9) and a backward looking fashion (Q10). Users think that it is significantly easier for them to integrate the current system question to what will be discussed in the future if the NM is present (Q9). Also, if the NM is present, it is easier for users to integrate the current question to the discussion so far (Q10, trend). For Q10, there is no difference for *F* users but a significant one for *S* users. We hypothesize that domain learning is involved here: *F* users learn better from the first problem (NM) and thus have less issues solving the second problem (noNM). In contrast, *S* users have more difficulties in the first problem (noNM), but the presence of the NM eases their task in the second problem.

Correctness. The correct answer NM feature is useful for users too. There is a trend that it is easier for users to know the correct answer if the NM is present (Q13). We hypothesize that speech recognition and language understanding errors are re-

[1] Since in this version of ANOVA the NM/noNM ratings come from two different problems based on the condition, we also run an ANOVA in which the within-subjects factor was the problem (Prob). In this case, the NM effect corresponds to an effect from Prob*Cond which is identical in significance with that of NMPres.

[2] We refer to the significance of the NMPres factor (Table 1, column 2). When discussing individual experimental conditions, we refer to the post-hoc t-tests.

Question	ANOVA			Average rating: F condition				S condition			
	NMPres	Cond	NMPres* Cond	P1		P2		P2		P1	
Overall				NM		noNM		NM		noNM	
1. The tutor increased my understanding of the subject	0.518	0.898	0.862	4.0	>	3.9		4.0	>	3.9	
2. It was easy to learn from the tutor	**0.100**	0.813	0.947	3.9	>	3.6		3.9	>	3.5	
3. The tutor helped me to concentrate	**0.016**	0.156	0.854	3.5	>	3.0		3.9	$>^t$	3.4	
4. The tutor worked the way I expected it to	**0.034**	0.886	0.157	3.5	>	3.4		3.9	$>^s$	3.1	
5. I enjoyed working with the tutor	0.154	0.513	0.917	3.5	>	3.2		3.7	>	3.4	
6. Based on my experience using the tutor to learn physics, I would like to use such a tutor regularly	**0.004**	0.693	0.988	3.7	$>^s$	3.2		3.5	$>^s$	3.0	
During the conversation with the tutor:											
7. ... a high level of concentration is required to follow the tutor	**0.004**	0.534	0.545	3.5	$<^s$	4.2		3.9	$<^t$	4.3	
8. ... the tutor had a clear and structured agenda behind its explanations	**0.008**	0.340	0.104	4.4	$>^s$	3.6		4.3	>	4.1	
9. ... it was easy to figure out where the tutor's instruction was leading me	**0.017**	0.472	0.593	4.0	$>^s$	3.4		4.1	>	3.7	
10. ... when the tutor asked me a question I knew why it was asking me that question	**0.054**	0.191	**0.054**	3.5	~	3.5		4.3	$>^s$	3.5	
11. ... it was easy to loose track of where I was in the interaction with the tutor	**0.012**	0.766	**0.048**	2.5	$<^s$	3.5		2.9	<	3.0	
12. ... I knew whether my answer to the tutor's question was correct or incorrect	0.358	0.635	0.804	3.5	>	3.3		3.7	>	3.4	
13. ... whenever I answered incorrectly, it was easy to know the correct answer after the tutor corrected me	**0.085**	**0.044**	0.817	3.8	>	3.5		4.3	>	3.9	
At the end of the conversation with the tutor:											
14. ... it was easy to understand the tutor's main point	**0.071**	**0.056**	0.894	4.0	>	3.6		4.4	>	4.1	
15. ... I knew what was wrong or missing from my essay	0.340	0.965	0.340	3.9	~	3.9		3.7	<	4.0	
16. ... I knew how to modify my essay	0.791	0.478	0.327	4.1	>	3.9		3.7	<	3.8	

Table 1. System questionnaire results

sponsible for the non-significant NM effect on the dimension captured by Q12.

Concentration. Users also think that the NM enabled version of the system requires less effort in terms of concentration (Q7). We believe that having the discourse segment purpose as visual input allows the users to concentrate more easily on what the system is uttering. In many of the open question interviews users stated that it was easier for them to listen to the system when they had the discourse segment purpose displayed on the screen.

Results for Q14-16

Questions Q14-16 were included to probe user's post tutoring perceptions. We find a trend that in the NM problems it was easier for users to understand the system's main point (Q14). However, in terms of identifying (Q15) and correcting (Q16) problems in their essay the results are inconclusive. We believe that this is due to the fact that the essay interpretation component was disabled in this experiment. As a result, the instruction did not match the initial essay quality. Nonetheless, in the open-question interviews, many users indicated using the NM as a reference while updating their essay.

In addition to the 16 questions, in the system questionnaire after the second problem users were asked to choose which version of the system they preferred the most (i.e. the first or the second problem version). 24 out 28 users (86%) preferred the NM enabled version. In the open-question interview, the 4 users that preferred the noNM version (2 in each condition) indicated that it was harder for them to concurrently concentrate on the audio and the visual input (divided attention problem) and/or that the NM was changing too fast.

To further strengthen our conclusions from the system questionnaire analysis, we would like to note that users were not asked to directly compare the two versions but they were asked to individually rate two versions which is a noisier process (e.g. users need to recall their previous ratings).

The NM survey

While the system questionnaires probed users' NM usage indirectly, in the second to last step in the experiments, users had to fill a NM survey

which explicitly asked how the NM helped them, if at all. The answers were on the same 1 to 5 scale. We find that the majority of users (75%-86%) agreed or strongly agreed that the NM helped them follow the dialogue, learn more easily, concentrate and update the essay. These findings are on par with those from the system questionnaire analysis.

5.2 Objective metrics

Our analysis of the subjective user evaluations shows that users think that the NM is helpful. We would like to see if this perceived usefulness is reflected in any objective metrics of performance. Due to how our experiment was designed, the effect of the NM can be reliably measured only in the first problem as in the second problem the NM is toggled[3]; for the same reason, we can not use the pretest/posttest information.

Our preliminary investigation [4] found several dimensions on which the two conditions differed in the first problem (*F* users had NM, *S* users did not). We find that if the NM was present the interaction was shorter on average and users gave more correct answers; however these differences are not statistically significant (Table 2). In terms of speech recognition performance, we looked at two metrics: AsrMis and SemMis (ASR/Semantic Misrecognition). A user turn is labeled as AsrMis if the output of the speech recognition is different from the human transcript (i.e. a binary version of Word Error Rate). SemMis are AsrMis that change the correctness interpretation. We find that if the NM was present users had fewer AsrMis and fewer SemMis (trend for SemMis, $p<0.09$).

In addition, a χ^2 dependency analysis showed that the NM presence interacts significantly with both AsrMis ($p<0.02$) and SemMis ($p<0.001$), with fewer than expected AsrMis and SemMis in the NM condition. The fact that in the second problem the differences are much smaller (e.g. 2% for AsrMis) and that the NM-AsrMis and NM-SemMis interactions are not significant anymore, suggests that our observations can not be attributed to a difference in population with respect to system's ability to recognize their speech. We hypothesize that these differences are due to the NM text influencing users' lexical choice.

Metric	*F* (NM)	*S* (noNM)	p
# user turns	21.8 (5.3)	22.8 (6.5)	0.65
% correct turns	72% (18%)	67% (22%)	0.59
AsrMis	37% (27%)	46% (28%)	0.46
SemMis	5% (6%)	12% (14%)	0.09

Table 2. Average (standard deviation) for objective metrics in the first problem

6 Related work

Discourse structure has been successfully used in non-interactive settings (e.g. understanding specific lexical and prosodic phenomena (Hirschberg and Nakatani, 1996) , natural language generation (Hovy, 1993), essay scoring (Higgins et al., 2004) as well as in interactive settings (e.g. predictive/generative models of postural shifts (Cassell et al., 2001), generation/interpretation of anaphoric expressions (Allen et al., 2001), performance modeling (Rotaru and Litman, 2006)).

In this paper, we study the utility of the discourse structure on the user side of a dialogue system. One related study is that of (Rich and Sidner, 1998). Similar to the NM, they use the discourse structure information to display a segmented interaction history (**SIH**): an indented view of the interaction augmented with purpose information. This paper extends over their work in several areas. The most salient difference is that here we investigate the benefits of displaying the discourse structure information for the users. In contrast, (Rich and Sidner, 1998) never test the utility of the SIH. Their system uses a GUI-based interaction (no speech/text input, no speech output) while we look at a speech-based system. Also, their underlying task (air travel domain) is much simpler than our tutoring task. In addition, the SIH is not always available and users have to activate it manually.

Other visual improvements for dialogue-based computer tutors have been explored in the past (e.g. talking heads (Graesser et al., 2003)). However, implementing the NM in a new domain requires little expertise as previous work has shown

[3] Due to random assignment to conditions, before the first problem the *F* and *S* populations are similar (e.g. no difference in pretest); thus any differences in metrics can be attributed to the NM presence/absence. However, in the second problem, the two populations are not similar anymore as they have received different forms of instruction; thus any difference has to be attributed to the NM presence/absence in this problem as well as to the NM absence/presence in the previous problem.

[4] Due to logging issues, 2 *S* users are excluded from this analysis (13 *F* and 13 *S* users remaining). We run the subjective metric analysis from Section 5.1 on this subset and the results are similar.

that naïve users can reliably annotate the information needed for the NM (Passonneau and Litman, 1993). Our NM design choices should also have an equivalent in a new domain (e.g. displaying the recognized user answer can be the equivalent of the correct answers). Other NM usages can also be imagined: e.g. reducing the length of the system turns by removing text information that is implicitly represented in the NM.

7 Conclusions & Future work

In this paper we explore the utility of the Navigation Map, a graphical representation of the discourse structure. As our first step towards understanding the benefits of the NM, we ran a user study to investigate if users perceive the NM as useful. From the users' perspective, the NM presence allows them to better identify and follow the tutoring plan and to better integrate the instruction. It was also easier for users to concentrate and to learn from the system if the NM was present. Our preliminary analysis on objective metrics shows that users' preference for the NM version is reflected in more correct user answers and less speech recognition problems in the NM version.

These findings motivate future work in understanding the effects of the NM. We would like to continue our objective metrics analysis (e.g. see if users are better in the NM condition at updating their essay and at answering questions that require combining facts previously discussed). We also plan to run an additional user study with a between-subjects experimental design geared towards objective metrics. The experiment will have two conditions: NM present/absent for all problems. The conditions will then be compared in terms of various objective metrics. We would also like to know which information sources represented in the NM (e.g. discourse segment purpose, limited horizon, correct answers) has the biggest impact.

Abstract

Motivated by psycholinguistic findings that eye gaze is tightly linked to human language production, we developed an unsupervised approach based on translation models to automatically learn the mappings between words and objects on a graphic display during human machine conversation. The experimental results indicate that user eye gaze can provide useful information to establish such mappings, which have important implications in automatically acquiring and interpreting user vocabularies for conversational systems.

1 Introduction

To facilitate effective human machine conversation, it is important for a conversational system to have knowledge about user vocabularies and understand how these vocabularies are mapped to the internal entities for which the system has representations. For example, in a multimodal conversational system that allows users to converse with a graphic interface, the system needs to know what vocabularies users tend to use to describe objects on the graphic display and what (type of) object(s) a user is attending to when a particular word is expressed. Here, we use *acquisition* to refer to the process of acquiring relevant vocabularies describing internal entities, and *interpretation* to refer to the process of automatically identifying internal entities given a particular word. Both acquisition and interpretation have been traditionally approached by either knowledge engineering (e.g., manually created lexicons) or supervised learning from annotated data. In this paper, we describe an unsupervised approach that relies on naturally co-occurred eye gaze and spoken utterances during human machine conversation to automatically acquire and interpret vocabularies.

Motivated by psycholinguistic studies (Just and Carpenter, 1976; Griffin and Bock, 2000; Tenenhaus et al., 1995) and recent investigations on computational models for language acquisition and grounding (Siskind, 1995; Roy and Pentland, 2002; Yu and Ballard, 2004), we are particularly interested in two unique questions related to multimodal conversational systems: (1) In a multimodal conversation that involves more complex tasks (e.g., both user initiated tasks and system initiated tasks), is there a reliable temporal alignment between eye gaze and spoken references so that the coupled inputs can be used for automated vocabulary acquisition and interpretation? (2) If such an alignment exists, how can we model this alignment and automatically acquire and interpret the vocabularies?

To address the first question, we conducted an empirical study to examine the temporal relationships between eye fixations and their corresponding spoken references. As shown later in section 4, although a larger variance (compared to the findings from psycholinguistic studies) exists in terms of how eye gaze is linked to speech production during human machine conversation, eye fixations and the corresponding spoken references still occur in a very close vicinity to each other. This natural coupling between eye gaze and speech provides an opportunity to automatically learn the mappings between

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 368–375,
Prague, Czech Republic, June 2007.

words and objects without any human supervision.

Because of the larger variance, it is difficult to apply rule-based approaches to quantify this alignment. Therefore, to address the second question, we developed an approach based on statistical translation models to explore the co-occurrence patterns between eye fixated objects and spoken references. Our preliminary experiment results indicate that the translation model can reliably capture the mappings between the eye fixated objects and the corresponding spoken references. Given an object, this model can provide possible words describing this object, which represents the acquisition process; given a word, this model can also provide possible objects that are likely to be described, which represents the interpretation process.

In the following sections, we first review some related work and introduce the procedures used to collect eye gaze and speech data during human machine conversation. We then describe our empirical study and the unsupervised approach based on translation models. Finally, we present experiment results and discuss their implications in natural language processing applications.

2 Related Work

Our work is motivated by previous work in the following three areas: psycholinguistics studies, multimodal interactive systems, and computational modeling of language acquisition and grounding.

Previous psycholinguistics studies have shown that the direction of gaze carries information about the focus of the user's attention (Just and Carpenter, 1976). Specifically, in human language processing tasks, eye gaze is tightly linked to language production. The perceived visual context influences spoken word recognition and mediates syntactic processing (Tenenhaus et al., 1995). Additionally, before speaking a word, the eyes usually move to the objects to be mentioned (Griffin and Bock, 2000). These psycholinguistics findings have provided a foundation for our investigation.

In research on multimodal interactive systems, recent work indicates that the speech and gaze integration patterns can be modeled reliably for individual users and therefore be used to improve multimodal system performances (Kaur et al., 2003). Studies have also shown that eye gaze has a potential to improve resolution of underspecified referring expressions in spoken dialog systems (Campana et al., 2001) and to disambiguate speech input (Tanaka, 1999). In contrast to these earlier studies, our work focuses on a different goal of using eye gaze for automated vocabulary acquisition and interpretation.

The third area of research that influenced our work is computational modeling of language acquisition and grounding. Recent studies have shown that multisensory information (e.g., through vision and language processing) can be combined to effectively acquire words to their perceptually grounded objects in the environment (Siskind, 1995; Roy and Pentland, 2002; Yu and Ballard, 2004). Especially in (Yu and Ballard, 2004), an unsupervised approach based on a generative correspondence model was developed to capture the mapping between spoken words and the occurring perceptual features of objects. This approach is most similar to the translation model used in our work. However, compared to this work where multisensory information comes from vision and language processing, our work focuses on a different aspect. Here, instead of applying vision processing on objects, we are interested in eye gaze behavior when users interact with a graphic display. Eye gaze is an implicit and subconscious input modality during human machine interaction. Eye gaze data inevitably contain a significant amount of noise. Therefore, it is the goal of this paper to examine whether this modality can be utilized for vocabulary acquisition for conversational systems.

3 Data Collection

We used a *simplified* multimodal conversational system to collect synchronized speech and eye gaze data. A room interior scene was displayed on a computer screen, as shown in Figure 1. While watching the graphical display, users were asked to communicate with the system on topics about the room decorations. A total of 28 objects (e.g., multiple lamps and picture frames, a bed, two chairs, a candle, a dresser, etc., as marked in Figure 1) are explicitly modeled in this scene. The system is *simplified* in the sense that it only supports 14 tasks during human machine interaction. These tasks are designed to cover both open-ended utterances (e.g., the system

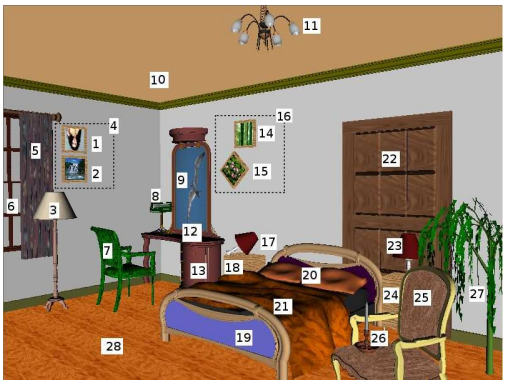

Figure 1: The room interior scene for user studies. For easy reference, we give each object an ID. These IDs are hidden from the system users.

asks users to describe the room) and more restricted utterances (e.g., the system asks the user whether he/she likes the bed) that are commonly supported in conversational systems. Seven human subjects participated in our study.

User speech inputs were recorded using the Audacity software[1], with each utterance time-stamped. Eye movements were recorded using an EyeLink II eye tracker sampled at 250Hz. The eye tracker automatically saved two-dimensional coordinates of a user's eye fixations as well as the time-stamps when the fixations occurred.

The collected raw gaze data is extremely noisy. To refine the gaze data, we further eliminated invalid and saccadic gaze points (known as "saccadic suppression" in vision studies). Since eyes do not stay still but rather make small, frequent jerky movements, we also smoothed the data by averaging nearby gaze locations to identify fixations.

4 Empirical Study on Speech-Gaze Alignment

Based on the data collected, we investigated the temporal alignment between co-occurred eye gaze and spoken utterances. In particular, we examined the temporal alignment between eye gaze fixations and the corresponding spoken references (i.e., the spoken words that are used to refer to the objects on the graphic display).

According to the time-stamp information, we can measure the length of time gap between a user's eye fixation falling on an object and the corresponding spoken reference being uttered (which we refer to as "length of time gap" for brevity). Also, we can count the number of times that user fixations happen to change their target objects during this time gap (which we refer to as "number of fixated object changes" for brevity). The nine most frequently occurred spoken references in utterances from all users (as shown in Table 1) are chosen for this empirical study. For each of those spoken references, we use human judgment to decide which object is referred to. Then, from both before and after the onset of the spoken reference, we find the closest occurrence of the fixation falling on that particular object. Altogether we have 96 such speech-gaze pairs. In 54 pairs, the eye gaze fixation occurred before the corresponding speech reference was uttered; and in the other 42 pairs, the eye fixation occurred after the corresponding speech reference was uttered. This observation suggests that in human machine conversation, eye fixation on an object does not necessarily always proceed the utterance of the corresponding speech reference.

Further, we computed the average *absolute* length of the time gap and the average number of fixated object changes, as well as their variances for each of 5 selected users[2] as shown in Table 1. From Table 1, it is easy to observe that: **(I)** A spoken reference always appears within a short period of time (usually 1-2 seconds) *before or after* the corresponding eye gaze fixation. But, the exact length of the period is far from constant. **(II)** It is not necessary for a user to utter the corresponding spoken reference *immediately* before or after the eye gaze fixation falls on that particular object. Eye gaze fixations may move back and forth. Between the time an object is fixated and the corresponding spoken reference is uttered, a user's eye gaze may fixate on a few other objects (reflected by the average number of eye fixated object changes shown in the table). **(III)** There is a large variance in both the length of time gap and the number of fixated object changes in terms of 1) the same user and the same spoken reference at different time-stamps, 2) the same user but different spo-

Table 1: The average absolute length of time and the number of eye fixated object changes within the time gap of eye gaze and corresponding spoken references. Variances are also listed. Some of the entries are not available because the spoken references were never or rarely used by the corresponding users.

ken references, and 3) the same spoken reference but different users. We believe this is due to the different dialog scenarios and user language habits.

To summarize our empirical study, we find that in human machine conversation, there still exists a natural temporal coupling between user speech and eye gaze, i.e. the spoken reference and the corresponding eye fixation happen within a close vicinity of each other. However, a large variance is also observed in terms of these temporal vicinities, which indicates an intrinsically more complex gaze-speech pattern. Therefore, it is hard to directly quantify the temporal or ordering relationship between spoken references and corresponding eye fixated objects (for example, through rules).

To better handle the complexity in the gaze-speech pattern, we propose to use statistical translation models. Given a time window of enough length, a speech input that contains a list of spoken references (e.g., definite noun phrases) is always accompanied by a list of naturally occurred eye fixations and therefore a list of objects receiving those fixations. All those pairs of speech references and corresponding fixated objects could be viewed as *parallel*, i.e. they *co-occur within the time window*. This situation is very similar to the training process of translation models in statistical machine translation (Brown et al., 1993), where parallel corpus is used to find the mappings between words from different languages by exploiting their co-occurrence patterns. The same idea can be borrowed here: by exploring the co-occurrence statistics, we hope to uncover the exact mapping between those eye fixated objects and spoken references. The intuition is that, the more often a fixation is found to exclusively co-occur with a spoken reference, the more likely a mapping should be established between them.

5 Translation Models for Vocabulary Acquisition and Interpretation

Formally, we denote the set of observations by $\mathbf{D} = \{\mathbf{w}_i, \mathbf{o}_i\}_{i=1}^{N}$ where $\mathbf{w}_i$ and $\mathbf{o}_i$ refers to the i-th speech utterance (i.e., a list of words of spoken references) and the i-th corresponding eye gaze pattern (i.e., a list of eye fixated objects) respectively. When we study the problem of mapping given objects to words (for vocabulary acquisition), the parameter space $\mathbf{\Theta} = \{\Pr(w_j|o_k), 1 \leq j \leq m^w, 1 \leq k \leq m^o\}$ consists of the mapping probabilities of an arbitrary word w_j to an arbitrary object o_k, where m^w and m^o represent the total number of unique words and objects respectively. Those mapping probabilities are subject to constraints $\sum_{j=1}^{m^w} \Pr(w_j|o_k) = 1$. Note that $\Pr(w_j|o_k) = 0$ if the corresponding word w_j and o_k never co-occur in any observed list pair $(\mathbf{w}_i, \mathbf{o}_i)$.

Let l_i^w and l_i^o denote the length of lists $\mathbf{w}_i$ and $\mathbf{o}_i$ respectively. To distinguish with the notations w_j and o_k whose subscripts are indices for *unique* words and objects respectively, we use $\tilde{w}_{i,j}$ to denote the word in the j-th position of the list $\mathbf{w}_i$ and $\tilde{o}_{i,k}$ to denote the object in the k-th position of the list $\mathbf{o}_i$. In translation models, we assume that any word in the list $\mathbf{w}_i$ is mapped to an object in the corresponding list $\mathbf{o}_i$ or a *null object* (we reserve the position 0 for it in every object list). To denote all the word-object mappings in the i-th list pair, we introduce an alignment vector $\mathbf{a}_i$, whose element $a_{i,j}$ takes the value k if the word $\tilde{w}_{i,j}$ is mapped to $\tilde{o}_{i,k}$.

Then, the likelihood of the observations given the

parameters can be computed as follows

$$\Pr(\mathbf{D};\mathbf{\Theta}) = \prod_{i=1}^{N}\Pr(\mathbf{w}_i|\mathbf{o}_i) = \prod_{i=1}^{N}\sum_{\mathbf{a}_i}\Pr(\mathbf{w}_i,\mathbf{a}_i|\mathbf{o}_i)$$
$$= \prod_{i=1}^{N}\sum_{\mathbf{a}_i}\frac{\Pr(l_i^w|\mathbf{o}_i)}{(l_i^o+1)^{l_i^w}}\prod_{j=1}^{l_i^w}\Pr(\tilde{w}_{i,j}|\tilde{o}_{a_{i,j}})$$
$$= \prod_{i=1}^{N}\frac{\Pr(l_i^w|\mathbf{o}_i)}{(l_i^o+1)^{l_i^w}}\sum_{\mathbf{a}_i}\prod_{j=1}^{l_i^w}\Pr(\tilde{w}_{i,j}|\tilde{o}_{a_{i,j}})$$

Note that the following equation holds:

$$\prod_{j=1}^{l_i^w}\sum_{k=0}^{l_i^o}\Pr(\tilde{w}_{i,j}|\tilde{o}_{i,k}) = \sum_{a_{i,1}=1}^{l_i^o}\cdots\sum_{a_{i,l_i^w}=1}^{l_i^o}\prod_{j=1}^{l_i^w}\Pr(\tilde{w}_{i,j}|\tilde{o}_{a_{i,j}})$$

where the right-hand side is actually the expansion of $\sum_{\mathbf{a}_i}\prod_j^{l_i^w}\Pr(\tilde{w}_{i,j}|\tilde{o}_{a_{i,j}})$. Therefore, the likelihood can be simplified as

$$\Pr(\mathbf{D};\mathbf{\Theta}) = \prod_{i=1}^{N}\frac{\Pr(l_i^w|\mathbf{o}_i)}{(l_i^o+1)^{l_i^w}}\prod_{j=1}^{l_i^w}\sum_{k=0}^{l_i^o}\Pr(\tilde{w}_{i,j}|\tilde{o}_{i,k})$$

Switching to the notations w_j and o_k, we have

$$\Pr(\mathbf{D};\mathbf{\Theta}) = \prod_{i=1}^{N}\frac{\Pr(l_i^w|\mathbf{o}_i)}{(l_i^o+1)^{l_i^w}}\prod_{j=1}^{m^w}\left[\sum_{k=0}^{m^o}\Pr(w_j|o_k)\delta_{i,k}^o\right]^{\delta_{i,j}^w}$$

where $\delta_{i,j}^w = 1$ if $\tilde{w}_{i,j} \in \mathbf{w}_i$ and $\delta_{i,j}^w = 0$ otherwise, and $\delta_{i,k}^o = 1$ if $\tilde{o}_{i,k} \in \mathbf{o}_i$ and $\delta_{i,k}^o = 0$ otherwise.

Finally, the translation model can be formalized as the following optimization problem

$$\begin{aligned}\arg\max_{\mathbf{\Theta}} \quad & \log\Pr(\mathbf{D};\mathbf{\Theta}) \\ s.t. \quad & \sum_{j=1}^{m^w}\Pr(w_j|o_k) = 1, \forall k\end{aligned}$$

This optimization problem can be solved by the EM algorithm (Brown et al., 1993).

The above model is developed in the context of mapping given objects to words, i.e., its solution yields a set of conditional probabilities $\{\Pr(w_j|o_k), \forall j\}$ for each object o_k, indicating how likely every word is mapped to it. Similarly, we can develop the model in the context of mapping given words to objects (for vocabulary interpretation), whose solution leads to another set of probabilities $\{\Pr(o_k|w_j), \forall k\}$ for each word w_j indicating how likely every object is mapped to it. In our experiments, both models are implemented and we will present the results later.

6 Experiments

We experimented our proposed statistical translation model on the collected data mentioned in Section 3.

6.1 Preprocessing

The main purpose of preprocessing is to create a "parallel corpus" for training a translation model. Here, the "parallel corpus" refers to a series of speech-gaze pairs, each of them consisting of a list of words from the spoken references in the user utterances and a list of objects that are fixated upon within the same time window.

Specifically, we first transcribed the user speech into scripts by automatic speech recognition software and then refined them manually. A time-stamp was associated with each word in the speech script. Further, we detected long pauses in the speech script as splitting points to create time windows, since a long pause usually marks the start of a sentence that indicates a user's attention shift. In our experiment, we set the threshold of judging a long pause to be 1 second. From all the data gathered from 7 users, we get 357 such time windows (which typically contain 10-20 spoken words and 5-10 fixated object changes).

Given a time window, we then found the objects being fixated upon by eye gaze (represented by their IDs as shown in Figure 1). Considering that eye gaze fixation could occur during the pauses in speech, we expanded each time window by a fixed length at both its start and end to find the fixations. In our experiments, the expansion length is set to 0.5 seconds.

Finally, we applied a part-of-speech tagger to each sentence in the user script and only singled out nouns as potential spoken references in the word list. The Porter stemming algorithm was also used to get the normalized forms of those nouns.

The translation model was trained based on this preprocessed parallel data.

6.2 Evaluation Metrics

As described in Section 5, by using a statistical translation model we can get a set of translation probabilities, either from any given spoken word to all the objects, or from any given object to all the spoken words. To evaluate the two sets of translation probabilities, we use *precision* and *recall* as

#Rank	Precision	Recall	#Rank	Precision	Recall
1	0.6667	0.2593	6	0.2302	0.5370
2	0.4524	0.3519	7	0.2041	0.5556
3	0.3810	0.4444	8	0.1905	0.5926
4	0.3095	0.4815	9	0.1799	0.6296
5	0.2667	0.5185	10	0.1619	0.6296

Table 2: Average precision/recall of mapping given objects to words (i.e., acquisition)

#Rank	Precision	Recall	#Rank	Precision	Recall
1	0.7826	0.3214	6	0.3043	0.7500
2	0.5870	0.4821	7	0.2671	0.7679
3	0.4638	0.5714	8	0.2446	0.8036
4	0.3804	0.6250	9	0.2293	0.8393
5	0.3478	0.7143	10	0.2124	0.8571

Table 3: Average precision/recall of mapping given words to objects.(i.e., interpretation)

evaluation metrics.

Specifically, for a given object o_k the translation model will yield a set of probabilities $\{\Pr(w_j|o_k), \forall j\}$. We can sort the probabilities and get a ranked list. Let us assume that we have the ground truth about all the spoken words to which the given object should be mapped. Then, at a given number n of top ranked words, the *precision* of mapping the given object o_k to words is defined as

$$\frac{\text{\# words that } o_k \text{ is correctly mapped to}}{\text{\# words that } o_k \text{ is mapped to}}$$

and the *recall* is defined as

$$\frac{\text{\# words that } o_k \text{ is correctly mapped to}}{\text{\# words that } o_k \text{ should be mapped to}}$$

All the counting above is done within the top n rank. Therefore, we can get different precision/recall at different ranks. At each rank, the overall performance can be evaluated by averaging the precision/recall for all the given objects. Human judgment is used to decide whether an object-word mapping is correct or not, as ground truth for evaluation.

Similarly, based on the set of probabilities of mapping a given object with spoken words, we can find a ranked list of objects for a given word, i.e. $\{\Pr(o_k|w_j), \forall k\}$. Thus, at a given rank the *precision* and *recall* of mapping a given word w_j to objects can be measured.

6.3 Experiment Results

Vocabulary acquisition is the process of finding the appropriate word(s) for any given object. For the sake of statistical significance, our evaluation is done on 21 objects that were mentioned at least 3 times by the users.

Table 2 gives the average precision/recall evaluated at the top 10 ranks. As we can see, if we use the most probable word acquired for each object, about 66.67% of them are appropriate. With the rank increasing, more and more appropriate words can be acquired. About 62.96% of all the appropriate words are included within the top 10 probable words found. The results indicate that by using a translation model, we can obtain the words that are used by the users to describe the objects with reasonable accuracy.

Table 4 presents the top 3 most probable words found for each object. It shows that although there may be more than one word appropriate to describe a given object, those words with highest probabilities always suggest the most popular way of describing the corresponding object among the users. For example, for the object with ID 26, the word `candle` gets a higher probability than the word `candlestick`, which is in accordance with our observation that in our user study, on most occasions users tend to use the word `candle` rather than the word `candlestick`.

Vocabulary interpretation is the process of finding the appropriate object(s) for any given spoken word. Out of 176 nouns in the user vocabulary, we only evaluate those used at least three times for statistical significance concerns. Further, abstract words (such as `reason, position`) and general words (such as `room, furniture`) are not evaluated since they do not refer to any particular objects in the scene. Finally, 23 nouns remain for evaluation.

We manually enumerated all the object(s) that those 23 nouns refer to as the ground truth in our evaluation. Note that a given noun can possibly be used to refer to multiple objects, such as `lamp`, since we have several lamps (with object ID 3, 8, 17, and 23) in the experiment setting, and `bed`, since bed frame, bed spread, and pillows (with object ID 19, 21, and 20 respectively) are all part of a bed. Also, an object can be referred to by multiple nouns. For example, the words `painting, picture`, or `waterfall` can all be used to refer to the object with ID 15.

Object	Rank 1	Rank 2	Rank 3
1	paint (0.254) *	wall (0.191)	left (0.150)

Table 5: Objects found for given words. Each row lists the 4 most probable object IDs for the corresponding given words (being stemmed), with the mapping probabilities in parentheses. Asterisks indicate correctly identified objects. Note that some objects are heavily overlapped, such as the candle (with object ID 26) and the chair (with object ID 25), and both were considered correct for the respective spoken words.

Table 3 gives the average precision/recall evaluated at the top 10 ranks. As we can see, if we use the most probable object found for each speech word, about 78.26% of them are appropriate. With the rank increasing, more and more appropriate objects can be found. About 85.71% of all the appropriate objects are included within the top 10 probable objects found. The results indicate that by using a translation model, we can predict the objects from user spoken words with reasonable accuracy.

Table 5 lists the top 4 probable objects found for each spoken word being evaluated. A close look reveals that in general, the top ranked objects tend to gather around the correct object for a given spoken word. This is consistent with the fact that eye gaze tends to move back and forth. It also indicates that the mappings established by the translation model can effectively find the approximate area of the corresponding fixated object, even if it cannot find the object due to the noisy and jerky nature of eye gaze.

The precision/recall in vocabulary acquisition is not as high as that in vocabulary interpretation, partially due to the relatively small scale of our experiment data. For example, with only 7 users' speech data on 14 conversational tasks, some words were only spoken a few times to refer to an object, which prevented them from getting a significant portion of probability mass among all the words in the vocabulary. This degrades both precision and recall. We believe that in large scale experiments or real-world applications, the performance will be improved.

7 Discussion and Conclusion

Previous psycholinguistic findings have shown that eye gaze is tightly linked with human language production. During human machine conversation, our study shows that although a larger variance is observed on how eye fixations are exactly linked with corresponding spoken references (compared to the psycholinguistic findings), eye gaze in general is closely coupled with corresponding referring expressions in the utterances. This close coupling nature between eye gaze and speech utterances provides an opportunity for the system to automatically

acquire different words related to different objects without any human supervision. To further explore this idea, we developed a novel unsupervised approach using statistical translation models.

Our experimental results have shown that this approach can reasonably uncover the mappings between words and objects on the graphical display. The main advantages of this approach include: 1) It is an unsupervised approach with minimum human inference; 2) It does not need any prior knowledge to train a statistical translation model; 3) It yields probabilities that indicate the reliability of the mappings.

Certainly, our current approach is built upon simplified assumptions. It is quite challenging to incorporate eye gaze information since it is extremely noisy with large variances. Recent work has shown that the effect of eye gaze in facilitating spoken language processing varies among different users (Qu and Chai, 2007). In addition, visual properties of the interface also affect user gaze behavior and thus influence the predication of attention (Prasov et al., 2007) based on eye gaze. Our future work will develop models to address these variations.

Nevertheless, the results from our current work have several important implications in building robust conversational interfaces. First of all, most conversational systems are built with static knowledge space (e.g., vocabularies) and can only be updated by the system developers. Our approach can potentially allow the system to automatically acquire knowledge and vocabularies based on the natural interactions with the users without human intervention. Furthermore, the automatically acquired mappings between words and objects can also help language interpretation tasks such as reference resolution. Given the recent advances in eye tracking technology (Duchowski, 2002), integrating non-intrusive and high performance eye trackers with conversational interfaces becomes feasible. The work reported here can potentially be integrated in practical systems to improve the overall robustness of human machine conversation.

Abstract

In order to effectively access the rapidly increasing range of media content available in the home, new kinds of more natural interfaces are needed. In this paper, we explore the application of multimodal interface technologies to searching and browsing a database of movies. The resulting system allows users to access movies using speech, pen, remote control, and dynamic combinations of these modalities. An experimental evaluation, with more than 40 users, is presented contrasting two variants of the system: one combining speech with traditional remote control input and a second where the user has a tablet display supporting speech and pen input.

1 Introduction

As traditional entertainment channels and the internet converge through the advent of technologies such as broadband access, movies-on-demand, and streaming video, an increasingly large range of content is available to consumers in the home. However, to benefit from this new wealth of content, users need to be able to rapidly and easily find what they are actually interested in, and do so effortlessly while relaxing on the couch in their living room — a location where they typically do not have easy access to the keyboard, mouse, and close-up screen display typical of desktop web browsing.

Current interfaces to cable and satellite television services typically use direct manipulation of a graphical user interface using a remote control. In order to find content, users generally have to either navigate a complex, pre-defined, and often deeply embedded menu structure or type in titles or other key phrases using an onscreen keyboard or triple tap input on a remote control keypad. These interfaces are cumbersome and do not scale well as the range of content available increases (Berglund, 2004; Mitchell, 1999).

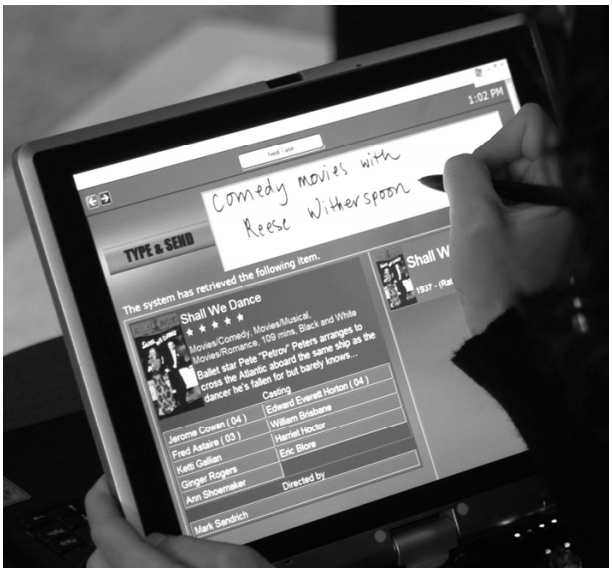

Figure 1 Multimodal interface on tablet

In this paper we explore the application of multimodal interface technologies (See André (2002) for an overview) to the creation of more effective systems used to search and browse for entertainment content in the home. A number of previous systems have investigated the addition of unimodal spoken search queries to a graphical electronic program guide (Ibrahim and Johansson, 2002

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 376–383,
Prague, Czech Republic, June 2007.

(NokiaTV); Goto et al., 2003; Wittenburg et al., 2006). Wittenburg et al experiment with unrestricted speech input for electronic program guide search, and use a highlighting mechanism to provide feedback to the user regarding the "relevant" terms the system understood and used to make the query. However, their usability study results show this complex output can be confusing to users and does not correspond to user expectations. Others have gone beyond unimodal speech input and added multimodal commands combining speech with pointing (Johansson, 2003; Portele et al, 2006). Johansson (2003) describes a movie recommender system MadFilm where users can use speech and pointing to accept/reject recommended movies. Portele et al (2006) describe the SmartKom-Home system which includes multimodal electronic program guide on a tablet device.

In our work we explore a broader range of interaction modalities and devices. The system provides users with the flexibility to interact using spoken commands, handwritten commands, unimodal pointing (GUI) commands, and multimodal commands combining speech with one or more pointing gestures made on a display. We compare two different interaction scenarios. The first utilizes a traditional remote control for direct manipulation and pointing, integrated with a wireless microphone for speech input. In this case, the only screen is the main TV display (far screen). In the second scenario, the user also has a second graphical display (close screen) presented on a mobile tablet which supports speech and pen input, including both pointing and handwriting (Figure 1). Our application task also differs, focusing on search and browsing of a large database of movies-on-demand and supporting queries over multiple simultaneous dimensions. This work also differs in the scope of the evaluation. Prior studies have primarily conducted qualitative evaluation with small groups of users (5 or 6). A quantitative and qualitative evaluation was conducted examining the interaction of 44 naïve users with two variants of the system. We believe this to be the first broad scale experimental evaluation of a flexible multimodal interface for searching and browsing large databases of movie content.

In Section 2, we describe the interface and illustrate the capabilities of the system. In Section 3, we describe the underlying multimodal processing architecture and how it processes and integrates user inputs. Section 4 describes our experimental evaluation and comparison of the two systems. Section 5 concludes the paper.

2 Interacting with the system

The system described here is an advanced user interface prototype which provides multimodal access to databases of media content such as movies or television programming. The current database is harvested from publicly accessible web sources and contains over 2000 popular movie titles along with associated metadata such as cast, genre, director, plot, ratings, length, etc.

The user interacts through a graphical interface augmented with speech, pen, and remote control input modalities. The remote control can be used to move the current focus and select items. The pen can be used both for selecting items (pointing at them) and for handwritten input. The graphical user interface has three main screens. The main screen is the search screen (Figure 2). There is also a control screen used for setting system parameters and a third comparison display used for showing movie details side by side (Figure 4). The user can select among the screens using three icons in the navigation bar at the top left of the screen. The arrows provide 'Back' and 'Next' for navigation through previous searches. Directly below, there is a feedback window which indicates whether the system is listening and provides feedback on speech recognition and search. In the tablet variant, the microphone and speech recognizer are activated by tapping on 'CLICK TO SPEAK' with the pen. In the remote control version, the recognizer can also be activated using a button on the remote control. The main section of the search display (Figure 2) contains two panels. The right panel (results panel) presents a scrollable list of thumbnails for the movies retrieved by the current search. The left panel (details panel) provides details on the currently selected title in the results panel. These include the genre, plot summary, cast, and director.

The system supports a speech modality, a handwriting modality, pointing (unimodal GUI) modality, and composite multimodal input where the user utters a spoken command which is combined with pointing 'gestures' the user has made towards screen icons using the pen or the remote control.

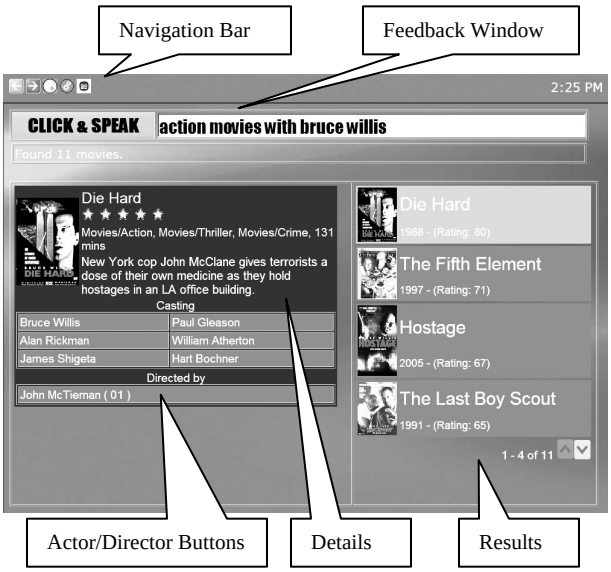

Figure 2 Graphical user interface

Speech: The system supports speech search over multiple different dimensions such as title, genre, cast, director, and year. Input can be more telegraphic with searches such as "Legally Blonde", "Romantic comedy", and "Reese Witherspoon", or more verbose natural language queries such as "I'm looking for a movie called Legally Blonde" and "Do you have romantic comedies". An important advantage of speech is that it makes it easy to combine multiple constraints over multiple dimensions within a single query (Cohen, 1992). For example, queries can indicate co-stars: "movies starring Ginger Rogers and Fred Astaire", or constrain genre and cast or director at the same time: "Meg Ryan Comedies", "show drama directed by Woody Allen" and "show comedy movies directed by Woody Allen and starring Mira Sorvino".

Handwriting: Handwritten pen input can also be used to make queries. When the user's pen approaches the feedback window, it expands allowing for freeform pen input. In the example in Figure 3, the user requests comedy movies with Bruce Willis using unimodal handwritten input. This is an important input modality as it is not impacted by ambient noise such as crosstalk from other viewers or currently playing content.

Figure 3 Handwritten query

Pointing/GUI: In addition to the recognition-based modalities, speech and handwriting, the interface also supports more traditional graphical user interface (GUI) commands. In the details panel, the actors and directors are presented as buttons. Pointing at (i.e., clicking on) these buttons results in a search for all of the movies with that particular actor or director, allowing users to quickly navigate from an actor or director in a specific title to other material they may be interested in. The buttons in the results panel can be pointed at (clicked on) in order to view the details in the left panel for that particular title.

Figure 4 Comparison screen

Composite multimodal input: The system also supports true composite multimodality when spoken or handwritten commands are integrated with pointing gestures made using the pen (in the tablet version) or by selecting items (in the remote control version). This allows users to quickly execute more complex commands by combining the ease of reference of pointing with the expressiveness of spoken constraints. While by unimodally pointing at an actor button you can search for all of the actor's movies, by adding speech you can narrow the search to, for example, all of their comedies by saying: "show comedy movies with THIS actor". Multimodal commands with multiple pointing gestures are also supported, allowing the user to 'glue' together references to multiple actors or directors in order to constrain the search. For example, they can say "movies with THIS actor and THIS director" and point at the 'Alan Rickman' button and then the 'John McTiernan' button in turn (Figure 2). Comparison commands can also be multimo-

dal; for example, if the user says "compare THIS movie and THIS movie" and clicks on the two buttons on the right display for 'Die Hard' and the 'The Fifth Element' (Figure 2), the resulting display shows the two movies side-by-side in the comparison screen (Figure 4).

3 Underlying multimodal architecture

The system consists of a series of components which communicate through a facilitator component (Figure 5). This develops and extends upon the multimodal architecture underlying the MATCH system (Johnston et al., 2002).

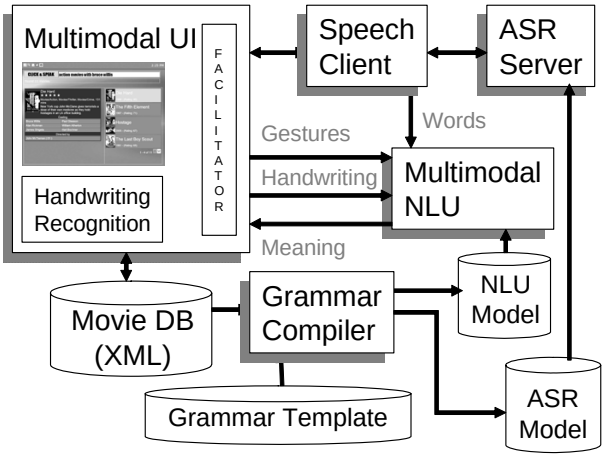

Figure 5 System architecture

The underlying database of movie information is stored in XML format. When a new database is available, a Grammar Compiler component extracts and normalizes the relevant fields from the database. These are used in conjunction with a predefined multimodal grammar template and any available corpus training data to build a multimodal understanding model and speech recognition language model.

The user interacts with the multimodal user interface client (Multimodal UI), which provides the graphical display. When the user presses 'CLICK TO SPEAK' a message is sent to the Speech Client, which activates the microphone and ships audio to a speech recognition server. Handwritten inputs are processed by a handwriting recognizer embedded within the multimodal user interface client. Speech recognition results, pointing gestures made on the display, and handwritten inputs, are all passed to a multimodal understanding server which uses finite-state multimodal language processing techniques (Johnston and Bangalore, 2005) to interpret and integrate the speech and gesture. This model combines alignment of multimodal inputs, multimodal integration, and language understanding within a single mechanism. The resulting combined meaning representation (represented in XML) is passed back to the multimodal user interface client, which translates the understanding results into an XPATH query and runs it against the movie database to determine the new series of results. The graphical display is then updated to represent the latest query.

The system first attempts to find an exact match in the database for all of the search terms in the user's query. If this returns no results, a back off and query relaxation strategy is employed. First the system tries a search for movies that have all of the search terms, except stop words, independent of the order (an AND query). If this fails, then it backs off further to an OR query of the search terms and uses an edit machine, using Levenshtein distance, to retrieve the most similar item to the one requested by the user.

4 Evaluation

After designing and implementing our initial prototype system, we conducted an extensive multimodal data collection and usability study with the two different interaction scenarios: tablet versus remote control. Our main goals for the data collection and statistical analysis were three-fold: collect a large corpus of natural multimodal dialogue for this media selection task, investigate whether future systems should be paired with a remote control or tablet-like device, and determine which types of search and input modalities are more or less desirable.

4.1 Experimental set up

The system evaluation took place in a conference room set up to resemble a living room (Figure 6). The system was projected on a large screen across the room from a couch.

An adjacent conference room was used for data collection (Figure 7). Data was collected in sound files, videotapes, and text logs. Each subject's spoken utterances were recorded by three microphones: wireless, array and stand alone. The wireless microphone was connected to the system while the array and stand alone microphones were

around 10 feet away.[1] Test sessions were recorded with two video cameras – one captured the system's screen using a scan converter while the other recorded the user and couch area. Lastly, the user's interactions and the state of the system were captured by the system's logger. The logger is an additional agent added to the system architecture for the purposes of the evaluation. It receives log messages from different system components as interaction unfolds and stores them in a detailed XML log file. For the specific purposes of this evaluation, each log file contains: general information about the system's components, a description and timestamp for each system event and user event, names and timestamps for the system-recorded sound files, and timestamps for the start and end of each scenario.

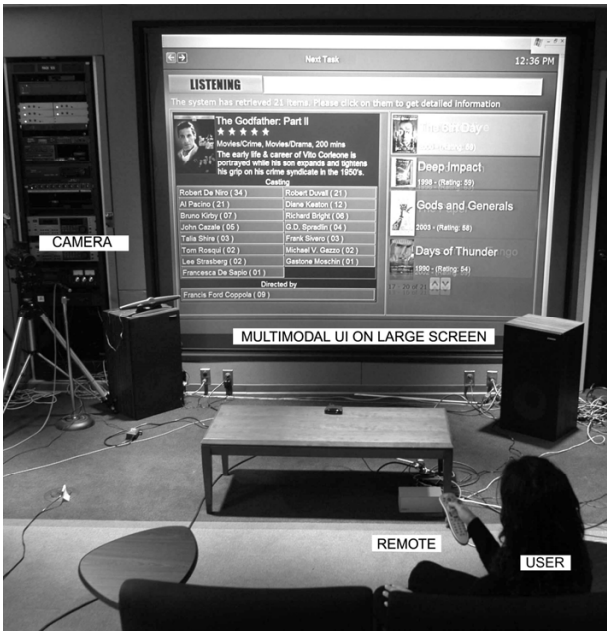

Figure 6 Data collection environment

Forty-four subjects volunteered to participate in this evaluation. There were 33 males and 11 females, ranging from 20 to 66 years of age. Each user interacted with both the remote control and tablet variants of the system, completing the same two sets of scenarios and then freely interacting with each system. For counterbalancing purposes, half of the subjects used the tablet and then the remote control and the other half used the remote control and then the tablet. The scenario set assigned to each version was also counterbalanced.

Figure 7 Data collection room

Each set of scenarios consisted of seven defined tasks, four user-specialized tasks and five open-ended tasks. Defined tasks were presented in chart form and had an exact answer, such as the movie title that two specified actors/actresses starred in. For example, users had to find the movie in the database with Matthew Broderick and Denzel Washington. User-specialized tasks relied on the specific user's preferences, such as "What type of movie do you like to watch on a Sunday evening? Find an example from that genre and write down the title". Open-ended tasks prompted users to search for any type of information with any input modality. The tasks in the two sets paralleled each other. For example, if one set of tasks asked the user to find the highest ranked comedy movie with Reese Witherspoon, the other set of tasks asked the user to find the highest ranked comedy movie with Will Smith. Within each task set, the defined tasks appeared first, then the user-specialized tasks and lastly the open-ended tasks. However, for each participant, the order of defined tasks was randomized, as well as the order of user-specialized tasks.

At the beginning of the session, users read a short tutorial about the system's GUI, the experiment, and available input modalities. Before interacting with each version, users were given a manual on operating the tablet/remote control. To minimize bias, the manuals gave only a general overview with few examples and during the experiment users were alone in the room.

At the end of each session, users completed a user-satisfaction/preference questionnaire and then a qualitative interview. The questionnaire consisted

[1] Here we report results for the wireless microphone only. Analysis of the other microphone conditions is ongoing.

of 25 statements about the system in general, the two variants of the system, input modality options and search options. For example, statements ranged from "If I had [the system], I would use the tablet with it" to "If my spoken request was misunderstood, I would want to try again with speaking". Users responded to each statement with a 5-point Likert scale, where 1 = 'I strongly agree', 2 = 'I mostly agree', 3 = 'I can't say one way or the other', 4 = 'I mostly do not agree' and 5 = 'I do not agree at all'. The qualitative interview allowed for more open-ended responses, where users could discuss reasons for their preferences and their likes and dislikes regarding the system.

4.2 Results

Data was collected from all 44 participants. Due to technical problems, five participants' logs or sound files were not recorded in parts of the experiment. All collected data was used for the overall statistics but these five participants had to be excluded from analyses comparing remote control to tablet.

Spoken utterances: After removing empty sound files, the full speech corpus consists of 3280 spoken utterances. Excluding the five participants subject to technical problems, the total is 3116 utterances (1770 with the remote control and 1346 with the tablet).

The set of 3280 utterances averages 3.09 words per utterance. There was not a significant difference in utterance length between the remote control and tablet conditions. Users' averaged 2.97 words per utterance with the remote control and 3.16 words per utterance with the tablet, paired t (38) = 1.182, p = n.s. However, users spoke significantly more often with the remote control. On average, users spoke 34.51 times with the tablet and 45.38 times with the remote control, paired t (38) = -3.921, $p < .01$.

ASR performance: Over the full corpus of 3280 speech inputs, word accuracy was 44% and sentence accuracy 38%. In the tablet condition, word accuracy averaged 46% and sentence accuracy 41%. In the remote control condition, word accuracy averaged 41% and sentence accuracy 38%. The difference across conditions was only significant for word accuracy, paired t (38) = 2.469, $p < .02$. In considering the ASR performance, it is important to note that 55% of the 3280 speech inputs were out of grammar, and perhaps more importantly 34% were out of the functionality of the system entirely. On within functionality inputs, word accuracy is 62% and sentence accuracy 57%. On the in grammar inputs, word accuracy is 86% and sentence accuracy 83%. The vocabulary size was 3851 for this task. In the corpus, there are a total of 356 out-of-vocabulary words.

Handwriting recognition: Performance was determined by manual inspection of screen capture video recordings.[2] There were a total of 384 handwritten requests with overall 66% sentence accuracy and 76% word accuracy.

Task completion: Since participants had to record the task answers on a paper form, task completion was calculated by whether participants wrote down the correct answer. Overall, users had little difficulty completing the tasks. On average, participants completed 11.08 out of the 14 defined tasks and 7.37 out of the 8 user-specialized tasks. The number of tasks completed did not differ across system variants.[3] For the seven defined tasks within each condition, users averaged 5.69 with the remote control and 5.40 with the tablet, paired t (34) = -1.203, p = n.s. For the four user-specialized task within each condition, users averaged 3.74 on the remote control and 3.54 on the tablet, paired t (34) = -1.268, p = n.s.

Input modality preference: During the interview, 55% of users reported preferring the pointing (GUI) input modality over speech and multimodal input. When asked about handwriting, most users were hesitant to place it on the list. They also discussed how speech was extremely important, and given a system with a low error speech recognizer, using speech for input probably would be their first choice. In the questionnaire, the majority of users (93%) 'strongly agree' or 'mostly agree' with the importance of making a pointing request. The importance of making a request by speaking had the next highest average, where 57% 'strongly agree' or 'mostly agree' with the statement. The importance of multimodal and handwriting requests had the lowest averages, where 39% agreed with the former and 25% for the latter. However, in the open-ended interview, users mentioned handwriting as an important back-up input choice for cases when the speech recognizer fails.

[2] One of the 44 participants videotape did not record and so is not included in the statistics.

[3] Four participants did not properly record their task answers and had to be eliminated from the 39 participants being used in the remote control versus tablet statistics.

Further support for input modality preference was gathered from the log files, which showed that participants mostly searched using unimodal speech commands and GUI buttons. Out of a total of 6082 user inputs to the systems, 48% were unimodal speech and 39% were unimodal GUI (pointing and clicking). Participants requested information with composite multimodal commands 7% of the time and with handwriting 6% of the time.

Search preference: Users most strongly agreed with movie title being the most important way to search. For searching by title, more than half the users chose 'strongly agree' and 91% of users chose 'strongly agree' or 'mostly agree'. Slightly more than half chose 'strongly agree' with searching by actor/actress and slightly less than half chose 'strongly agree' with the importance of searching by genre. During the open ended interview, most users reported title as the most important means for searching.

Variant preference: Results from the qualitative interview indicate that 67% of users preferred the remote control over the tablet variant of the system. The most common reported reasons were familiarity, physical comfort and ease of use. Remote control preference is further supported from the user-preference questionnaire, where 68% of participants 'mostly agree' or 'strongly agree' with wanting to use the remote control variant of the system, compared to 30% of participants choosing 'mostly agree' or 'strongly agree' with wanting to use the tablet version of the system.

5 Conclusion

With the range of entertainment content available to consumers in their homes rapidly expanding, the current access paradigm of direct manipulation of complex graphical menus and onscreen keyboards, and remote controls with way too many buttons is increasingly ineffective and cumbersome. In order to address this problem, we have developed a highly flexible multimodal interface that allows users to search for content using speech, handwriting, pointing (using pen or remote control), and dynamic multimodal combinations of input modes. Results are presented in a straightforward graphical interface similar to those found in current systems but with the addition of icons for actors and directors that can be used both for unimodal GUI and multimodal commands. The system allows users to search for movies over multiple different dimensions of classification (title, genre, cast, director, year) using the mode or modes of their choice. We have presented the initial results of an extensive multimodal data collection and usability study with the system.

Users in the study were able to successfully use speech in order to conduct searches. Almost half of their inputs were unimodal speech (48%) and the majority of users strongly agreed with the importance of using speech as an input modality for this task. However, as also reported in previous work (Wittenburg et al 2006), recognition accuracy remains a serious problem. To understand the performance of speech recognition here, detailed error analysis is important. The overall word accuracy was 44% but the majority of errors resulted from requests from users that lay outside the functionality of the underlying system, involving capabilities the system did not have or titles/cast absent from the database (34% of the 3280 spoken and multimodal inputs). No amount of speech and language processing can resolve these problems. This highlights the importance of providing more detailed help and tutorial mechanisms in order to appropriately ground users' understanding of system capabilities. Of the remaining 66% of inputs (2166) which were within the functionality of the system, 68% were in grammar. On the within functionality portion of the data, the word accuracy was 62%, and on in grammar inputs it is 86%. Since this was our initial data collection, an un-weighted finite-state recognition model was used. The performance will be improved by training stochastic language models as data become available and employing robust understanding techniques. One interesting issue in this domain concerns recognition of items that lie outside of the current database. Ideally the system would have a far larger vocabulary than the current database so that it would be able to recognize items that are outside the database. This would allow feedback to the user to differentiate between lack of results due to recognition or understanding problems versus lack of items in the database. This has to be balanced against degradation in accuracy resulting from increasing the vocabulary.

In practice we found that users, while acknowledging the value of handwriting as a back-up mode, generally preferred the more relaxed and familiar style of interaction with the remote control. However, several factors may be at play here.

The tablet used in the study was the size of a small laptop and because of cabling had a fixed location on one end of the couch. In future, we would like to explore the use of a smaller, more mobile, tablet that would be less obtrusive and more conducive to leaning back on the couch. Another factor is that the in-lab data collection environment is somewhat unrealistic since it lacks the noise and disruptions of many living rooms. It remains to be seen whether in a more realistic environment we might see more use of handwritten input. Another factor here is familiarity. It may be that users have more familiarity with the concept of speech input than handwriting. Familiarity also appears to play a role in user preferences for remote control versus tablet. While the tablet has additional capabilities such handwriting and easier use of multimodal commands, the remote control is more familiar to users and allows for a more relaxed interaction since they can lean back on the couch. Also many users are concerned about the quality of their handwriting and may avoid this input mode for that reason.

Another finding is that it is important not to underestimate the importance of GUI input. 39% of user commands were unimodal GUI (pointing) commands and 55% of users reported a preference for GUI over speech and handwriting for input. Clearly, the way forward for work in this area is to determine the optimal way to combine more traditional graphical interaction techniques with the more conversational style of spoken interaction.

Most users employed the composite multimodal commands, but they make up a relatively small proportion of the overall number of user inputs in the study data (7%). Several users commented that they did not know enough about the multimodal commands and that they might have made more use of them if they had understood them better. This, along with the large number of inputs that were out of functionality, emphasizes the need for more detailed tutorial and online help facilities. The fact that all users were novices with the system may also be a factor. In future, we hope to conduct a longer term study with repeat users to see how previous experience influences use of newer kinds of inputs such as multimodal and handwriting.

Abstract

This paper describes an incremental parser and an unsupervised learning algorithm for inducing this parser from plain text. The parser uses a representation for syntactic structure similar to dependency links which is well-suited for incremental parsing. In contrast to previous unsupervised parsers, the parser does not use part-of-speech tags and both learning and parsing are local and fast, requiring no explicit clustering or global optimization. The parser is evaluated by converting its output into equivalent bracketing and improves on previously published results for unsupervised parsing from plain text.

1 Introduction

Grammar induction, the learning of the grammar of a language from unannotated example sentences, has long been of interest to linguists because of its relevance to language acquisition by children. In recent years, interest in unsupervised learning of grammar has also increased among computational linguists, as the difficulty and cost of constructing annotated corpora led researchers to look for ways to train parsers on unannotated text. This can either be semi-supervised parsing, using both annotated and unannotated data (McClosky et al., 2006) or unsupervised parsing, training entirely on unannotated text.

The past few years have seen considerable improvement in the performance of unsupervised parsers (Klein and Manning, 2002; Klein and Manning, 2004; Bod, 2006a; Bod, 2006b) and, for the first time, unsupervised parsers have been able to improve on the right-branching heuristic for parsing English. All these parsers learn and parse from sequences of part-of-speech tags and select, for each sentence, the binary parse tree which maximizes some objective function. Learning is based on global maximization of this objective function over the whole corpus.

In this paper I present an unsupervised parser from plain text which does not use parts-of-speech. Learning is local and parsing is (locally) greedy. As a result, both learning and parsing are fast. The parser is incremental, using a new link representation for syntactic structure. Incremental parsing was chosen because it considerably restricts the search space for both learning and parsing. The representation the parser uses is designed for incremental parsing and allows a prefix of an utterance to be parsed before the full utterance has been read (see section 3). The representation the parser outputs can be converted into bracketing, thus allowing evaluation of the parser on standard treebanks.

To achieve completely unsupervised parsing, standard unsupervised parsers, working from part-of-speech sequences, need first to induce the parts-of-speech for the plain text they need to parse. There are several algorithms for doing so (Schütze, 1995; Clark, 2000), which cluster words into classes based on the most frequent neighbors of each word. This step becomes superfluous in the algorithm I present here: the algorithm collects lists of labels for each word, based on neighboring words, and then directly

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 384–391,
Prague, Czech Republic, June 2007.

uses these labels to parse. No clustering is performed, but due to the Zipfian distribution of words, high frequency words dominate these lists and parsing decisions for words of similar distribution are guided by the same labels.

Section 2 describes the syntactic representation used, section 3 describes the general parser algorithm and sections 4 and 5 complete the details by describing the learning algorithm, the lexicon it constructs and the way the parser uses this lexicon. Section 6 gives experimental results.

2 Common Cover Links

The representation of syntactic structure which I introduce in this paper is based on links between pairs of words. Given an utterance and a bracketing of that utterance, *shortest common cover link sets* for the bracketing are defined. The original bracketing can be reconstructed from any of these link sets.

2.1 Basic Definitions

An *utterance* is a sequence of words $\langle x_1, \ldots, x_n \rangle$ and a *bracket* is any sub-sequence $\langle x_i, \ldots, x_j \rangle$ of consecutive words in the utterance. A set $\mathcal{B}$ of brackets over an utterance U is a *bracketing* of U if every word in U is in some bracket and for any $X, Y \in \mathcal{B}$ either $X \cap Y = \emptyset$, $X \subseteq Y$ or $Y \subseteq X$ (non-crossing brackets). The *depth* of a word $x \in U$ under a bracket $B \in \mathcal{B}$ ($x \in B$) is the maximal number of brackets $X_1, \ldots, X_n \in \mathcal{B}$ such that $x \in X_1 \subset \ldots \subset X_n \subset B$. A word x is a *generator* of depth d of B in $\mathcal{B}$ if x is of minimal depth under B (among all words in B) and that depth is d. A bracket may have more than one generator.

2.2 Common Cover Link Sets

A *common cover link* over an utterance U is a triple $x \xrightarrow{d} y$ where $x, y \in U$, $x \neq y$ and d is a non-negative integer. The word x is the *base* of the link, the word y is its *head* and d is the *depth* of the link. The common cover link set $R_{\mathcal{B}}$ associated with a bracketing $\mathcal{B}$ is the set of common cover links over U such that $x \xrightarrow{d} y \in R_{\mathcal{B}}$ iff the word x is a generator of depth d of the smallest bracket $B \in \mathcal{B}$ such that $x, y \in B$ (see figure 1(a)).

Given $R_{\mathcal{B}}$, a simple algorithm reconstructs the bracketing $\mathcal{B}$: for each word x and depth $0 \leq d$, create a bracket covering x and all y such that for some $d' \leq d$, $x \xrightarrow{d'} y \in R_{\mathcal{B}}$.

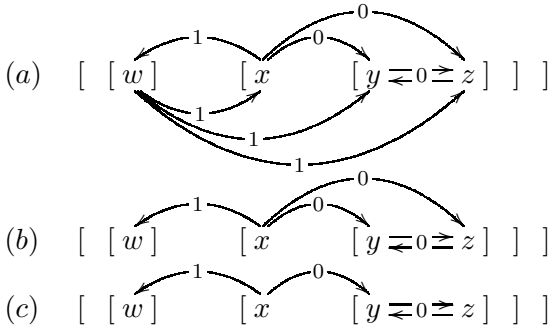

Figure 1: (a) The common cover link set $R_{\mathcal{B}}$ of a bracketing $\mathcal{B}$, (b) a representative subset R of $R_{\mathcal{B}}$, (c) the shortest common cover link set based on R.

Some of the links in the common cover link set $R_{\mathcal{B}}$ are redundant. The first redundancy is the result of brackets having more than one generator. The bracketing reconstruction algorithm outlined above can construct a bracket from the links based at any of its generators. The bracketing $\mathcal{B}$ can therefore be reconstructed from a subset $R \subseteq R_{\mathcal{B}}$ if, for every bracket $B \in \mathcal{B}$, R contains the links based at least at one generator[1] of B. Such a set R is a *representative subset* of $R_{\mathcal{B}}$ (see figure 1(b)).

A second redundancy in the set $R_{\mathcal{B}}$ follows from the *linear transitivity* of $R_{\mathcal{B}}$:

Lemma 1 *If y is between x and z, $x \xrightarrow{d_1} y \in R_{\mathcal{B}}$ and $y \xrightarrow{d_2} z \in R_{\mathcal{B}}$ then $x \xrightarrow{d} z \in R_{\mathcal{B}}$ where if there is a link $y \xrightarrow{d'} x \in R_{\mathcal{B}}$ then $d = \max(d_1, d_2)$ and $d = d_1$ otherwise.*

This property implies that longer links can be deduced from shorter links. It is, therefore, sufficient to leave only the shortest necessary links in the set. Given a representative subset R of $R_{\mathcal{B}}$, a *shortest common cover link set* of $R_{\mathcal{B}}$ is constructed by removing any link which can be deduced from shorter links by linear transitivity. For each representative subset $R \subseteq R_{\mathcal{B}}$, this defines a unique shortest common cover link set (see figure 1(c)).

Given a shortest common cover link set S, the bracketing which it represents can be calculated by

[1] From the bracket reconstruction algorithm it can be seen that links of depth 0 may never be dropped.

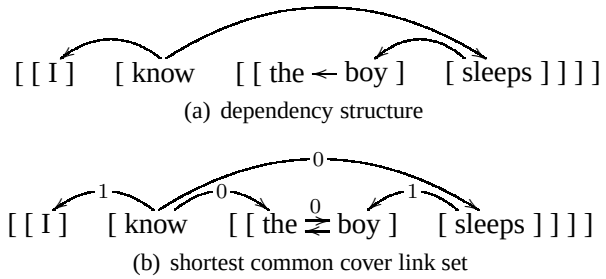

Figure 2: A dependency structure and shortest common cover link set of the same sentence.

first using linear transitivity to deduce missing links and then applying the bracket reconstruction algorithm outlined above for $R_{\mathcal{B}}$.

2.3 Comparison with Dependency Structures

Having defined a link-based representation of syntactic structure, it is natural to wonder what the relation is between this representation and standard dependency structures. The main differences between the two representations can all be seen in figure 2. The first difference is in the linking of the NP *the boy*. While the shortest common cover link set has an exocentric construction for this NP (that is, links going back and forth between the two words), the dependency structure forces us to decide which of the two words in the NP is its head. Considering that linguists have not been able to agree whether it is the determiner or the noun that is the head of an NP, it may be easier for a learning algorithm if it did not have to make such a choice.

The second difference between the structures can be seen in the link from *know* to *sleeps*. In the shortest common cover link set, there is a path of links connecting *know* to each of the words separating it from *sleeps*, while in the dependency structure no such links exist. This property, which I will refer to as *adjacency* plays an important role in incremental parsing, as explained in the next section.

The last main difference between the representations is the assignment of depth to the common cover links. In the present example, this allows us to distinguish between the attachment of the external (subject) and the internal (object) arguments of the verb. Dependencies cannot capture this difference without additional labeling of the links. In what follows, I will restrict common cover links to having depth 0 or 1. This restriction means that any tree represented by a shortest common cover link set will be skewed - every subtree must have a short branch. It seems that this is indeed a property of the syntax of natural languages. Building this restriction into the syntactic representation considerably reduces the search space for both parsing and learning.

3 Incremental Parsing

To calculate a shortest common cover link for an utterance, I will use an incremental parser. Incrementality means that the parser reads the words of the utterance one by one and, as each word is read, the parser is only allowed to add links which have one of their ends at that word. Words which have not yet been read are not available to the parser at this stage. This restriction is inspired by psycholinguistic research which suggests that humans process language incrementally (Crocker et al., 2000). If the incrementality of the parser roughly resembles that of human processing, the result is a significant restriction of parser search space which does not lead to too many parsing errors.

The adjacency property described in the previous section makes shortest common cover link sets especially suitable for incremental parsing. Consider the example given in figure 2. When the word *the* is read, the parser can already construct a link from *know* to *the* without worrying about the continuation of the sentence. This link is part of the correct parse whether the sentence turns out to be *I know the boy* or *I know the boy sleeps*. A dependency parser, on the other hand, cannot make such a decision before the end of the sentence is reached. If the sentence is *I know the boy* then a dependency link has to be created from *know* to *boy* while if the sentence is *I know the boy sleeps* then such a link is wrong. This problem is known in psycholinguistics as the problem of reanalysis (Sturt and Crocker, 1996).

Assume the incremental parser is processing a prefix $\langle x_1, \ldots, x_k \rangle$ of an utterance and has already deduced a set of links L for this prefix. It can now only add links which have one of their ends at x_k and it may never remove any links. From the definitions in section 2.2 it is possible to derive an exact characterization of the links which may be added at each step such that the resulting link set represents some

bracketing. It can be shown that any shortest common cover link set can be constructed incrementally under these conditions. As the full specification of these conditions is beyond the scope of this paper, I will only give the main condition, which is based on adjacency. It states that a link may be added from x to y only if for every z between x and y there is a path of links (in L) from x to z but no link from z to y. In the example in figure 2 this means that when the word *sleeps* is first read, a link to *sleeps* can be created from *know*, *the* and *boy* but not from *I*.

Given these conditions, the parsing process is simple. At each step, the parser calculates a non-negative weight (section 5) for every link which may be added between the prefix $\langle x_1, \ldots, x_{k-1} \rangle$ and x_k. It then adds the link with the strongest positive weight and repeats the process (adding a link can change the set of links which may be added). When all possible links are assigned a zero weight by the parser, the parser reads the next word of the utterance and repeats the process. This is a greedy algorithm which optimizes every step separately.

4 Learning

The weight function which assigns a weight to a candidate link is lexicalized: the weight is calculated based on the lexical entries of the words which are to be connected by the link. It is the task of the learning algorithm to learn the lexicon.

4.1 The Lexicon

The lexicon stores for each word x a lexical entry. Each such lexical entry is a sequence of *adjacency points*, holding statistics relevant to the decision whether to link x to some other word. These statistics are given as weights assigned to labels and linking properties. Each adjacency point describes a different link based at x, similar to the specification of the arguments of a word in dependency parsing.

Let W be the set of words in the corpus. The set of *labels* $L(W) = W \times \{0, 1\}$ consists of two labels based on every word w: a *class label* $(w, 0)$ (denoted by $[w]$) and an *adjacency label* $(w, 1)$ (denoted by $[w\_]$ or $[\_w]$). The two labels $(w, 0)$ and $(w, 1)$ are said to be *opposite labels* and, for $l \in L(W)$, I write l^{-1} for the opposite of l. In addition to the labels, there is also a finite set $P = \{Stop, In^*, In, Out\}$ of *linking properties*. The $Stop$ specifies the strength of non-attachment, In and Out specify the strength of inbound and outbound links and In^* is an intermediate value in the induction of inbound and outbound strengths. A *lexicon* $\mathcal{L}$ is a function which assigns each word $w \in W$ a lexical entry $(\ldots, A^w_{-2}, A^w_{-1}, A^w_1, A^w_2, \ldots)$. Each of the A^w_i is an *adjacency point*.

Each A^w_i is a function $A^w_i : L(W) \cup P \to \mathbb{R}$ which assigns each label in $L(W)$ and each linking property in P a real valued *strength*. For each A^w_i, $\#(A^w_i)$ is the *count* of the adjacency point: the number of times the adjacency point was updated. Based on this count, I also define a normalized version of A^w_i: $\bar{A}^w_i(l) = A^w_i(l)/\#(A^w_i)$.

4.2 The Learning Process

Given a sequence of training utterances $(U_t)_{0 \le t}$, the *learner* constructs a sequence of lexicons $(\mathcal{L}_s)_{0 \le s}$ beginning with the zero lexicon $\mathcal{L}_0$ (which assigns a zero strength to all labels and linking properties). At each step, the learner uses the parsing function $\mathcal{P}_{\mathcal{L}_s}$ based on the previously learned lexicon $\mathcal{L}_s$ to extend the parse L of an utterance U_t. It then uses the result of this parse step (together with the lexicon $\mathcal{L}_s$) to create a new lexicon $\mathcal{L}_{s+1}$ (it may be that $\mathcal{L}_s = \mathcal{L}_{s+1}$). This operation is a *lexicon update*. The process then continues with the new lexicon $\mathcal{L}_{s+1}$. Any of the lexicons $\mathcal{L}_s$ constructed by the learner may be used for parsing any utterance U, but as s increases, parsing accuracy should improve. This learning process is open-ended: additional training text can always be added without having to re-run the learner on previous training data.

4.3 Lexicon Update

To define a lexicon update, I extend the definition of an utterance to be $U = \langle \emptyset_l, x_1, \ldots, x_n, \emptyset_r \rangle$ where $\emptyset_l$ and $\emptyset_r$ are boundary markers. The property of adjacency can now be extended to include the boundary markers. A symbol $\alpha \in U$ is *adjacent* to a word x relative to a set of links L over U if for every word z between x and α there is a path of links in L from x to z but there is no link from z to α. In the following example, the adjacencies of x_1 are $\emptyset_l$, x_2 and x_3:

$$x_1 \text{—}0\text{→} x_2 \qquad x_3 \qquad x_4$$

If a link is added from x_2 to x_3, x_4 becomes adjacent to x_1 instead of x_3 (the adjacencies of x_1 are then $\emptyset_l$, x_2 and x_4):

$$x_1 \text{ —}0\text{→ } x_2 \text{ —}0\text{→ } x_3 \qquad x_4$$

The positions in the utterance adjacent to a word x are indexed by an index i such that $i < 0$ to the left of x, $i > 0$ to the right of x and $|i|$ increases with the distance from x.

The parser may only add a link from a word x to a word y adjacent to x (relative to the set of links already constructed). Therefore, the lexical entry of x should collect statistics about each of the adjacency positions of x. As seen above, adjacency positions may move, so the learner waits until the parser completes parsing the utterance and then updates each adjacency point A_i^x with the symbol α at the ith adjacency position of x (relative to the parse generated by the parser). It should be stressed that this update does not depend on whether a link was created from x to α. In particular, whatever links the parser assigns, $A^x_{(-1)}$ and A^x_1 are always updated by the symbols which appear immediately before and after x.

The following example should clarify the picture. Consider the fragment:

$$\text{put} \text{ —}0\text{→ } \text{the} \rightleftarrows 0 \rightleftarrows \text{box} \qquad \text{on}$$

All the links in this example, including the absence of a link from *box* to *on*, depend on adjacency points of the form $A^x_{(-1)}$ and A^x_1 which are updated independently of any links. Based on this alone and regardless of whether a link is created from *put* to *on*, A_2^{put} will be updated by the word *on*, which is indeed the second argument of the verb *put*.

4.4 Adjacency Point Update

The update of A_i^x by α is given by operations $A_i^x(p)$ += $f(A^\alpha_{(-1)}, A^\alpha_1)$ which make the value of $A_i^x(p)$ in the new lexicon $\mathcal{L}_{s+1}$ equal to the sum $A_i^x(p) + f(A^\alpha_{(-1)}, A^\alpha_1)$ in the old lexicon $\mathcal{L}_s$.

Let $Sign(i)$ be 1 if $0 < i$ and -1 otherwise. Let

$${}_\bullet A_i^\alpha = \begin{cases} true & \text{if } \nexists l \in L(W) : \\ & \quad A_i^\alpha(l) > A_i^\alpha(Stop) \\ false & \text{otherwise} \end{cases}$$

The update of A_i^x by α begins by incrementing the count:

$$\#(A_i^x) \text{ += } 1$$

If α is a boundary symbol ($\emptyset_l$ or $\emptyset_r$) or if x and α are words separated by stopping punctuation (full stop, question mark, exclamation mark, semicolon, comma or dash):

$$A_i^x(Stop) \text{ += } 1$$

Otherwise, for every $l \in L(W)$:

$$A_i^x(l^{-1}) \text{ += } \begin{cases} 1 & \text{if } l = [\alpha] \\ \bar{A}^\alpha_{Sign(-i)}(l) & \text{otherwise} \end{cases}$$

(In practice, only $l = [\alpha]$ and the 10 strongest labels in $A^\alpha_{Sign(-i)}$ are updated. Because of the exponential decay in the strength of labels in $A^\alpha_{Sign(-i)}$, this is a good approximation.)

If $i = -1, 1$ and α is not a boundary or blocked by punctuation, simple bootstrapping takes place by updating the following properties:

$$A_i^x(In^*) \text{ += } \begin{cases} -1 & \text{if } {}_\bullet A^\alpha_{Sign(-i)} \\ +1 & \text{if } \neg {}_\bullet A^\alpha_{Sign(-i)} \wedge {}_\bullet A^\alpha_{Sign(i)} \\ 0 & \text{otherwise} \end{cases}$$

$$A_i^x(Out) \text{ += } \bar{A}^\alpha_{Sign(-i)}(In^*)$$

$$A_i^x(In) \text{ += } \bar{A}^\alpha_{Sign(-i)}(Out)$$

4.5 Discussion

To understand the way the labels and properties are calculated, it is best to look at an example. The following table gives the linking properties and strongest labels for the determiner *the* as learned from the complete Wall Street Journal corpus (only $A^{the}_{(-1)}$ and A^{the}_1 are shown):

the

A_{-1}		A_1

A strong class label $[w]$ indicates that the word w frequently appears in contexts which are similar to *the*. A strong adjacency label $[w\_]$ (or $[\_w]$) indicates

that w either frequently appears next to *the* or that w frequently appears in the same contexts as words which appear next to *the*.

The property $Stop$ counts the number of times a boundary appeared next to *the*. Because *the* can often appear at the beginning of an utterance but must be followed by a noun or an adjective, it is not surprising that $Stop$ is stronger than any label on the left but weaker than all labels on the right. In general, it is unlikely that a word has an outbound link on the side on which its $Stop$ strength is stronger than that of any label. The opposite is not true: a label stronger than $Stop$ indicates an attachment but this may also be the result of an inbound link, as in the following entry for *to*, where the strong labels on the left are a result of an inbound link:

to

A_{-1}		A_1	
$Stop$	822	$Stop$	48
In^*	-4250	In^*	-981
In	-57	In	-1791
Out	-3053	Out	4010
[to]	5912	[to]	7009
[%␣]	848	[␣the]	3851
[in]	844	[␣be]	2208
[the]	813	[will]	1414
[of]	624	[␣a]	1158
[a]	599	[the]	954

For this reason, the learning process is based on the property $\bullet A_i^x$ which indicates where a link is *not possible*. Since an outbound link on one word is inbound on the other, the inbound/outbound properties of each word are then calculated by a simple bootstrapping process as an average of the opposite properties of the neighboring words.

5 The Weight Function

At each step, the parser must assign a non-negative weight to every candidate link $x \xrightarrow{d} y$ which may be added to an utterance prefix $\langle x_1, \ldots, x_k \rangle$, and the link with the largest (non-zero) weight (with a preference for links between x_{k-1} and x_k) is added to the parse. The weight could be assigned directly based on the In and Out properties of either x or y but this method is not satisfactory for three reasons: first, the values of these properties on low frequency words are not reliable; second, the values of the properties on x and y may conflict; third, some words are ambiguous and require different linking in different contexts. To solve these problems, the weight of the link is taken from the values of In and Out on the best matching label between x and y. This label depends on both words and is usually a frequent word with reliable statistics. It serves as a prototype for the relation between x and y.

5.1 Best Matching Label

A label l is a *matching label* between A_i^x and $A^y_{Sign(-i)}$ if $A_i^x(l) > A_i^x(Stop)$ and either $l = (y, 1)$ or $A^y_{Sign(-i)}(l^{-1}) > 0$. The *best matching label* at A_i^x is the matching label l such that the *match strength* $\min(\bar{A}_i^x(l), \bar{A}^y_{Sign(-i)}(l^{-1}))$ is maximal (if $l = (y, 1)$ then $\bar{A}^y_{Sign(-i)}(l^{-1})$ is defined to be 1). In practice, as before, only the top 10 labels in A_i^x and $A^y_{Sign(-i)}$ are considered.

The *best matching label from x to y* is calculated between A_i^x and $A^y_{Sign(-i)}$ such that A_i^x is on the same side of x as y and was either already used to create a link or is the first adjacency point on that side of x which was not yet used. This means that the adjacency points on each side have to be used one by one, but may be used more than once. The reason is that optional arguments of x usually do not have an adjacency point of their own but have the same labels as obligatory arguments of x and can share their adjacency point. The A_i^x with the strongest matching label is selected, with a preference for the unused adjacency point.

As in the learning process, label matching is blocked between words which are separated by stopping punctuation.

5.2 Calculating the Link Weight

The best matching label $l = (w, \delta)$ from x to y can be either a class ($\delta = 0$) or an adjacency ($\delta = 1$) label at A_i^x. If it is a class label, w can be seen as taking the place of x and all words separating it from y (which are already linked to x). If l is an adjacency label, w can be seen to take the place of y. The calculation of the weight $Wt(x \xrightarrow{d} y)$ of the link from x to y is therefore based on the strengths of the In and Out properties of A_σ^w where $\sigma = Sign(i)$ if $l = (w, 0)$ and $\sigma = Sign(-i)$ if $l = (w, 1)$. In addition, the weight is bounded from above by the best label match strength, $s(l)$:

- If $l = (w, 0)$ and $A_\sigma^w(Out) > 0$:

$$Wt(x \xrightarrow{0} y) = \min(s(l), \bar{A}_\sigma^w(Out))$$

Incremental (right to left)	75.9	72.5	74.2	59.3	52.2	55.6	50.4	68.3	58.0	32.9	45.5	38.2

Table 1: Parsing results on WSJ10, WSJ40, Negra10 and Negra40.

- If $l = (w, 1)$:
  - If $A^w_\sigma(In) > 0$:
    $$Wt(x \xrightarrow{d} y) = \min(s(l), \bar{A}^w_\sigma(In))$$
  - Otherwise, if $A^w_\sigma(In^*) \geq |A^w_\sigma(In)|$:
    $$Wt(x \xrightarrow{d} y) = \min(s(l), \bar{A}^w_\sigma(In^*))$$

  where if $A^w_\sigma(In^*) < 0$ and $A^w_\sigma(Out) \leq 0$ then $d = 1$ and otherwise $d = 0$.
- If $A^w_\sigma(Out) \leq 0$ and $A^w_\sigma(In) \leq 0$ and either $l = (w, 1)$ or $A^w_\sigma(Out) = 0$:
  $$Wt(x \xrightarrow{0} y) = s(l)$$
- In all other cases, $Wt(x \xrightarrow{d} y) = 0$.

A link $x \xrightarrow{1} y$ attaches x to y but does not place y inside the smallest bracket covering x. Such links are therefore created in the second case above, when the attachment indication is mixed.

To explain the third case, recall that $s(l) > 0$ means that the label l is stronger than $Stop$ on A^x_i. This implies a link unless the properties of w block it. One way in which w can block the link is to have a positive strength for the link in the opposite direction. Another way in which the properties of w can block the link is if $l = (w, 0)$ and $A^w_\sigma(Out) < 0$, that is, if the learning process has explicitly determined that no outbound link from w (which represents x in this case) is possible. The same conclusion cannot be drawn from a negative value for the In property when $l = (w, 1)$ because, as with standard dependencies, a word determines its outbound links much more strongly than its inbound links.

6 Experiments

The incremental parser was tested on the Wall Street Journal and Negra Corpora.[2] Parsing accuracy was evaluated on the subsets WSJX and Negra$X$ of these corpora containing sentences of length at most X (excluding punctuation). Some of these subsets were used for scoring in (Klein and Manning, 2004; Bod, 2006a; Bod, 2006b). I also use the same precision and recall measures used in those papers: multiple brackets and brackets covering a single word were not counted, but the top bracket was.

The incremental parser learns while parsing, and it could, in principle, simply be evaluated for a single pass of the data. But, because the quality of the parses of the first sentences would be low, I first trained on the full corpus and then measured parsing accuracy on the corpus subset. By training on the full corpus, the procedure differs from that of Klein, Manning and Bod who only train on the subset of bounded length sentences. However, this excludes the induction of parts-of-speech for parsing from plain text. When Klein and Manning induce the parts-of-speech, they do so from a much larger corpus containing the full WSJ treebank together with additional WSJ newswire (Klein and Manning, 2002). The comparison between the algorithms remains, therefore, valid.

Table 1 gives two baselines and the parsing results for WSJ10, WSJ40, Negra10 and Negra40 for recent unsupervised parsing algorithms: CCM

[2] I also tested the incremental parser on the Chinese Treebank version 5.0, achieving an F_1 score of 54.6 on CTB10 and 38.0 on CTB40. Because this version of the treebank is newer and clearly different from that used by previous papers, the results are not comparable and only given here for completeness.

and DMV+CCM (Klein and Manning, 2004), U-DOP (Bod, 2006b) and UML-DOP (Bod, 2006a). The middle part of the table gives results for parsing from part-of-speech sequences extracted from the treebank while the bottom part of the table given results for parsing from plain text. Results for the incremental parser are given for learning and parsing from left to right and from right to left.

The first baseline is the standard right-branching baseline. The second baseline modifies right-branching by using punctuation in the same way as the incremental parser: brackets (except the top one) are not allowed to contain stopping punctuation. It can be seen that punctuation accounts for merely a small part of the incremental parser's improvement over the right-branching heuristic.

Comparing the two algorithms parsing from plain text (of WSJ10), it can be seen that the incremental parser has a somewhat higher combined F_1 score, with better precision but worse recall. This is because Klein and Manning's algorithms (as well as Bod's) always generate binary parse trees, while here no such condition is imposed. The small difference between the recall (76.2) and precision (75.6) of the incremental parser shows that the number of brackets induced by the parser is very close to that of the corpus[3] and that the parser captures the same depth of syntactic structure as that which was used by the corpus annotators.

Incremental parsing from right to left achieves results close to those of parsing from left to right. This shows that the incremental parser has no built-in bias for right branching structures.[4] The slight degradation in performance may suggest that language should not, after all, be processed backwards.

While achieving state of the art accuracy, the algorithm also proved to be fast, parsing (on a 1.86GHz Centrino laptop) at a rate of around 4000 words/sec. and learning (including parsing) at a rate of 3200 – 3600 words/sec. The effect of sentence length on parsing speed is small: the full WSJ corpus was parsed at 3900 words/sec. while WSJ10 was parsed at 4300 words/sec.

[3]The algorithm produced 35588 brackets compared with 35302 brackets in the corpus.

[4]I would like to thank Alexander Clark for suggesting this test.

7 Conclusions

The unsupervised parser I presented here attempts to make use of several universal properties of natural languages: it captures the skewness of syntactic trees in its syntactic representation, restricts the search space by processing utterances incrementally (as humans do) and relies on the Zipfian distribution of words to guide its parsing decisions. It uses an elementary bootstrapping process to deduce the basic properties of the language being parsed. The algorithm seems to successfully capture some of these basic properties, but can be further refined to achieve high quality parsing. The current algorithm is a good starting point for such refinement because it is so very simple.

Acknowledgments I would like to thank Dick de Jongh for many hours of discussion, and Remko Scha, Reut Tsarfaty and Jelle Zuidema for reading and commenting on various versions of this paper.

Abstract

This paper introduces a Maximum Entropy dependency parser based on an efficient k-best Maximum Spanning Tree (MST) algorithm. Although recent work suggests that the edge-factored constraints of the MST algorithm significantly inhibit parsing accuracy, we show that generating the 50-best parses according to an edge-factored model has an oracle performance well above the 1-best performance of the best dependency parsers. This motivates our parsing approach, which is based on reranking the k-best parses generated by an edge-factored model. Oracle parse accuracy results are presented for the edge-factored model and 1-best results for the reranker on eight languages (seven from CoNLL-X and English).

1 Introduction

The Maximum Spanning Tree algorithm[1] was recently introduced as a viable solution for non-projective dependency parsing (McDonald et al., 2005b). The dependency parsing problem is naturally a spanning tree problem; however, efficient spanning-tree optimization algorithms assume a cost function which assigns scores independently to edges of the graph. In dependency parsing, this effectively constrains the set of models to those which independently generate parent-child pairs; these are known as edge-factored models. These models are limited to relatively simple features which exclude *linguistic* constructs such as verb sub-categorization/valency, lexical selectional preferences, etc.[2]

In order to explore a rich set of syntactic features in the MST framework, we can either approximate the optimal non-projective solution as in McDonald and Pereira (2006), or we can use the constrained MST model to select a subset of the set of dependency parses to which we then apply less-constrained models. An efficient algorithm for generating the k-best parse trees for a constituency-based parser was presented in Huang and Chiang (2005); a variation of that algorithm was used for generating projective dependency trees for parsing in Dreyer et al. (2006) and for training in McDonald et al. (2005a). However, prior to this paper, an efficient non-projective k-best MST dependency parser has not been proposed.[3]

In this paper we show that the naïve edge-factored models are effective at selecting sets of parses on which the oracle parse accuracy is high. The oracle parse accuracy for a set of parse trees is the highest accuracy for any individual tree in the set. We show that the 1-best accuracy and oracle accuracy can differ by as much as an absolute 9% when the oracle is computed over a small set generated by edge-factored models ($k = 50$).

[1] In this paper we deal only with MSTs on directed graphs. These are often referred to in the graph-theory literature as Maximum Spanning Arborescences.

[2] Labeled edge-factored models can capture selectional preference; however, the unlabeled models presented here are limited to modeling head-child relationships without predicting the *type* of relationship.

[3] The work of McDonald et al. (2005b) would also benefit from a k-best non-projective parser for training.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 392–399,
Prague, Czech Republic, June 2007.

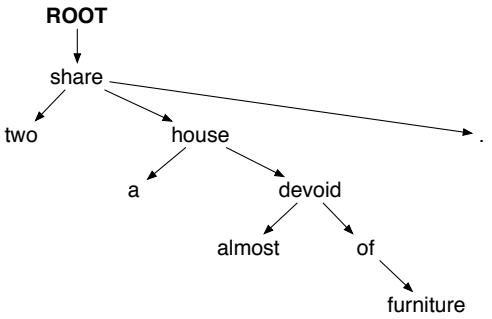

Figure 1: A dependency graph for an English sentence in our development set (Penn WSJ section 24): *Two share a house almost devoid of furniture.*

The combination of two discriminatively trained models, a k-best MST parser and a parse tree reranker, results in an efficient parser that includes complex tree-based features. In the remainder of the paper, we first describe the core of our parser, the k-best MST algorithm. We then introduce the features that we use to compute edge-factored scores as well as tree-based scores. Following, we outline the technical details of our training procedure and finally we present empirical results for the parser on seven languages from the CoNLL-X shared-task and a dependency version of the WSJ Penn Treebank.

2 MST in Dependency Parsing

Work on statistical dependency parsing has utilized either dynamic-programming (DP) algorithms or variants of the Edmonds/Chu-Liu MST algorithm (see Tarjan (1977)). The DP algorithms are generally variants of the CKY bottom-up chart parsing algorithm such as that proposed by Eisner (1996). The Eisner algorithm efficiently ($O(n^3)$) generates projective dependency trees by assembling structures over contiguous words in a clever way to minimize book-keeping. Other DP solutions use constituency-based parsers to produce phrase-structure trees, from which dependency structures are extracted (Collins et al., 1999). A shortcoming of the DP-based approaches is that they are unable to generate non-projective structures. However, non-projectivity is necessary to capture syntactic phenomena in many languages.

McDonald et al. (2005b) introduced a model for dependency parsing based on the Edmonds/Chu-Liu algorithm. The work we present here extends their work by exploring a k-best version of the MST algorithm. In particular, we consider an algorithm proposed by Camerini et al. (1980) which has a worst-case complexity of $O(km\log(n))$, where k is the number of parses we want, n is the number of words in the input sentence, and m is the number of edges in the hypothesis graph. This can be reduced to $O(kn^2)$ in dense graphs[4] by choosing appropriate data structures (Tarjan, 1977). Under the models considered here, all pairs of words are considered as candidate parents (children) of another, resulting in a fully connected graph, thus $m = n^2$.

In order to incorporate second-order features (specifically, sibling features), McDonald et al. proposed a dependency parser based on the Eisner algorithm (McDonald and Pereira, 2006). The second-order features allow for more complex phrasal relationships than the edge-factored features which only include parent/child features. Their algorithm finds the best solution according to the Eisner algorithm and then searches for the single valid edge change that increases the tree score. The algorithm iterates until no better single edge substitution can improve the score of the tree. This greedy approximation allows for second-order constraints and non-projectivity. They found that applying this method to trees generated by the Eisner algorithm using second-order features performs better than applying it to the best tree produced by the MST algorithm with first-order (edge-factored) features.

In this paper we provide a new evaluation of the efficacy of edge-factored models, k-best oracle results. We show that even when k is small, the edge-factored models select k-best sets which contain good parses. Furthermore, these good parses are even better than the parses selected by the best dependency parsers.

2.1 k-best MST Algorithm

The k-best MST algorithm we introduce in this paper is the algorithm described in Camerini et al. (1980). For proofs of complexity and correctness, we defer to the original paper. This section is intended to provide the intuitions behind the algorithm and allow for an understanding of the key data-structures necessary to ensure the theoretical guarantees.

[4] A dense graph is one in which the number of edges is close to the number of edges in a fully connected graph (i.e., n^2).

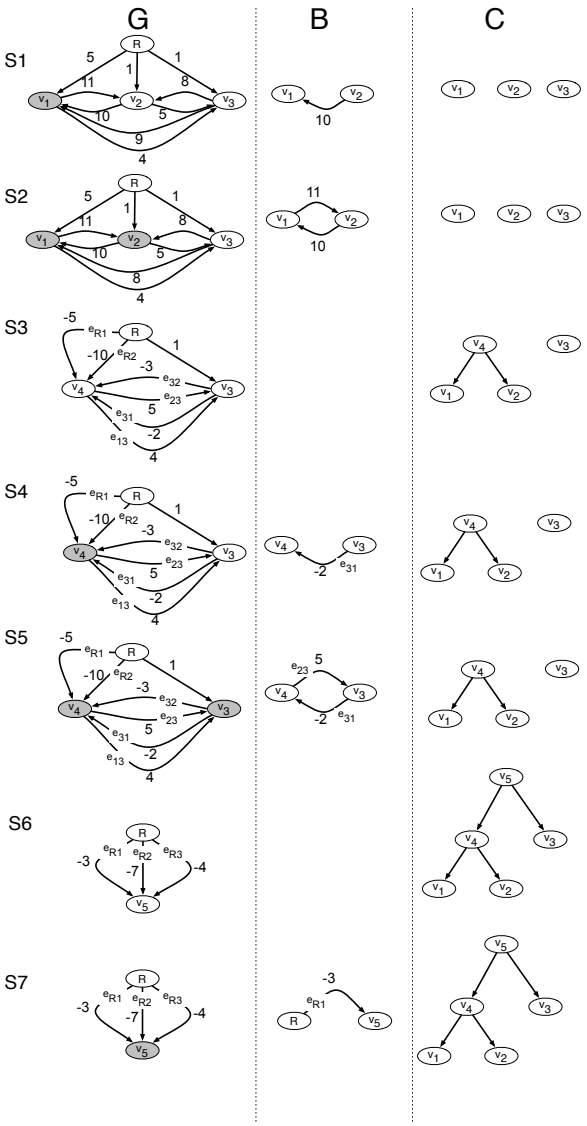

Figure 2: Simulated 1-best MST algorithm.

Let $G = \{V, E\}$ be a directed graph where $V = \{R, v_1, \ldots, v_n\}$ and $E = \{e_{11}, e_{12}, \ldots, e_{1n}, e_{21}, \ldots, e_{nn}\}$. We refer to edge e_{ij} as the edge that is directed from v_i into v_j in the graph. The initial dependency graph in Figure 2 (column **G**) contains three regular nodes and a root node.

Algorithm 1 is a version of the MST algorithm as presented by Camerini et al. (1980); subtleties of the algorithm have been omitted. Arguments Y (a branching[5]) and Z (a set of edges) are constraints on the edges that can be part of the solution, A. Edges in Y are required to be in the solution and edges in

[5]A branching is a subgraph that contains no cycles and no more than one edge directed into each node.

Algorithm 1 Sketch of 1-best MST algorithm

```
procedure BEST(G, Y, Z)
    G = (G ∪ Y) − Z
    B = ∅
    C = V
 5: for unvisited vertex v_i ∈ V do
        mark v_i as visited
        get best in-edge b ∈ {e_jk : k = i} for v_i
        B = B ∪ b
        β(v_i) = b
10:     if B contains a cycle C then
            create a new node v_{n+1}
            C = C ∪ v_{n+1}
            make all nodes of C children of v_{n+1} in C
            COLLAPSE all nodes of C into v_{n+1}
15:         ADD v_{n+1} to list of unvisited vertices
            n = n + 1
            B = B − C
        end if
    end for
20: EXPAND C choosing best way to break cycles
    Return best A = {b ∈ E|∃v ∈ V : β(v) = b}
      and C
end procedure
```

Z cannot be part of the solution. The branching C stores a hierarchical history of cycle collapses, encapsulating embedded cycles and allowing for an *expanding* procedure, which breaks cycles while maintaining an optimal solution.

Figure 2 presents a view of the algorithm when run on a three node graphs (plus a specified root node). Steps S1, S2, S4, and S5 depict the processing of lines 5 to 8, recording in β the best input edges for each vertex. Steps S3 and S6 show the process of *collapsing* a cycle into a new node (lines 10 to 16).

The main loop of the algorithm processes each vertex that has not yet been visited. We look up the best incoming edge (which is stored in a priority-queue). This value is recorded in β and the edge is added to the current *best* graph B. We then check to see if adding this new edge would create a cycle in B. If so, we create a new node and *collapse* the cycle into it. This can be seen in Step S3 in Figure 2.

The process of collapsing a cycle into a node involves removing the edges in the cycle from B, and adjusting the weights of all edges directed into any node in the cycle. The weights are adjusted so that they reflect the relative difference of choosing the new in-edge rather than the edge in the cycle. In step S3, observe that edge e_{R1} had a weight of 5, but now that it points into the new node v_4, we subtract the weight of the edge e_{21} that also pointed into v_1,

which was 10. Additionally, we record in C the relationship between the new node v_4 and the original nodes v_1 and v_2.

This process continues until we have visited all original and newly created nodes. At that point, we *expand* the cycles encoded in C. For each node not originally in G (e.g., v_5, v_4), we retrieve the edge e_r pointing into this node, recorded in β. We identify the node v_s to which e_r pointed in the original graph G and set $\beta(v_s) = e_r$.

Algorithm 2 Sketch of next-best MST algorithm

```
    procedure NEXT(G, Y, Z, A, C)
        δ ← +∞
        for unvisited vertex v do
            get best in-edge b for v
 5:         if b ∈ A − Y then
                f ← alternate edge into v
                if swapping f with b results in smaller δ then
                    update δ, let e ← f
                end if
10:         end if
            if b forms a cycle then
                Resolve as in 1-best
            end if
        end for
15:     Return edge e and δ
    end procedure
```

Algorithm 2 returns the single edge, e, of the 1-best solution A that, when removed from the graph, results in a graph for which the best solution is the next best solution after A. Additionally, it returns δ, the difference in score between A and the next best tree. The branching C is passed in from Algorithm 1 and is used here to efficiently identify alternate edges, f, for edge e.

Y and Z in Algorithms 1 and 2 are used to construct the next best solutions efficiently. We call $G_{Y,Z}$ a constrained graph; the constraints being that Y restricts the in-edges for a subset of nodes: for each vertex with an in-edge in Y, only the edge of Y can be an in-edge of the vertex. Also, edges in Z are removed from the graph. A constrained spanning tree for $G_{Y,Z}$ (a tree covering all nodes in the graph) must satisfy: $Y \subseteq A \subseteq E - Z$.

Let A be the (constrained) solution to a (constrained) graph and let e be the edge that leads to the next best solution. The third-best solution is either the second-best solution to $G_{Y,\{Z \cup e\}}$ or the second-best solution to $G_{\{Y \cup e\},Z}$. The k-best ranking algorithm uses this fact to incrementally partition the solution space: for each solution, the next best either will include e or will not include e.

Algorithm 3 k-best MST ranking algorithm

```
    procedure RANK(G, k)
        A, C ← best(E, V, ∅, ∅)
        (e, δ) ← next(E, V, ∅, ∅, A, C)
        bestList ← A
 5:     Q ← enqueue(s(A) − δ, e, A, C, ∅, ∅)
        for j ← 2 to k do
            (s, e, A, C, Y, Z) = dequeue(Q)
            Y′ = Y ∪ e
            Z′ = Z ∪ e
10:         A′, C′ ← best(E, V, Y, Z′)
            bestList ← A′
            e′, δ′ ← next(E, V, Y′, Z, A′, C′)
            Q ← enqueue(s(A) − δ′, e′, A′, C′, Y′, Z)
            e′, δ′ ← next(E, V, Y, Z′, A′, C′)
15:         Q ← enqueue(s(A) − δ′, e′, A′, C′, Y, Z′)
        end for
        Return bestList
    end procedure
```

The k-best ranking procedure described in Algorithm 3 uses a priority queue, Q, keyed on the first parameter to $enqueue$ to keep track of the horizon of next best solutions. The function $s(A)$ returns the score associated with the tree A. Note that in each iteration there are two new elements enqueued representing the sets $G_{Y,\{Z \cup e\}}$ and $G_{\{Y \cup e\},Z}$.

Both Algorithms 1 and 2 run in $O(m \log(n))$ time and can run in quadratic time for dense graphs with the use of an efficient priority-queue[6] (i.e., based on a Fibonacci heap). Algorithm 3 runs in constant time, resulting in an $O(km \log n)$ algorithm (or $O(kn^2)$ for dense graphs).

3 Dependency Models

Each of the two stages of our parser is based on a discriminative training procedure. The edge-factored model is based on a conditional log-linear model trained using the Maximum Entropy constraints.

3.1 Edge-factored MST Model

One way in which dependency parsing differs from constituency parsing is that there is a fixed amount of structure in every tree. A dependency tree for a sentence of n words has exactly n edges,[7] each repre-

[6] Each vertex keeps a priority queue of candidate parents. When a cycles is collapsed, the new vertex inherits the union of queues associated with the vertices of the cycle.

[7] We assume each tree has a *root* node.

senting a *syntactic* or *semantic* relationship, depending on the linguistic model assumed for annotation. A spanning tree (equivalently, a dependency parse) is a subgraph for which each node has one in-edge, the root node has zero in-edges, and there are no cycles.

Edge-factored features are defined over the edge and the input sentence. For each of the n^2 parent/child pairs, we extract the following features:

Node-type There are three basic node-type features: word *form*, morphologically reduced *lemma*, and part-of-speech (*POS*) tag. The CoNLL-X data format[8] describes two part-of-speech tag types, we found that features derived from the coarse tags are more reliable. We consider both unigram (parent or child) and bigram (composite parent/child) features. We refer to parent features with the prefix p- and child feature with the prefix c-; for example: p–pos, p–form, c–pos, and c–form. In our model we use both word form and POS tag and include the composite form/POS features: p–form/c–pos and p–pos/c–form.

Branch A binary feature which indicates whether the child is to the left or right of the parent in the input string. Additionally, we provide composite features p–pos/branch and p–pos/c–pos/branch.

Distance The number of words occurring between the parent and child word. These distances are bucketed into 7 buckets (1 through 6 plus an additional single bucket for distances greater than 6). Additionally, this feature is combined with node-type features: p–pos/dist, c–pos/dist, p–pos/c–pos/dist.

Inside POS tags of the words between the parent and child. A count of each tag that occurs is recorded, the feature is identified by the tag and the feature value is defined by the count. Additional composite features are included combining the inside and node-type: for each type t_i the composite features are: p–pos/t_i, c–pos/t_i, p–pos/c–pos/t_i.

Outside Exactly the same as the **Inside** feature except that it is defined over the features to the left and right of the span covered by this parent-child pair.

Extra-Feats Attribute-value pairs from the CoNLL *FEATS* field including combinations with parent/child node-types. These features represent word-level annotations provided in the treebank and include morphological and lexical-semantic features. These do not exist in the English data.

Inside Edge Similar to *Inside* features, but only includes nodes immediately to left and right within the span covered by the parent/child pair. We include the following features where i^l and i^r are the inside left and right POS tags and i^p is the inside POS tag closest to the parent: i^l/i^r, p–pos/i^p, p–pos/i^l/i^r/c–pos,

Outside Edge An *Outside* version of the *Inside Edge* feature type.

Many of the features above were introduced in McDonald et al. (2005a); specifically, the *node-type*, *inside*, and *edge* features. The number of features can grow quite large when form or lemma features are included. In order to handle large training sets with a large number of features we introduce a bagging-based approach, described in Section 4.2.

3.2 Tree-based Reranking Model

The second stage of our dependency parser is a reranker that operates on the output of the k-best MST parser. Features in this model are not constrained as in the edge-factored model. Many of the model features have been inspired by the constituency-based features presented in Charniak and Johnson (2005). We have also included features that exploit non-projectivity where possible. The node-type is the same as defined for the MST model.

MST score The score of this parse given by the first-stage MST model.

Sibling The POS-tag of immediate siblings. Intended to capture the preference for particular immediate siblings such as modifiers.

Valency Count of the number of children for each word (indexed by POS-tag of the word). These

[8] The 2006 CoNLL-X data format can be found on-line at: `http://nextens.uvt.nl/~conll/`.

counts are bucketed into 4 buckets. For example, a feature may look like p–pos=VB/v=4, meaning the POS tag of the parent is 'VB' and it had 4 dependents.

Sub-categorization A string representing the sequence of child POS tags for each parent POS-tag.

Ancestor Grandparent and great grandparent POS-tag for each word. Composite features are generated with the label c–pos/p–pos/gp–pos and c–pos/p–pos/ggp–pos (where gp is the grand-parent and ggp is the great grand-parent).

Edge POS-tag to the left and right of the subtree, both inside and outside the subtree. For example, say a subtree with parent POS-tag p–pos spans from i to j, we include composite *outside* features: p–pos/n_{i-1}–pos/n_{j+1}–pos, p–pos/n_{i-1}–pos, p–pos/n_{j+1}–pos; and composite inside features: p–pos/n_{i+1}–pos/n_{j-1}–pos, p–pos/n_{i+1}–pos, p–pos/n_{j-1}–pos.

Branching Factor Average number of left/right branching nodes per POS-tag. Additionally, we include a boolean feature indicating the overall left/right preference.

Depth Depth of the tree and depth normalized by sentence length.

Heavy Number of dominated nodes per POS-tag. We also include the average number of nodes dominated by each POS-tag.

4 MaxEnt Training

We have adopted the conditional Maximum Entropy (MaxEnt) modeling paradigm as outlined in Charniak and Johnson (2005) and Riezler et al. (2002). We can partition the training examples into independent subsets, Y_s: for the edge-factored MST models, each set represents a word and its candidate parents; for the reranker, each set represents the k-best trees for a particular sentence. We wish to estimate the conditional distribution over hypotheses in the set y_i, given the set: $p(y_i|Y_s) = \frac{\exp(\sum_k \lambda_k f_{ik})}{\sum_{j:y_j \in Y_s} \exp(\sum_{k'} \lambda k' f_{jk'})}$, where f_{ik} is the k^{th} feature function in the model for example y_i.

4.1 MST Training

Our MST parser training procedure involves enumerating the n^2 potential tree edges (parent/child pairs). Unlike the training procedure employed by McDonald et al. (2005b) and McDonald and Pereira (2006), we provide positive and negative examples in the training data. A node can have at most one parent, providing a natural split of the n^2 training examples. For each node n_i, we wish to estimate a distribution over n nodes[9] as potential parents, $p(v_i, e_{ji}|e_{\_i})$, the probability of the correct parent of v_i being v_j given the set of edges associated with its candidate parents $e_{\_i}$. We call this the parent-prediction model.

4.2 MST Bagging

The complexity of the training procedure is a function of the number of features and the number of examples. For large datasets, we use an ensemble technique inspired by *Bagging* (Breiman, 1996). Bagging is generally used to mitigate high variance in datasets by sampling, with replacement, from the training set. Given that we wish to include some of the less frequent examples and therefore are not necessarily avoiding high variance, we partition the data into disjoint sets.

For each of the sets, we train a model independently. Furthermore, we only allow the parameters to be changed for those features observed in the training set. At inference time, we apply each model to the training data and then combine the prediction probabilities.

$$\tilde{p}_\theta(y_i|Y_s) = \max_m p_{\theta_m}(y_i|Y_s) \quad (1)$$

$$\tilde{p}_\theta(y_i|Y_s) = \frac{1}{M}\sum_m p_{\theta_m}(y_i|Y_s) \quad (2)$$

$$\tilde{p}_\theta(y_i|Y_s) = \left(\prod_m p_{\theta_m}(y_i|Y_s)\right)^{1/M} \quad (3)$$

$$\tilde{p}_\theta(y_i|Y_s) = \frac{M}{\sum_m \frac{1}{p_{\theta_m}(y_i|Y_s)}} \quad (4)$$

Equations 1, 2, 3, and 4 are the maximum, average, geometric mean, and harmonic mean, respectively. We performed an exploration of these on the

[9] Recall that in addition to the $n-1$ other nodes in the graph, there is a root node for which we know has no parents.

development data and found that the geometric mean produces the best results (Equation 3); however, we observed only very small differences in the accuracy among models where only the combination function differed.

4.3 Reranker Training

The second stage of parsing is performed by our tree-based reranker. The input to the reranker is a list of k parses generated by the k-best MST parser. For each input sentence, the hypothesis set is the k parses. At inference time, predictions are made independently for each hypothesis set Y_s and therefore the normalization factor can be ignored.

5 Empirical Evaluation

The CoNLL-X shared task on dependency parsing provided data for a number of languages in a common data format. We have selected seven of these languages for which the data is available to us. Additionally, we have automatically generated a dependency version of the Penn WSJ treebank.[10] As we are only interested in the structural component of a parse in this paper, we present results for unlabeled dependency parsing. A second labeling stage can be applied to get labeled dependency structures as described in (McDonald et al., 2006).

In Table 1 we report the accuracy for seven of the CoNLL languages and English.[11] Already, at $k = 50$, we see the oracle rate climb as much as 9.25% over the 1-best result (Dutch). Continuing to increase the size of the k-best lists adds to the oracle accuracy, but the relative improvement appears to be increasing at a logarithmic rate. The k-best parser is used both to train the k-best reranker and, at inference time, to select a set of hypotheses to rerank. It is not necessary that training is done with the same size hypothesis set as test, we explore the matched and mismatched conditions in our reranking experiments.

[10]The Penn WSJ treebank was converted using the conversion program described in (Johansson and Nugues, 2007) and available on the web at: `http://nlp.cs.lth.se/pennconverter/`

[11]The **Best Reported** results is from the CoNLL-X competition. The best result reported for English is the Charniak parser (without reranking) on Section 23 of the WSJ Treebank using the same head-finding rules as for the evaluation data.

Table 2 shows the reranking results for the set of languages. For each language, we select model parameters on a development set prior to running on the test data. These parameters include a feature count threshold (the minimum number of observations of a feature before it is included in a model) and a mixture weight controlling the contribution of a quadratic regularizer (used in MaxEnt training). For Czech, German, and English, we use the MST bagging technique with 10 bags. These test results are for the models which performed best on the development set (using 50-best parses).

We see minor improvements over the 1-best baseline MST output (repeated in this table for comparison). We believe this is due to the overwhelming number of parameters in the reranking models and the relatively small amount of training data. Interestingly, increasing the number of hypotheses helps for some languages and hurts the others.

6 Conclusion

Although the edge-factored constraints of MST parsers inhibit accuracy in 1-best parsing, edge-factored models are effective at selecting high accuracy k-best sets. We have introduced the Camerini et al. (1980) k-best MST algorithm and have shown how to efficiently train MaxEnt models for dependency parsing. Additionally, we presented a unified modeling and training setting for our two-stage parser; MaxEnt training is used to estimate the parameters in both models. We have introduced a particular ensemble technique to accommodate the large training sets generated by the first-stage edge-factored modeling paradigm. Finally, we have presented a reranker which attempts to select the best tree from the k-best set. In future work we wish to explore more robust feature sets and experiment with feature selection techniques to accommodate them.

Is the End of Supervised Parsing in Sight?

Rens Bod

Abstract

How far can we get with unsupervised parsing if we make our training corpus several orders of magnitude larger than has hitherto be attempted? We present a new algorithm for unsupervised parsing using an all-subtrees model, termed U-DOP*, which parses directly with packed forests of all binary trees. We train both on Penn's WSJ data and on the (much larger) NANC corpus, showing that U-DOP* outperforms a treebank-PCFG on the standard WSJ test set. While U-DOP* performs worse than state-of-the-art supervised parsers on hand-annotated sentences, we show that the model outperforms supervised parsers when evaluated as a language model in syntax-based machine translation on Europarl. We argue that supervised parsers miss the fluidity between constituents and non-constituents and that in the field of syntax-based language modeling the end of supervised parsing has come in sight.

1 Introduction

A major challenge in natural language parsing is the unsupervised induction of syntactic structure. While most parsing methods are currently supervised or semi-supervised (McClosky et al. 2006; Henderson 2004; Steedman et al. 2003), they depend on hand-annotated data which are difficult to come by and which exist only for a few languages. Unsupervised parsing methods are becoming increasingly important since they operate with raw, unlabeled data of which unlimited quantities are available.

There has been a resurgence of interest in unsupervised parsing during the last few years. Where van Zaanen (2000) and Clark (2001) induced unlabeled phrase structure for small domains like the ATIS, obtaining around 40% unlabeled f-score, Klein and Manning (2002) report 71.1% f-score on Penn WSJ part-of-speech strings ≤ 10 words (WSJ10) using a constituent-context model called CCM. Klein and Manning (2004) further show that a hybrid approach which combines constituency and dependency models, yields 77.6% f-score on WSJ10.

While Klein and Manning's approach may be described as an "all-substrings" approach to unsupervised parsing, an even richer model consists of an "all-subtrees" approach to unsupervised parsing, called U-DOP (Bod 2006). U-DOP initially assigns all unlabeled binary trees to a training set, efficiently stored in a packed forest, and next trains subtrees thereof on a held-out corpus, either by taking their relative frequencies, or by iteratively training the subtree parameters using the EM algorithm (referred to as "UML-DOP"). The main advantage of an all-subtrees approach seems to be the direct inclusion of *discontiguous* context that is not captured by (linear) substrings. Discontiguous context is important not only for learning structural dependencies but also for learning a variety of non-contiguous constructions such as *nearest … to…* or *take … by surprise*. Bod (2006) reports 82.9% unlabeled f-score on the same WSJ10 as used by Klein and Manning (2002, 2004). Unfortunately, his experiments heavily depend on a priori sampling of subtrees, and the model becomes highly inefficient if larger corpora are used or longer sentences are included.

In this paper we will also test an alternative model for unsupervised all-subtrees

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 400–407,
Prague, Czech Republic, June 2007.

parsing, termed U-DOP*, which is based on the DOP* estimator by Zollmann and Sima'an (2005), and which computes the shortest derivations for sentences from a held-out corpus using all subtrees from all trees from an extraction corpus. While we do not achieve as high an f-score as the UML-DOP model in Bod (2006), we will show that U-DOP* can operate without subtree sampling, and that the model can be trained on corpora that are two orders of magnitude larger than in Bod (2006). We will extend our experiments to 4 million sentences from the NANC corpus (Graff 1995), showing that an f-score of 70.7% can be obtained on the standard Penn WSJ test set by means of unsupervised parsing. Moreover, U-DOP* can be directly put to use in bootstrapping structures for concrete applications such as syntax-based machine translation and speech recognition. We show that U-DOP* outperforms the supervised DOP model if tested on the German-English Europarl corpus in a syntax-based MT system.

In the following, we first explain the DOP* estimator and discuss how it can be extended to unsupervised parsing. In section 3, we discuss how a PCFG reduction for supervised DOP can be applied to packed parse forests. In section 4, we will go into an experimental evaluation of U-DOP* on annotated corpora, while in section 5 we will evaluate U-DOP* on unlabeled corpora in an MT application.

2 From DOP* to U-DOP*

DOP* is a modification of the DOP model in Bod (1998) that results in a statistically consistent estimator and in an efficient training procedure (Zollmann and Sima'an 2005). DOP* uses the all-subtrees idea from DOP: given a treebank, take all subtrees, regardless of size, to form a stochastic tree-substitution grammar (STSG). Since a parse tree of a sentence may be generated by several (leftmost) derivations, the probability of a tree is the sum of the probabilities of the derivations producing that tree. The probability of a derivation is the product of the subtree probabilities. The original DOP model in Bod (1998) takes the occurrence frequencies of the subtrees in the trees normalized by their root frequencies as subtree parameters. While efficient algorithms have been developed for this DOP model by converting it into a PCFG reduction (Goodman 2003), DOP's estimator was shown to be inconsistent by Johnson (2002). That is, even with unlimited training data, DOP's estimator is not guaranteed to converge to the correct distribution.

Zollmann and Sima'an (2005) developed a statistically consistent estimator for DOP which is based on the assumption that maximizing the joint probability of the parses in a treebank can be approximated by maximizing the joint probability of their shortest derivations (i.e. the derivations consisting of the fewest subtrees). This assumption is in consonance with the principle of simplicity, but there are also empirical reasons for the shortest derivation assumption: in Bod (2003) and Hearne and Way (2006), it is shown that DOP models that select the preferred parse of a test sentence using the shortest derivation criterion perform very well.

On the basis of this shortest-derivation assumption, Zollmann and Sima'an come up with a model that uses held-out estimation: the training corpus is randomly split into two parts proportional to a fixed ratio: an *extraction corpus* EC and a *held-out* corpus HC. Applied to DOP, held-out estimation would mean to extract fragments from the trees in EC and to assign their weights such that the likelihood of HC is maximized. If we combine their estimation method with Goodman's reduction of DOP, Zollman and Sima'an's procedure operates as follows:

(1) Divide a treebank into an EC and HC
(2) Convert the subtrees from EC into a PCFG reduction
(3) Compute the shortest derivations for the sentences in HC (by simply assigning each subtree equal weight and applying Viterbi 1-best)
(4) From those shortest derivations, extract the subtrees and their relative frequencies in HC to form an STSG

Zollmann and Sima'an show that the resulting estimator is consistent. But equally important is the fact that this new DOP* model does not suffer from a decrease in parse accuracy if larger subtrees are included, whereas the original DOP model needs to be redressed by a correction factor to maintain this property (Bod 2003). Moreover, DOP*'s estimation procedure is very efficient, while the EM training procedure for UML-DOP

proposed in Bod (2006) is particularly time consuming and can only operate by randomly sampling trees.

Given the advantages of DOP*, we will generalize this model in the current paper to *unsupervised* parsing. We will use the same all-subtrees methodology as in Bod (2006), but now by applying the efficient and consistent DOP*-based estimator. The resulting model, which we will call U-DOP*, roughly operates as follows:

(1) Divide a corpus into an EC and HC
(2) Assign all unlabeled binary trees to the sentences in EC, and store them in a shared parse forest
(3) Convert the subtrees from the parse forests into a compact PCFG reduction (see next section)
(4) Compute the shortest derivations for the sentences in HC (as in DOP*)
(5) From those shortest derivations, extract the subtrees and their relative frequencies in HC to form an STSG
(6) Use the STSG to compute the most probable parse trees for new test data by means of Viterbi *n*-best (see next section)

We will use this U-DOP* model to investigate our main research question: *how far can we get with unsupervised parsing if we make our training corpus several orders of magnitude larger than has hitherto be attempted?*

3 Converting shared parse forests into PCFG reductions

The main computational problem is how to deal with the immense number of subtrees in U-DOP*. There exists already an efficient *supervised* algorithm that parses a sentence by means of all subtrees from a treebank. This algorithm was extensively described in Goodman (2003) and converts a DOP-based STSG into a compact PCFG reduction that generates eight rules for each node in the treebank. The reduction is based on the following idea: every node in every treebank tree is assigned a unique number which is called its address. The notation $A@k$ denotes the node at address k where A is the nonterminal labeling that node. A new nonterminal is created for each node in the training data. This nonterminal is called A_k. Let a_j represent the number of subtrees headed by the node $A@j$, and let a represent the number of subtrees headed by nodes with nonterminal A, that is $a = \Sigma_j\ a_j$. Then there is a PCFG with the following property: for every subtree in the training corpus headed by A, the grammar will generate an isomorphic subderivation. For example, for a node $(A@j\ (B@k,\ C@l))$, the following eight PCFG rules in figure 1 are generated, where the number following a rule is its weight.

$A_j \rightarrow BC$	$(1/a_j)$	$A \rightarrow BC$	$(1/a)$
$A_j \rightarrow B_kC$	(b_k/a_j)	$A \rightarrow B_kC$	(b_k/a)
$A_j \rightarrow BC_l$	(c_l/a_j)	$A \rightarrow BC_l$	(c_l/a)
$A_j \rightarrow B_kC_l$	(b_kc_l/a_j)	$A \rightarrow B_kC_l$	(b_kc_l/a)

Figure 1. PCFG reduction of supervised DOP

By simple induction it can be shown that this construction produces PCFG derivations isomorphic to DOP derivations (Goodman 2003: 130-133). The PCFG reduction is linear in the number of nodes in the corpus.

While Goodman's reduction method was developed for supervised DOP where each training sentence is annotated with exactly one tree, the method can be generalized to a corpus where each sentence is annotated with all possible binary trees (labeled with the generalized category X), as long as we represent these trees by a shared parse forest. A shared parse forest can be obtained by adding pointers from each node in the chart (or tabular diagram) to the nodes that caused it to be placed in the chart. Such a forest can be represented in cubic space and time (see Billot and Lang 1989). Then, instead of assigning a unique address to each node in each tree, as done by the PCFG reduction for supervised DOP, we now assign a unique address to each node in each parse forest for each sentence. However, the same node may be part of more than one tree. A shared parse forest is an AND-OR graph where AND-nodes correspond to the usual parse tree nodes, while OR-nodes correspond to distinct subtrees occurring in the same context. The total number of nodes is cubic in sentence length n. This means that there are $O(n^3)$ many nodes that receive a unique address as described above, to which next our PCFG reduction is applied. This is a huge reduction compared to Bod (2006) where

the number of subtrees of all trees increases with the Catalan number, and only ad hoc sampling could make the method work.

Since U-DOP* computes the shortest derivations (in the training phase) by combining subtrees from unlabeled binary trees, the PCFG reduction in figure 1 can be represented as in figure 2, where *X* refers to the generalized category while *B* and *C* either refer to part-of-speech categories or are equivalent to *X*. The equal weights follow from the fact that the shortest derivation is equivalent to the most probable derivation if all subtrees are assigned equal probability (see Bod 2000; Goodman 2003).

$X_j \rightarrow BC$	1	$X \rightarrow BC$	0.5
$X_j \rightarrow B_kC$	1	$X \rightarrow B_kC$	0.5
$X_j \rightarrow BC_l$	1	$X \rightarrow BC_l$	0.5
$X_j \rightarrow B_kC_l$	1	$X \rightarrow B_kC_l$	0.5

Figure 2. PCFG reduction for U-DOP*

Once we have parsed HC with the shortest derivations by the PCFG reduction in figure 2, we extract the subtrees from HC to form an STSG. The number of subtrees in the shortest derivations is linear in the number of nodes (see Zollmann and Sima'an 2005, theorem 5.2). This means that U-DOP* results in an STSG which is much more succinct than previous DOP-based STSGs. Moreover, as in Bod (1998, 2000), we use an extension of Good-Turing to smooth the subtrees and to deal with 'unknown' subtrees.

Note that the direct conversion of parse forests into a PCFG reduction also allows us to efficiently implement the maximum likelihood extension of U-DOP known as UML-DOP (Bod 2006). This can be accomplished by training the PCFG reduction on the held-out corpus HC by means of the expectation-maximization algorithm, where the weights in figure 1 are taken as initial parameters. Both U-DOP*'s and UML-DOP's estimators are known to be statistically consistent. But while U-DOP*'s training phase merely consists of the computation of the shortest derivations and the extraction of subtrees, UML-DOP involves iterative training of the parameters.

Once we have extracted the STSG, we compute the most probable parse for new sentences by Viterbi *n*-best, summing up the probabilities of derivations resulting in the same tree (the exact computation of the most probable parse is NP hard – see Sima'an 1996). We have incorporated the technique by Huang and Chiang (2005) into our implementation which allows for efficient Viterbi *n*-best parsing.

4 Evaluation on hand-annotated corpora

To evaluate U-DOP* against UML-DOP and other unsupervised parsing models, we started out with three corpora that are also used in Klein and Manning (2002, 2004) and Bod (2006): Penn's WSJ10 which contains 7422 sentences ≤ 10 words after removing empty elements and punctuation, the German NEGRA10 corpus and the Chinese Treebank CTB10 both containing 2200+ sentences ≤ 10 words after removing punctuation. As with most other unsupervised parsing models, we train and test on p-o-s strings rather than on word strings. The extension to word strings is straightforward as there exist highly accurate unsupervised part-of-speech taggers (e.g. Schütze 1995) which can be directly combined with unsupervised parsers, but for the moment we will stick to p-o-s strings (we will come back to word strings in section 5). Each corpus was divided into 10 training/test set splits of 90%/10% (*n*-fold testing), and each training set was randomly divided into two equal parts, that serve as EC and HC and vice versa. We used the same evaluation metrics for unlabeled precision (UP) and unlabeled recall (UR) as in Klein and Manning (2002, 2004). The two metrics of UP and UR are combined by the unlabeled f-score F1 = 2*UP*UR/(UP+UR). All trees in the test set were binarized beforehand, in the same way as in Bod (2006).

For UML-DOP the decrease in cross-entropy became negligible after maximally 18 iterations. The training for U-DOP* consisted in the computation of the shortest derivations for the HC from which the subtrees and their relative frequencies were extracted. We used the technique in Bod (1998, 2000) to include 'unknown' subtrees. Table 1 shows the f-scores for U-DOP* and UML-DOP against the f-scores for U-DOP reported in Bod (2006), the CCM model in Klein and Manning (2002), the DMV dependency model in Klein and Manning (2004) and their combined model DMV+CCM.

Model	English (WSJ10)	German (NEGRA10)	Chinese (CTB10)
CCM	71.9	61.6	45.0
DMV	52.1	49.5	46.7
DMV+CCM	77.6	63.9	43.3
U-DOP	78.5	65.4	46.6
U-DOP*	77.9	63.8	42.8
UML-DOP	79.4	65.2	45.0

Table 1. F-scores of U-DOP* and UML-DOP compared to other models on the same data.

It should be kept in mind that an exact comparison can only be made between U-DOP* and UML-DOP in table 1, since these two models were tested on 90%/10% splits, while the other models were applied to the full WSJ10, NEGRA10 and CTB10 corpora. Table 1 shows that U-DOP* performs worse than UML-DOP in all cases, although the differences are small and was statistically significant only for WSJ10 using paired *t*-testing.

As explained above, the main advantage of U-DOP* over UML-DOP is that it works with a more succinct grammar extracted from the shortest derivations of HC. Table 2 shows the size of the grammar (number of rules or subtrees) of the two models for resp. Penn WSJ10, the entire Penn WSJ and the first 2 million sentences from the NANC (North American News Text) corpus which contains a total of approximately 24 million sentences from different news sources.

Model	Size of STSG for WSJ10	Size of STSG for Penn WSJ	Size of STSG for 2,000K NANC
U-DOP*	2.2×10^4	9.8×10^5	7.2×10^6
UML-DOP	1.5×10^6	8.1×10^7	5.8×10^9

Table 2. Grammar size of U-DOP* and UML-DOP for WSJ10 (7,7K sentences), WSJ (50K sentences) and the first 2,000K sentences from NANC.

Note that while U-DOP* is about 2 orders of magnitudes smaller than UML-DOP for the WSJ10, it is almost 3 orders of magnitudes smaller for the first 2 million sentences of the NANC corpus. Thus even if U-DOP* does not give the highest f-score in table 1, it is more apt to be trained on larger data sets. In fact, a well-known advantage of unsupervised methods over supervised methods is the availability of almost unlimited amounts of text. Table 2 indicates that U-DOP*'s grammar is still of manageable size even for text corpora that are (almost) two orders of magnitude larger than Penn's WSJ. The NANC corpus contains approximately 2 million WSJ sentences that do not overlap with Penn's WSJ and has been previously used by McClosky et al. (2006) in improving a supervised parser by self-training. In our experiments below we will start by mixing subsets from the NANC's WSJ data with Penn's WSJ data. Next, we will do the same with 2 million sentences from the LA Times in the NANC corpus, and finally we will mix all data together for inducing a U-DOP* model. From Penn's WSJ, we only use sections 2 to 21 for training (just as in supervised parsing) and section 23 (≤100 words) for testing, so as to compare our unsupervised results with some binarized supervised parsers.

The NANC data was first split into sentences by means of a simple discriminitive model. It was next p-o-s tagged with the the TnT tagger (Brants 2000) which was trained on the Penn Treebank such that the same tag set was used. Next, we added subsets of increasing size from the NANC p-o-s strings to the 40,000 Penn WSJ p-o-s strings. Each time the resulting corpus was split into two halfs and the shortest derivations were computed for one half by using the PCFG-reduction from the other half and vice versa. The resulting trees were used for extracting an STSG which in turn was used to parse section 23 of Penn's WSJ. Table 3 shows the results.

# sentences added	f-score by adding WSJ data	f-score by adding LA Times data
0 (baseline)	62.2	62.2
100k	64.7	63.0
250k	66.2	63.8
500k	67.9	64.1
1,000k	68.5	64.6
2,000k	69.0	64.9

Table 3. Results of U-DOP* on section 23 from Penn's WSJ by adding sentences from NANC's WSJ and NANC's LA Times

Table 3 indicates that there is a monotonous increase in f-score on the WSJ test set if NANC text is added to our training data in both cases, independent of whether the sentences come from the WSJ domain or the LA Times domain. Although the effect of adding LA Times data is weaker than adding WSJ data, it is noteworthy that the unsupervised induction of trees from the LA Times domain still improves the f-score even if the test data are from a different domain.

We also investigated the effect of adding the LA Times data to the total mix of Penn's WSJ and NANC's WSJ. Table 4 shows the results of this experiment, where the baseline of 0 sentences thus starts with the 2,040k sentences from the combined Penn-NANC WSJ data.

Sentences added from LA Times to Penn-NANC WSJ	f-score by adding LA Times data
0	69.0
100k	69.4
250k	69.9
500k	70.2
1,000k	70.4
2,000k	70.7

Table 4. Results of U-DOP* on section 23 from Penn's WSJ by mixing sentences from the combined Penn-NANC WSJ with additions from NANC's LA Times.

As seen in table 4, the f-score continues to increase even when adding LA Times data to the large combined set of Penn-NANC WSJ sentences. The highest f-score is obtained by adding 2,000k sentences, resulting in a total training set of 4,040k sentences. We believe that our result is quite promising for the future of unsupervised parsing.

In putting our best f-score in table 4 into perspective, it should be kept in mind that the gold standard trees from Penn-WSJ section 23 were binarized. It is well known that such a binarization has a negative effect on the f-score. Bod (2006) reports that an unbinarized treebank grammar achieves an average 72.3% f-score on WSJ sentences ≤ 40 words, while the binarized version achieves only 64.6% f-score. To compare U-DOP*'s results against some supervised parsers, we additionally evaluated a PCFG treebank grammar and the supervised DOP* parser using the same test set. For these supervised parsers, we employed the standard training set, i.e. Penn's WSJ sections 2-21, but only by taking the p-o-s strings as we did for our unsupervised U-DOP* model. Table 5 shows the results of this comparison.

Parser	f-score
U-DOP*	70.7
Binarized treebank PCFG	63.5
Binarized DOP*	80.3

Table 5. Comparison between the (best version of) U-DOP*, the supervised treebank PCFG and the supervised DOP* for section 23 of Penn's WSJ

As seen in table 5, U-DOP* outperforms the binarized treebank PCFG on the WSJ test set. While a similar result was obtained in Bod (2006), the absolute difference between unsupervised parsing and the treebank grammar was extremely small in Bod (2006): 1.8%, while the difference in table 5 is 7.2%, corresponding to 19.7% error reduction. Our f-score remains behind the supervised version of DOP* but the gap gets narrower as more training data is being added to U-DOP*.

5 Evaluation on unlabeled corpora in a practical application

Our experiments so far have shown that despite the addition of large amounts of unlabeled training data, U-DOP* is still outperformed by the supervised DOP* model when tested on hand-annotated corpora like the Penn Treebank. Yet it is well known that any evaluation on hand-annotated corpora unreasonably favors supervised parsers. There is thus a quest for designing an evaluation scheme that is independent of annotations. One way to go would be to compare supervised and unsupervised parsers as a syntax-based language model in a practical application such as machine translation (MT) or speech recognition.

In Bod (2007), we compared U-DOP* and DOP* in a syntax-based MT system known as Data-Oriented Translation or *DOT* (Poutsma 2000; Groves et al. 2004). The DOT model starts with a bilingual treebank where each tree pair constitutes an example translation and where translationally equivalent constituents are linked. Similar to DOP,

the DOT model uses all linked subtree pairs from the bilingual treebank to form an STSG of linked subtrees, which are used to compute the most probable translation of a target sentence given a source sentence (see Hearne and Way 2006).

What we did in Bod (2007) is to let both DOP* and U-DOP* compute the best trees directly for the *word strings* in the German-English Europarl corpus (Koehn 2005), which contains about 750,000 sentence pairs. Differently from U-DOP*, DOP* needed to be trained on annotated data, for which we used respectively the Negra and the Penn treebank. Of course, it is well-known that a supervised parser's f-score decreases if it is transferred to another domain: for example, the (non-binarized) WSJ-trained DOP model in Bod (2003) decreases from around 91% to 85.5% f-score if tested on the Brown corpus. Yet, this score is still considerably higher than the accuracy obtained by the unsupervised U-DOP model, which achieves 67.6% unlabeled f-score on Brown sentences. Our main question of interest is in how far this difference in accuracy on hand-annotated corpora carries over when tested in the context of a concrete application like MT. This is not a trivial question, since U-DOP* learns 'constituents' for word sequences such as *Ich möchte* ("I would like to") and *There are* (Bod 2007), which are usually hand-annotated as non-constituents. While U-DOP* is punished for this 'incorrect' prediction if evaluated on the Penn Treebank, it may be rewarded for this prediction if evaluated in the context of machine translation using the Bleu score (Papineni et al. 2002). Thus similar to Chiang (2005), U-DOP can discover non-syntactic phrases, or simply "phrases", which are typically neglected by linguistically syntax-based MT systems. At the same time, U-DOP* can also learn discontiguous constituents that are neglected by phrase-based MT systems (Koehn et al. 2003).

In our experiments, we used both U-DOP* and DOP* to predict the best trees for the German-English Europarl corpus. Next, we assigned links between each two nodes in the respective trees for each sentence pair. For a 2,000 sentence test set from a different part of the Europarl corpus we computed the most probable target sentence (using Viterbi *n* best). The Bleu score was used to measure translation accuracy, calculated by the NIST script with its default settings. As a baseline we compared our results with the publicly available phrase-based system Pharaoh (Koehn et al. 2003), using the default feature set. Table 6 shows for each system the Bleu score together with a description of the productive units. 'U-DOT' refers to 'Unsupervised DOT' based on U-DOP*, while DOT is based on DOP*.

System	Productive Units	Bleu-score
U-DOT / U-DOP*	Constituents and Phrases	0.280
DOT / DOP*	Constituents only	0.221
Pharaoh	Phrases only	0.251

Table 6. Comparing U-DOP* and DOP* in syntax-based MT on the German-English Europarl corpus against the Pharaoh system.

The table shows that the unsupervised U-DOT model outperforms the supervised DOT model with 0.059. Using Zhang's significance tester (Zhang et al. 2004), it turns out that this difference is statistically significant ($p < 0.001$). Also the difference between U-DOT and the baseline Pharaoh is statistically significant ($p < 0.008$). Thus even if supervised parsers like DOP* outperform unsupervised parsers like U-DOP* on hand-parsed data with >10%, the same supervised parser is outperformed by the unsupervised parser if tested in an MT application. Evidently, U-DOP's capacity to capture both constituents and phrases pays off in a concrete application and shows the shortcomings of models that only allow for either constituents (such as linguistically syntax-based MT) or phrases (such as phrase-based MT). In Bod (2007) we also show that U-DOT obtains virtually the same Bleu score as Pharaoh after eliminating subtrees with discontiguous yields.

6 Conclusion: future of supervised parsing

In this paper we have shown that the accuracy of unsupervised parsing under U-DOP* continues to grow when enlarging the training set with additional data. However, except for the simple treebank PCFG, U-DOP* scores worse than supervised parsers if evaluated on hand-annotated data. At the same time U-DOP* significantly outperforms the supervised DOP* if evaluated in a practical application like MT. We argued that this can be explained by the fact that U-DOP learns

both constituents and (non-syntactic) phrases while supervised parsers learn constituents only.

What should we learn from these results? We believe that parsing, when separated from a task-based application, is mainly an academic exercise. If we only want to mimick a treebank or implement a linguistically motivated grammar, then supervised, grammar-based parsers are preferred to unsupervised parsers. But if we want to improve a practical application with a syntax-based language model, then an unsupervised parser like U-DOP* might be superior.

The problem with most supervised (and semi-supervised) parsers is their rigid notion of constituent which excludes 'constituents' like the German *Ich möchte* or the French *Il y a*. Instead, it has become increasingly clear that the notion of constituent is a fluid which may sometimes be in agreement with traditional syntax, but which may just as well be in opposition to it. Any sequence of words can be a unit of combination, including non-contiguous word sequences like *closest* X *to* Y. A parser which does not allow for this fluidity may be of limited use as a language model. Since supervised parsers seem to stick to categorical notions of constituent, we believe that in the field of syntax-based language models the end of supervised parsing has come in sight.

An Ensemble Method for Selection of High Quality Parses

Abstract

While the average performance of statistical parsers gradually improves, they still attach to many sentences annotations of rather low quality. The number of such sentences grows when the training and test data are taken from different domains, which is the case for major web applications such as information retrieval and question answering.

In this paper we present a *Sample Ensemble Parse Assessment (SEPA)* algorithm for detecting parse quality. We use a function of the agreement among several copies of a parser, each of which trained on a different sample from the training data, to assess parse quality. We experimented with both generative and reranking parsers (Collins, Charniak and Johnson respectively). We show superior results over several baselines, both when the training and test data are from the same domain and when they are from different domains. For a test setting used by previous work, we show an error reduction of 31% as opposed to their 20%.

1 Introduction

Many algorithms for major NLP applications such as information extraction (IE) and question answering (QA) utilize the output of statistical parsers (see (Yates et al., 2006)). While the average performance of statistical parsers gradually improves, the quality of many of the parses they produce is too low for applications. When the training and test data are taken from different domains (the *parser adaptation* scenario) the ratio of such low quality parses becomes even higher. Figure 1 demonstrates these phenomena for two leading models, Collins (1999) model 2, a generative model, and Charniak and Johnson (2005), a reranking model. The parser adaptation scenario is the rule rather than the exception for QA and IE systems, because these usually operate over the highly variable Web, making it very difficult to create a representative corpus for manual annotation. Medium quality parses may seriously harm the performance of such systems.

In this paper we address the problem of assessing parse quality, using a *Sample Ensemble Parse Assessment (SEPA)* algorithm. We use the level of agreement among several copies of a parser, each of which trained on a different sample from the training data, to predict the quality of a parse. The algorithm does not assume uniformity of training and test data, and is thus suitable to web-based applications such as QA and IE.

Generative statistical parsers compute a probability $p(a, s)$ for each sentence annotation, so the immediate technique that comes to mind for assessing parse quality is to simply use $p(a, s)$. Another seemingly trivial method is to assume that shorter sentences would be parsed better than longer ones. However, these techniques produce results that are far from optimal. In Section 5 we show the superiority of our method over these and other baselines.

Surprisingly, as far as we know there is only one previous work explicitly addressing this problem (Yates et al., 2006). Their WOODWARD algorithm filters out high quality parses by performing seman-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 408–415,
Prague, Czech Republic, June 2007.

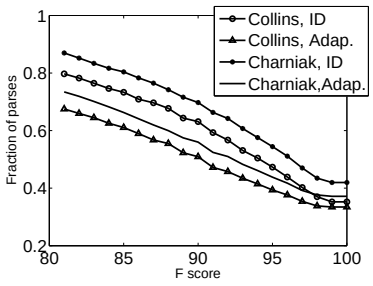

Figure 1: F-score vs. the fraction of parses whose f-score is at least that f-score. For the in-domain scenario, the parsers are tested on sec 23 of the WSJ Penn Treebank. For the parser adaptation scenario, they are tested on the Brown test section. In both cases they are trained on sections 2-21 of WSJ.

tic analysis. The present paper provides a detailed comparison between the two algorithms, showing both that SEPA produces superior results and that it operates under less restrictive conditions.

We experiment with both the generative parsing model number 2 of Collins (1999) and the reranking parser of Charniak and Johnson (2005), both when the training and test data belong to the same domain (the *in-domain* scenario) and in the parser adaptation scenario. In all four cases, we show substantial improvement over the baselines. The present paper is the first to use a reranking parser and the first to address the adaptation scenario for this problem.

Section 2 discusses relevant previous work, Section 3 describes the SEPA algorithm, Sections 4 and 5 present the experimental setup and results, and Section 6 discusses certain aspects of these results and compares SEPA to WOODWARD.

2 Related Work

The only previous work we are aware of that explicitly addressed the problem of detecting high quality parses in the output of statistical parsers is (Yates et al., 2006). Based on the observation that incorrect parses often result in implausible semantic interpretations of sentences, they designed the WOODWARD filtering system. It first maps the parse produced by the parser to a logic-based representation (relational conjunction (RC)) and then employs four methods for semantically analyzing whether a conjunct in the RC is likely to be reasonable. The filters use semantic information obtained from the Web. Measuring errors using filter f-score (see Section 3) and using the Collins generative model, WOODWARD reduces errors by 67% on a set of TREC questions and by 20% on a set of a 100 WSJ sentences. Section 5 provides a detailed comparison with our algorithm.

Reranking algorithms (Koo and Collins, 2005; Charniak and Johnson, 2005) search the list of best parses output by a generative parser to find a parse of higher quality than the parse selected by the generative parser. Thus, these algorithms in effect assess parse quality using syntactic and lexical features. The SEPA algorithm does not use such features, and is successful in detecting high quality parses even when working on the output of a reranker. Reranking and SEPA are thus relatively independent.

Bagging (Breiman, 1996) uses an ensemble of instances of a model, each trained on a sample of the training data[1]. Bagging was suggested in order to enhance classifiers; the classification outcome was determined using a majority vote among the models. In NLP, bagging was used for active learning for text classification (Argamon-Engelson and Dagan, 1999; McCallum and Nigam, 1998). Specifically in parsing, (Henderson and Brill, 2000) applied a constituent level voting scheme to an ensemble of bagged models to increase parser performance, and (Becker and Osborne, 2005) suggested an active learning technique in which the agreement among an ensemble of bagged parsers is used to predict examples valuable for human annotation. They reported experiments with small training sets only (up to 5,000 sentences), and their agreement function is very different from ours. Both works experimented with generative parsing models only.

Ngai and Yarowsky (2000) used an ensemble based on bagging and partitioning for active learning for base NP chunking. They select top items without any graded assessment, and their f-complement function, which slightly resembles our MF (see the next section), is applied to the output of a classifier, while our function is applied to structured output. A survey of several papers dealing with mapping

[1]Each sample is created by sampling, with replacement, L examples from the training pool, where L is the size of the training pool. Conversely, each of our samples is smaller than the training set, and is created by sampling without replacement. See Section 3 ('regarding S') for a discussion of this issue.

predictors in classifiers' output to posterior probabilities is given in (Caruana and Niculescu-Mizil, 2006). As far as we know, the application of a sample based parser ensemble for assessing parse quality is novel.

Many IE and QA systems rely on the output of parsers (Kwok et al., 2001; Attardi et al., 2001; Moldovan et al., 2003). The latter tries to address incorrect parses using complex relaxation methods. Knowing the quality of a parse could greatly improve the performance of such systems.

3 The Sample Ensemble Parse Assessment (SEPA) Algorithm

In this section we detail our parse assessment algorithm. Its input consists of a parsing algorithm A, an annotated training set TR, and an unannotated test set TE. The output provides, for each test sentence, the parse generated for it by A when trained on the full training set, and a grade assessing the parse's quality, on a continuous scale between 0 to 100. Applications are then free to select a sentence subset that suits their needs using our grades, e.g. by keeping only high-quality parses, or by removing low-quality parses and keeping the rest. The algorithm has the following stages:

1. Choose N random samples of size S from the training set TR. Each sample is selected without replacement.
2. Train N copies of the parsing algorithm A, each with one of the samples.
3. Parse the test set with each of the N models.
4. For each test sentence, compute the value of an agreement function F between the models.
5. Sort the test set according to F's value.

The algorithm uses the level of agreement among several copies of a parser, each trained on a different sample from the training data, to predict the quality of a parse. The higher the agreement, the higher the quality of the parse. Our approach assumes that if the parameters of the model are well designed to annotate a sentence with a high quality parse, then it is likely that the model will output the same (or a highly similar) parse even if the training data is somewhat changed. In other words, we rely on the stability of the parameters of statistical parsers. Although this is not always the case, our results confirm that strong correlation between agreement and parse quality does exist.

We explored several agreement functions. The one that showed the best results is *Mean F-score (MF)*[2], defined as follows. Denote the models by $m_1 \dots m_N$, and the parse provided by m_i for sentence s as $m_i(s)$. We randomly choose a model m_l, and compute

$$MF(s) = \frac{1}{N-1} \sum_{i \in [1 \dots N], i \neq l} fscore(m_i, m_l) \quad (1)$$

We use two measures to evaluate the quality of SEPA grades. Both measures are defined using a threshold parameter T, addressing only sentences whose SEPA grades are not smaller than T. We refer to these sentences as *T-sentences*.

The first measure is the average f-score of the parses of T-sentences. Note that we compute the f-score of each of the selected sentences and then average the results. This stands in contrast to the way f-score is ordinarily calculated, by computing the labeled precision and recall of the constituents in the whole set and using these as the arguments of the f-score equation. The ordinary f-score is computed that way mostly in order to overcome the fact that sentences differ in length. However, for applications such as IE and QA, which work at the single sentence level and which might reach erroneous decision due to an inaccurate parse, normalizing over sentence lengths is less of a factor. For this reason, in this paper we present detailed graphs for the average f-score. For completeness, Table 4 also provides some of the results using the ordinary f-score.

The second measure is a generalization of the filter f-score measure suggested by Yates et al. (2006). They define *filter precision* as the ratio of correctly parsed sentences in the *filtered set* (the set the algorithm choose) to total sentences in the filtered set and *filter recall* as the ratio of correctly parsed sentences in the filtered set to correctly parsed sentences in the

[2]Recall that sentence f-score is defined as: $f = \frac{2 \times P \times R}{P+R}$, where P and R are the labeled precision and recall of the constituents in the sentence relative to another parse.

whole set of sentences parsed by the parser (*unfiltered set* or *test set*). Correctly parsed sentences are sentences whose parse got f-score of 100%.

Since requiring a 100% may be too restrictive, we generalize this measure to *filter f-score with parameter* k. In our measure, the filter recall and precision are calculated with regard to sentences that get an f-score of k or more, rather than to correctly parsed sentences. Filtered f-score is thus a special case of our filtered f-score, with parameter 100.

We now discuss the effect of the number of models N and the sample size S. The discussion is based on experiments (using development data, see Section 4) in which all the parameters are fixed except for the parameter in question, using our development sections.

Regarding N (see Figure 2): As the number of models increases, the number of T-sentences selected by SEPA decreases and their quality improves, in terms of both average f-score and filter f-score (with $k = 100$). The fact that more models trained on different samples of the training data agree on the syntactic annotation of a sentence implies that this syntactic pattern is less sensitive to perturbations in the training data. The number of such sentences is small and it is likely the parser will correctly annotate them. The smaller T-set size leads to a decrease in filter recall, while the better quality leads to an increase in filter precision. Since the increase in filter precision is sharper than the decrease in filter recall, filter f-score increases with the number of models N.

Regarding S[3]: As the sample size increases, the number of T-sentences increases, and their quality degrades in terms of average f-score but improves in terms of filter f-score (again, with parameter $k = 100$). The overlap among smaller samples is small and the data they supply is sparse. If several models trained on such samples attach to a sentence the same parse, this syntactic pattern must be very prominent in the training data. The number of such sentences is small and it is likely that the parser will correctly annotate them. Therefore smaller sample size leads to smaller T-sets with high average f-score. As the sample size increases, the T-set becomes larger but the average f-score of a parse

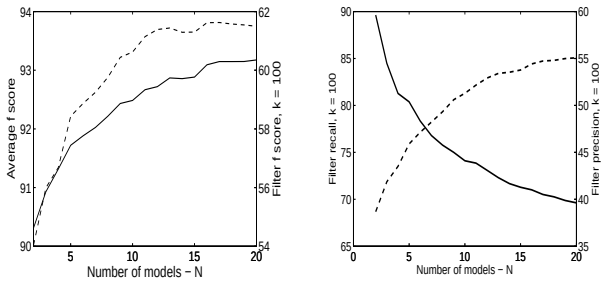

Figure 2: The effect of the number of models N on SEPA (Collins' model). The scenario is in-domain, sample size $S = 33,000$ and $T = 100$. We see: average f-score of T-sentences (left, solid curve and left y-axis), filter f-score with $k = 100$ (left, dashed curve and right y-axis), filter recall with $k = 100$ (right, solid curve and left y-axis), and filter precision with $k = 100$ (right, dashed curve and right y-axis).

decreases. The larger T-set size leads to increase in filter recall, while the lower average quality leads to decrease in filter precision. Since the increase in filter recall is sharper than the decrease in filter precision, the result is that filter f-score increases with the sample size S.

This discussion demonstrates the importance of using both average f-score and filter f-score, since the two measures reflect characteristics of the selected sample that are not necessarily highly (or positively) correlated.

4 Experimental Setup

We performed experiments with two parsing models, the Collins (1999) generative model number 2 and the Charniak and Johnson (2005) reranking model. For the first we used a reimplementation (**?**). We performed experiments with each model in two scenarios, in-domain and parser adaptation. In both experiments the training data are sections 02-21 of the WSJ PennTreebank (about 40K sentences). In the in-domain experiment the test data is section 23 (2416 sentences) of WSJ and in the parser adaptation scenario the test data is Brown test section (2424 sentences). Development sections are WSJ section 00 for the in-domain scenario (1981 sentences) and Brown development section for the adaptation scenario (2424 sentences). Following

[3]Graphs are not shown due to lack of space.

(Gildea, 2001), the Brown test and development sections consist of 10% of Brown sentences (the 9th and 10th of each 10 consecutive sentences in the development and test sections respectively).

We performed experiments with many configurations of the parameters *N* (number of models), *S* (sample size) and *F* (agreement function). Due to space limitations we describe only experiments where the values of the parameters *N*, *S* and *F* are fixed (*F* is MF, N and S are given in Section 5) and the threshold parameter T is changed.

5 Results

We first explore the quality of the selected set in terms of average f-score. In Section 3 we reported that the quality of a selected T-set of parses increases as the number of models N increases and sample size S decreases. We therefore show the results for relatively high N (20) and relatively low S (13,000, which is about a third of the training set). Denote the cardinality of the set selected by SEPA by n (it is actually a function of T but we omit the T in order to simplify notations).

We use several baseline models. The first, *confidence baseline (CB)*, contains the n sentences having the highest parser assigned probability (when trained on the whole training set). The second, *minimum length (ML)*, contains the n shortest sentences in the test set. Since many times it is easier to parse short sentences, a trivial way to increase the average f-score measure of a set is simply to select short sentences. The third, following (Yates et al., 2006), is *maximum recall (MR)*. MR simply predicts that all test set sentences should be contained in the selected T-set. The output set of this model gets filter recall of 1 for any k value, but its precision is lower. The MR baseline is not relevant to the average f-score measure, because it selects all of the sentences in a set, which leads to the same average as a random selection (see below). In order to minimize visual clutter, for the filter f-score measure we use the maximum recall (MR) baseline rather than the minimum length (ML) baseline, since the former outperforms the latter. Thus, ML is only shown for the average f-score measure. We have also experimented with a random baseline model (containing n randomly selected test sentences), whose results are the worst and which is shown for reference.

Readers of this section may get confused between the agreement threshold parameter T and the parameter k of the filter f-score measure. Please note: as to T, SEPA sorts the test set by the values of the agreement function. One can then select only sentences whose agreement score is at least T. T's values are on a continuous scale from 0 to 100. As to k, the filter f-score measure gives a grade. This grade combines three values: (1) the number of sentences in the set (selected by an algorithm) whose f-score relative to the gold standard parse is at least k, (2) the size of the selected set, and (3) the total number of sentences with such a parse in the whole test set. We did not introduce separate notations for these values.

Figure 3 (top) shows average f-score results where SEPA is applied to Collins' generative model in the in-domain (left) and adaptation (middle) scenarios. SEPA outperforms the baselines for all values of the agreement threshold parameter T. Furthermore, as T increases, not only does the SEPA set quality increase, but the quality differences between this set and the baseline sets increases as well. The graphs on the right show the number of sentences in the sets selected by SEPA for each T value. As expected, this number decreases as T increases.

Figure 3 (bottom) shows the same pattern of results for the Charniak reranking parser in the in-domain (left) and adaptation (middle) scenarios. We see that the effects of the reranker and SEPA are relatively independent. Even after some of the errors of the generative model were corrected by the reranker by selecting parses of higher quality among the 50-best, SEPA can detect parses of high quality from the set of parsed sentences.

To explore the quality of the selected set in terms of filter f-score, we recall that the quality of a selected set of parses increases as both the number of models N and the sample size S increase, and with T. Therefore, for $k = 85 \ldots 100$ we show the value of filter f-score with parameter k when the parameters configuration is a relatively high N (20), relatively high S (33,000, which are about 80% of the training set), and the highest T (100).

Figure 4 (top) shows filter f-score results for Collins' generative model in the in-domain (left) and adaptation (middle) scenarios. As these graphs show, SEPA outperforms CB and random for all val-

ues of the filter f-score parameter k, and outperforms the MR baseline where the value of k is 95 or more. Although for small k values MR gets a higher f-score than SEPA, the filter precision of SEPA is much higher (right, shown for adaptation. The in-domain pattern is similar and not shown). This stems from the definition of the MR baseline, which simply predicts any sentence to be in the selected set. Furthermore, since the selected set is meant to be the input for systems that require high quality parses, what matters most is that SEPA outperforms the MR baseline at the high k ranges.

Figure 4 (bottom) shows the same pattern of results for the Charniak reranking parser in the in-domain (left) and adaptation (middle) scenarios. As for the average f-score measure, it demonstrates that the effects of the reranker and SEPA algorithm are relatively independent.

Tables 1 and 2 show the error reduction achieved by SEPA for the filter f-score measure with parameters $k = 95, 97, 100$ (Table 1) and for the average f-score measure with several SEPA agreement threshold (T) values (Table 2) . The error reductions achieved by SEPA for both measures are substantial.

Table 3 compares SEPA and WOODWARD on the exact same test set used by (Yates et al., 2006) (taken from WSJ sec 23). SEPA achieves error reduction of 31% over the MR baseline on this set, compared to only 20% achieved by WOODWARD. Not shown in the table, in terms of ordinary f-score WOODWARD achieves error reduction of 37% while SEPA achieves 43%. These numbers were the only ones reported in (Yates et al., 2006).

For completeness of reference, Table 4 shows the superiority of SEPA over CB in terms of the usual f-score measure used by the parsing community (numbers are counted for constituents first). Results for other baselines are even more impressive. The configuration is similar to that of Figure 3.

	Filter f-score					
	In-domain			Adaptation		
k value	95	97	100	95	97	100
Coll. MR	3.5	20.1	29.2	22.8	29.8	33.6
Coll. CB	11.6	11.7	3.4	14.2	9.9	7.4
Char. MR	1.35	13.6	23.44	21.9	30	32.5
Char. CB	21.9	16.8	11.9	25	20.2	16.2

Table 1: Error reduction in the filter f-score measure obtained by SEPA with Collins' (top two lines) and Charniak's (bottom two lines) model, in the two scenarios (in-domain and adaptation), vs. the maximum recall (MR lines 1 and 3) and confidence (CB, lines 2 and 4) baselines, using $N = 20, T = 100$ and $S = 33,000$. Shown are parameter values $k = 95, 97, 100$. Error reduction numbers were computed by $100 \times (fscoreSEPA - fscorebaseline)/(1 - fscorebaseline)$.

	Average f-score					
	In-domain			Adaptation		
T	95	97	100	95	97	100
Coll. ML	32.6	37.2	60.8	46.8	52.7	70.7
Coll. CB	26.5	31.4	53.9	46.9	53.6	70
Char. ML	25.1	33.2	58.5	46.9	58.4	77.1
Char. CB	20.4	30	52	44.4	55.5	73.5

Table 2: Error reduction in the average f-score measure obtained by SEPA with Collins (top two lines) and Charniak (bottom two lines) model, in the two scenarios (in-domain and adaptation), vs. the minimum length (ML lines 1 and 3) and confidence (CB, lines 2 and 4) baselines, using $N = 20$ and $S = 13,000$. Shown are agreement threhsold parameter values $T = 95, 97, 100$. Error reduction numbers were computed by $100 \times (fscoreSEPA - fscorebaseline)/(1 - fscorebaseline)$.

	SEPA	WOODWARD	CB
ER	**31%**	20%	-31%

Table 3: Error reduction compared to the MR baseline, measured by filter f-score with parameter 100. The data is the WSJ sec 23 test set usd by (Yates et al., 2006). All three methods use Collins' model. SEPA uses $N = 20, S = 33,000, T = 100$.

6 Discussion

In this paper we introduced SEPA, a novel algorithm for assessing parse quality in the output of a statistical parser. SEPA is the first algorithm shown to be successful when a reranking parser is considered, even though such models use a reranker to detect and fix some of the errors made by the base generative model. WOODWARD, the only previously suggested algorithm for this problem, was tested with Collins' generative model only. Furthermore, this is the first time that an algorithm for this problem succeeds in a domain adaptation scenario, regardless of

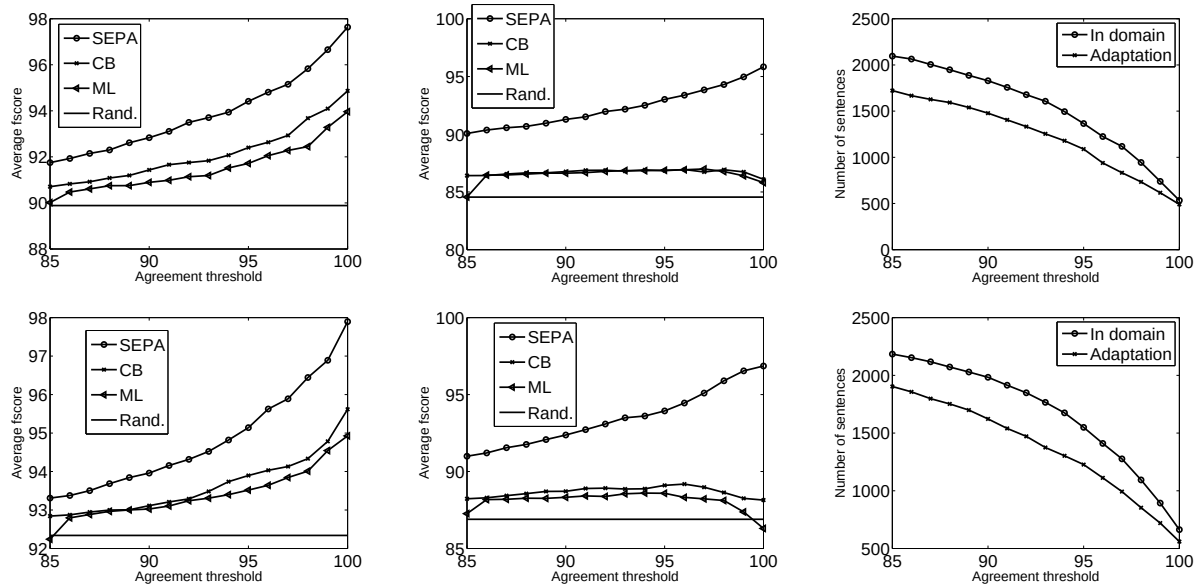

Figure 3: Agreement threshold T vs. average f-score (left and middle) and number of sentences in the selected set (right), for SEPA with Collins' generative model (top) and the Charniak reranking model (bottom). SEPA parameters are $S = 13,000, N = 20$. In both rows, SEPA results for the in-domain (left) and adaptation (middle) scenarios are compared to the confidence (CB) and minimum length (ML) baselines. The graphs on the right show the number of sentences in the selected set for both scenarios.

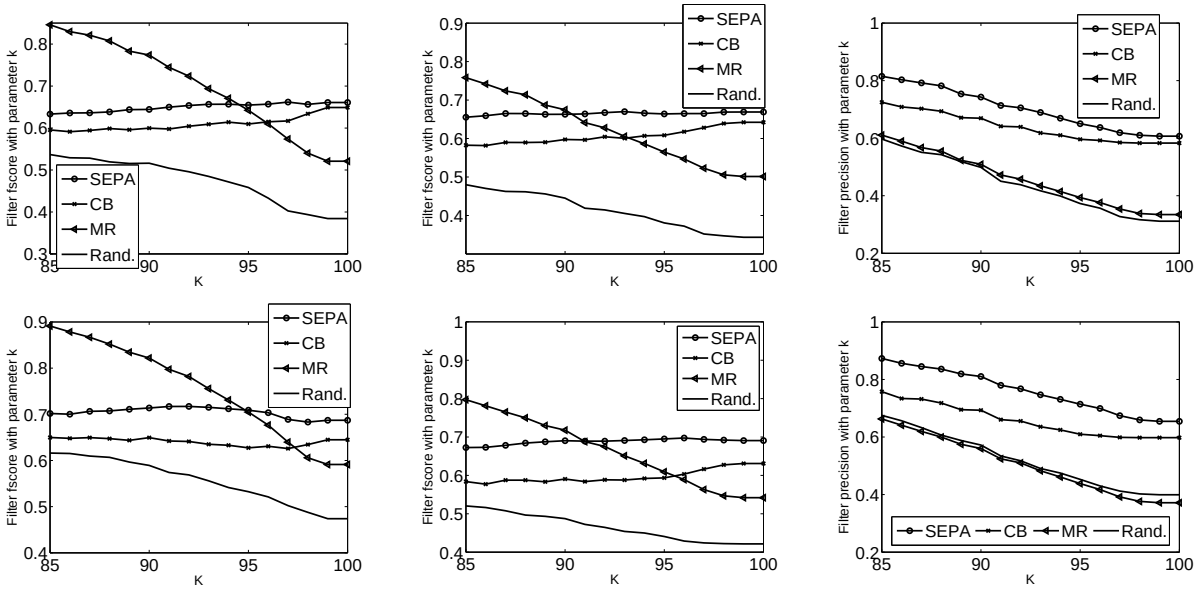

Figure 4: Parameter k vs. filter f-score (left and middle) and filter precision (right) with that parameter, for SEPA with Collins' generative model (top) and the Charniak reranking model (bottom). SEPA parameters are $S = 33,000, N = 20, T = 100$. In both rows, results for the in-domain (left) and adaptation (middle) scenarios. In two leftmost graphs, the performance of the algorithm is compared to the confidence baseline (CB) and maximum recall (MR). The graphs on the right compare the filter precision of SEPA with that of the MR and CB baselines.

the parsing model. In the Web environment this is the common situation.

The WSJ and Brown experiments performed with SEPA are much broader than those performed with WOODWARD, considering all sentences of WSJ sec 23 and Brown test section rather than a subset of carefully selected sentences from WSJ sec 23. However, we did not perform a TREC experiment, as (Yates et al., 2006) did. Our WSJ and Brown results outperformed several baselines. Moreover, WSJ (or Brown) sentences that contain conjunctions were avoided in the experiments of (Yates et al., 2006). We have verified that our algorithm shows substantial error reduction over the baselines for this type of sentences (in the ranges $13 - 46\%$ for the filter f-score with $k = 100$, and $30 - 60\%$ for the average f-score).

As Table 3 shows, on a WSJ sec 23 test set similar to that used by (Yates et al., 2006), SEPA achieves 31% error reduction compared to 20% of WOODWARD.

WOODWARD works under several assumptions. Specifically, it requires a corpus whose content overlaps at least in part with the content of the parsed sentences. This corpus is used to extract semantically related statistics for its filters. Furthermore, the filters of this algorithm (except of the QA filter) are focused on verb and preposition relations. Thus, it is more natural for it to deal with mistakes contained in such relations. This is reflected in the WSJ based test set on which it is tested. SEPA does not make any of these assumptions. It does not use any external information source and is shown to select high quality parses from diverse sets.

	In-domain		Adaptation	
	F	ER	F	ER
SEPA Collins	97.09	44.36%	95.38	66.38%
CB Collins	94.77	–	86.3	–
SEPA Charniak	97.21	35.69%	96.3	54.66%
CB Charniak	95.6	–	91.84	–

Table 4: SEPA error reduction vs. the CB baseline in the in-domain and adaptation scenarios, using the traditional f-score of the parsing literature. $N = 20, S = 13,000, T = 100$.

For future work, integrating SEPA into the reranking process seems a promising direction for enhancing overall parser performance.

Opinion Mining Using Econometrics: A Case Study on Reputation Systems

Abstract

Deriving the polarity and strength of opinions is an important research topic, attracting significant attention over the last few years. In this work, to measure the strength and polarity of an opinion, we consider the *economic context* in which the opinion is evaluated, instead of using human annotators or linguistic resources. We rely on the fact that text in on-line systems influences the behavior of humans and this effect can be observed using some easy-to-measure economic variables, such as revenues or product prices. By reversing the logic, we infer the semantic orientation and strength of an opinion by tracing the changes in the associated economic variable. In effect, we use econometrics to identify the "economic value of text" and assign a "dollar value" to each opinion phrase, measuring sentiment effectively and without the need for manual labeling. We argue that by interpreting opinions using econometrics, we have the first *objective*, *quantifiable*, and *context-sensitive* evaluation of opinions. We make the discussion concrete by presenting results on the reputation system of Amazon.com. We show that user feedback affects the pricing power of merchants and by measuring their pricing power we can infer the polarity and strength of the underlying feedback postings.

1 Introduction

A significant number of websites today allow users to post articles where they express opinions about products, firms, people, and so on. For example, users on Amazom.com post reviews about products they bought and users on eBay.com post feedback describing their experiences with sellers. The goal of opinion mining systems is to identify such pieces of the text that express opinions (Breck et al., 2007; König and Brill, 2006) and then measure the polarity and strength of the expressed opinions. While intuitively the task seems straightforward, there are multiple challenges involved.

- What makes an opinion positive or negative? Is there an *objective* measure for this task?
- How can we rank opinions according to their strength? Can we define an *objective* measure for ranking opinions?
- How does the *context* change the polarity and strength of an opinion and how can we take the context into consideration?

To evaluate the polarity and strength of opinions, most of the existing approaches rely either on training from human-annotated data (Hatzivassiloglou and McKeown, 1997), or use linguistic resources (Hu and Liu, 2004; Kim and Hovy, 2004) like WordNet, or rely on co-occurrence statistics (Turney, 2002) between words that are unambiguously positive (e.g., "excellent") and unambiguously negative (e.g., "horrible"). Finally, other approaches rely on reviews with numeric ratings from websites (Pang and Lee, 2002; Dave et al., 2003; Pang and Lee, 2004; Cui et al., 2006) and train (semi-)supervised learning algorithms to classify reviews as positive or negative, or in more fine-grained scales (Pang and Lee, 2005; Wilson et al., 2006). Implicitly, the supervised learning techniques assume that numeric ratings fully encapsulate the sentiment of the review.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 416–423,
Prague, Czech Republic, June 2007.

In this paper, we take a different approach and instead consider the *economic context* in which an opinion is evaluated. We observe that the text in on-line systems influence the behavior of the readers. This effect can be measured by observing some easy-to-measure *economic variable*, such as product prices. For instance, online merchants on eBay with "positive" feedback can sell products for higher prices than competitors with "negative" evaluations. Therefore, each of these (positive or negative) evaluations has a (positive or negative) effect on the prices that the merchant can charge. For example, everything else being equal, a seller with "speedy" delivery may be able to charge $10 more than a seller with "slow" delivery. Using this information, we can conclude that "speedy" is better than "slow" when applied to "delivery" and their difference is $10. Thus, we can infer the semantic orientation and the strength of an evaluation from the changes in the observed economic variable. Following this idea, we use techniques from econometrics to identify the "*economic value of text*" and assign a "dollar value" to each text snippet, measuring sentiment strength and polarity effectively and without the need for labeling or any other resource.

We argue that by interpreting opinions within an econometric framework, we have the first *objective* and *context-sensitive* evaluation of opinions. For example, consider the comment "good packaging," posted by a buyer to evaluate a merchant. This comment would have been considered unambiguously positive by the existing opinion mining systems. We observed, though, that within electronic markets, such as eBay, a posting that contains the words "good packaging" has actually *negative* effect on the power of a merchant to charge higher prices. This surprising effect reflects the nature of the comments in online marketplaces: buyers tend to use superlatives and highly enthusiastic language to praise a good merchant, and a lukewarm "good packaging" is interpreted as negative. By introducing the econometric interpretation of opinions we can effortlessly capture such challenging scenarios, something that is impossible to achieve with the existing approaches.

We focus our paper on reputation systems in electronic markets and we examine the effect of opinions on the pricing power of merchants in the marketplace of Amazon.com. (We discuss more applications in Section 7.) We demonstrate the value of our technique using a dataset with 9,500 transactions that took place over 180 days. We show that textual feedback affects the power of merchants to charge higher prices than the competition, for the same product, and still make a sale. We then reverse the logic and determine the contribution of each comment in the pricing power of a merchant. Thus, we discover the polarity and strength of each evaluation without the need for human annotation or any other form of linguistic resource.

The structure of the rest of the paper is as follows. Section 2 gives the basic background on reputation systems. Section 3 describes our methodology for constructing the data set that we use in our experiments. Section 4 shows how we combine established techniques from econometrics with text mining techniques to identify the strength and polarity of the posted feedback evaluations. Section 5 presents the experimental evaluations of our techniques. Finally, Section 6 discusses related work and Section 7 discusses further applications and concludes the paper.

2 Reputation Systems and Price Premiums

When buyers purchase products in an electronic market, they assess and pay not only for the product they wish to purchase but for a set of fulfillment characteristics as well, e.g., packaging, delivery, and the extent to which the product description matches the actual product. Electronic markets rely on reputation systems to ensure the quality of these characteristics for each merchant, and the importance of such systems is widely recognized in the literature (Resnick et al., 2000; Dellarocas, 2003). Typically, merchants' reputation in electronic markets is encoded by a "*reputation profile*" that includes: (a) the number of past transactions for the merchant, (b) a summary of numeric ratings from buyers who have completed transactions with the seller, and (c) a chronological list of textual feedback provided by these buyers.

Studies of online reputation, thus far, base a merchant's reputation on the *numeric* rating that characterizes the seller (e.g., average number of stars and number of completed transactions) (Melnik and Alm, 2002). The general conclusion of these studies show that merchants with higher (numeric) reputation can charge higher prices than the competition, for the same products, and still manage to make a sale. This *price premium* that the merchants can command over the competition is a measure of their reputation.

Definition 2.1 Consider a set of merchants $s_1, \ldots, s_n$ selling a product for prices $p_1, \ldots, p_n$. If s_i makes

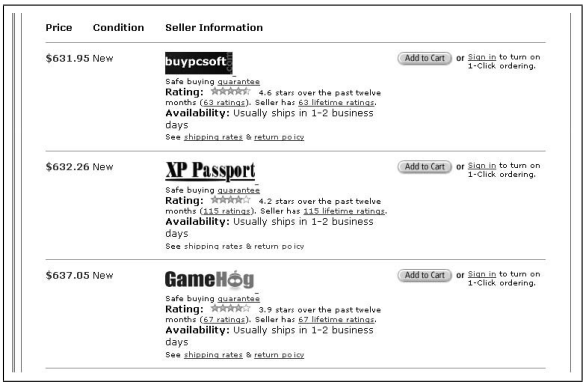

Figure 1: A set of merchants on Amazon.com selling an identical product for different prices

the sale for price p_i, then s_i commands a *price premium* equal to $p_i - p_j$ over s_j and a *relative price premium* equal to $\frac{p_i - p_j}{p_i}$. Hence, a transaction that involves n competing merchants generates $n-1$ price premiums.[1] The *average price premium* for the transaction is $\frac{\sum_{j \neq i}(p_i - p_j)}{n-1}$ and the *average relative price premium* is $\frac{\sum_{j \neq i}(p_i - p_j)}{p_i(n-1)}$. □

Example 2.1 Consider the case in Figure 1 where three merchants sell the same product for $631.95, $632.26, and $637.05, respectively. If *GameHog* sells the product, then the *price premium* against *XP Passport* is $4.79 (= $637.05 − $632.26) and against the merchant *BuyPCsoft* is $5.10. The *relative price premium* is 0.75% and 0.8%, respectively. Similarly, the *average price premium* for this transaction is $4.95 and the *average relative price premium* 0.78%. □

Different sellers in these markets derive their reputation from different characteristics: some sellers have a reputation for fast delivery, while some others have a reputation of having the lowest price among their peers. Similarly, while some sellers are praised for their packaging in the feedback, others get good comments for selling high-quality goods but are criticized for being rather slow with shipping. Even though previous studies have established the positive correlation between higher (numeric) reputation and higher price premiums, they ignored completely the role of the textual feedback and, in turn, the multi-dimensional nature of reputation in electronic markets. We show that the textual feedback adds significant *additional* value to the numerical scores, and affects the pricing power of the merchants.

[1] As an alternative definition we can ignore the *negative* price premiums. The experimental results are similar for both versions.

3 Data

We compiled a data set using software resellers from publicly available information on software product listings at Amazon.com. Our data set includes 280 individual software titles. The sellers' reputation matters when selling identical goods, and the price variation observed can be attributed primarily to variation in the merchant's reputation. We collected the data using Amazon Web Services over a period of 180 days, between October 2004 and March 2005. We describe below the two categories of data that we collected.

Transaction Data: The first part of our data set contains details of the transactions that took place on the marketplace of Amazon.com for each of the software titles. The Amazon Web Services associates a unique *transaction ID* for each unique product listed by a seller. This transaction ID enables us to distinguish between multiple or successive listings of identical products sold by the same merchant. Keeping with the methodology in prior research (Ghose et al., 2006), we crawl the Amazon's XML listings every 8 hours and when a transaction ID associated with a particular listing is removed, we infer that the listed product was successfully sold in the prior 8 hour window.[2] For each transaction that takes place, we keep the price at which the product was sold and the merchant's reputation at the time of the transaction (more on this later). Additionally, for each of the *competing listings for identical products*, we keep the listed price along with the competitors reputation. Using the collected data, we compute the price premium variables for each transaction[3] using Definition 2.1. Overall, our data set contains 1,078 merchants, 9,484 unique transactions and 107,922 price premiums (recall that each transaction generates multiple price premiums).

Reputation Data: The second part of our data set contains the reputation history of each merchant that had a (monitored) product for sale during our 180-day window. Each of these merchants has a feedback profile, which consists of numerical scores and text-based feedback, posted by buyers. We had an average of 4,932 postings per merchant. The numerical ratings

[2] Amazon indicates that their seller listings remain on the site indefinitely until they are sold and sellers can change the price of the product without altering the transaction ID.

[3] Ideally, we would also include the tax and shipping cost charged by each merchant in the computation of the price premiums. Unfortunately, we could not capture these costs using our methodology. Assuming that the fees for shipping and tax are independent of the merchants' reputation, our analysis is not affected.

are provided on a scale of one to five stars. These ratings are averaged to provide an overall score to the seller. Note that we collect all feedback (both numerical and textual) associated with a seller over the entire lifetime of the seller and we reconstruct each seller's exact feedback profile at the time of each transaction.

4 Econometrics-based Opinion Mining

In this section, we describe how we combine econometric techniques with NLP techniques to derive the semantic orientation and strength of the feedback evaluations. Section 4.1 describes how we structure the textual feedback and Section 4.2 shows how we use econometrics to estimate the polarity and strength of the evaluations.

4.1 Retrieving the Dimensions of Reputation

We characterize a merchant using a vector of reputation dimensions $X = (X_1, X_2, ..., X_n)$, representing its ability on each of n dimensions. We assume that each of these n dimensions is expressed by a *noun*, *noun phrase*, *verb*, or a *verb phrase* chosen from the set of all feedback postings, and that a merchant is evaluated on these n dimensions. For example, dimension 1 might be "*shipping*", dimension 2 might be "*packaging*" and so on. In our model, each of these dimensions is assigned a numerical score. Of course, when posting textual feedback, buyers do not assign explicit numeric scores to any dimension. Rather, they use *modifiers* (typically adjectives or adverbs) to evaluate the seller along each of these dimensions (we describe how we assign numeric scores to each modifier in Section 4.2). Once we have identified the set of all dimensions, we can then parse each of the feedback postings, associate a modifier with each dimension, and represent a feedback posting as an n-dimensional vector ϕ of modifiers.

Example 4.1 Suppose dimension 1 is "*delivery*," dimension 2 is "*packaging*," and dimension 3 is "*service*." The feedback posting *"I was impressed by the speedy delivery! Great service!"* is then encoded as $\phi_1 = [speedy, NULL, great]$, while the posting *"The item arrived in awful packaging, and the delivery was slow"* is encoded as $\phi_2 = [slow, awful, NULL]$. □

Let $\mathcal{M} = \{NULL, \mu_1, ..., \mu_M\}$ be the set of modifiers and consider a seller s_i with p postings in its reputation profile. We denote with $\mu^i_{jk} \in \mathcal{M}$ the modifier that appears in the j-th posting and is used to assess the k-th reputation dimension. We then structure the merchant's feedback as an $n \times p$ matrix $\mathbf{M}(s_i)$ whose rows are the p encoded vectors of modifiers associated with the seller. We construct $\mathbf{M}(s_i)$ as follows:

1. Retrieve the postings associated with a merchant.
2. Parse the postings to identify the dimensions across which the buyer evaluates a seller, keeping[4] the nouns, noun phrases, verbs, and verbal phrases as reputation characteristics.[5].
3. Retrieve adjectives and adverbs that refer to[6] dimensions (Step 2) and construct the ϕ vectors.

We have implemented this algorithm on the feedback postings of each of our sellers. Our analysis yields 151 unique dimensions, and a total of 142 modifiers (note that the same modifier can be used to evaluate multiple dimensions).

4.2 Scoring the Dimensions of Reputation

As discussed above, the textual feedback profile of merchant s_i is encoded as a $n \times p$ matrix $\mathbf{M}(s_i)$; the elements of this matrix belong to the set of modifiers $\mathcal{M}$. In our case, we are interested in computing the "score" $a(\mu, d, j)$ that a modifier $\mu \in \mathcal{M}$ assigns to the dimension d, when it appears in the j-th posting.

Since buyers tend to read only the first few pages of text-based feedback, we weight higher the influence of recent text postings. We model this by assuming that K is the number of postings that appear on each page ($K = 25$ on Amazon.com), and that c is the probability of clicking on the "Next" link and moving the next page of evaluations.[7] This assigns a posting-specific weight $r_j = c^{\lfloor \frac{j}{K} \rfloor} / \sum_{q=1}^{p} c^{\lfloor \frac{q}{K} \rfloor}$ for the j^{th} posting, where j is the rank of the posting, K is the number of postings per page, and p is the total number of postings for the given seller. Then, we set $a(\mu, d, j) = r_j \cdot a(\mu, d)$ where $a(\mu, d)$ is the "global" score that modifier μ assigns to dimension d.

Finally, since each reputation dimension has potentially a different weight, we use a weight vector $\mathbf{w}$ to

[4]We eliminate all dimensions appearing in the profiles of less than 50 (out of 1078) merchants, since we cannot extract statistically meaningful results for such sparse dimensions

[5]The technique as described in this paper, considers words like "shipping" and " delivery" as separate dimensions, although they refer to the same "real-life" dimension. We can use Latent Dirichlet Allocation (Blei et al., 2003) to reduce the number of dimensions, but this is outside the scope of this paper.

[6]To associate the adjectives and adverbs with the correct dimensions, we use the Collins HeadFinder capability of the Stanford NLP Parser.

[7]We report only results for $c = 0.5$. We conducted experiments other values of c as well and the results are similar.

weight the contribution of each reputation dimension to the overall "reputation score" $\Pi(s_i)$ of seller s_i:

$$\Pi(s_i) = \mathbf{r}^T \cdot \mathbf{A}(\mathbf{M}(s_i)) \cdot \mathbf{w} \quad (1)$$

where $\mathbf{r}^T = [r_1, r_2, ...r_p]$ is the vector of the posting-specific weights and $\mathbf{A}(\mathbf{M}(i))$ is a matrix that contains as element the score $a(\mu_j, d_k)$ where $\mathbf{M}(s_i)$ contains the modifier μ_j in the column of the dimension d_k. If we model the buyers' preferences as independently distributed along each dimension and each modifier score $a(\mu, d_k)$ also as an independent random variable, then the random variable $\Pi(s_i)$ is a sum of random variables. Specifically, we have:

$$\Pi(s_i) = \sum_{j=1}^{M} \sum_{k=1}^{n} \left(w_k \cdot a(\mu_j, d_k)\right) R(\mu_j, d_k) \quad (2)$$

where $R(\mu_j, d_k)$ is equal to the sum of the r_i weights across all postings in which the modifier μ_j modifies dimension d_k. We can easily compute the $R(\mu_j, d_k)$ values by simply counting appearances and weighting each appearance using the definition of r_i.

The question is, of course, how to estimate the values of $w_k \cdot a(\mu_j, d_k)$, which determine the polarity and intensity of the modifier μ_j modifying the dimension d_k. For this, we observe that the appearance of such modifier-dimension opinion phrases has an effect on the price premiums that a merchant can charge. Hence, there is a correlation between the reputation scores $\Pi(\cdot)$ of the merchants and the price premiums observed for each transaction. To discover the level of association, we use regression. Since we are dealing with panel data, we estimate *ordinary-least-squares (OLS) regression with fixed effects* (Greene, 2002), where the dependent variable is the *price premium* variable, and the independent variables are the reputation scores $\Pi(\cdot)$ of the merchants, together with a few other control variables. Generally, we estimate models of the form:

$$PricePremium_{ij} = \sum \beta_c \cdot X_{cij} + f_{ij} + \epsilon_{ij} + \beta_{t1} \cdot \Pi(merchant)_{ij} + \beta_{t2} \cdot \Pi(competitor)_{ij} \quad (3)$$

where $PricePremium_{ij}$ is one of the variations of price premium as given in Definition 2.1 for a seller s_i and product j, β_c, β_{t1}, and β_{t2} are the regressor coefficients, Xc are the control variables, $\Pi(\cdot)$ are the text reputation scores (see Equation 1), f_{ij} denotes the fixed effects and ϵ is the error term. In Section 5, we give the details about the control variables and the regression settings.

Interestingly, if we expand the $\Pi(\cdot)$ variables according to Equation 2, we can run the regression using the modifier-dimension pairs as independent variables, whose values are equal to the $R(\mu_j, d_k)$ values. After running the regression, the coefficients assigned to each modifier-dimension pair correspond to the value $w_k \cdot a(\mu_j, d_k)$ for each modifier-dimension pair. Therefore, we can easily estimate in economic terms the "value" of a particular modifier when used to evaluate a particular dimension.

5 Experimental Evaluation

In this section, we first present the experimental settings (Section 5.1), and then we describe the results of our experimental evaluation (Section 5.2).

5.1 Regression Settings

In Equation 3 we presented the general form of the regression for estimating the scores $a(\mu_j, d_k)$. Since we want to eliminate the effect of any other factors that may influence the price premiums, we also use a set of control variables. After all the control factors are taken into consideration, the modifier scores reflect the *additional* value of the text opinions. Specifically, we used as control variables the product's *price on Amazon*, the average *star rating of the merchant*, the *number of merchant's past transactions*, and the *number of sellers* for the product.

First, we ran OLS regressions with product-seller fixed effects controlling for unobserved heterogeneity across sellers and products. These fixed effects control for average product quality and differences in seller characteristics. We run multiple variations of our model, using different versions of the "price premium" variable as listed in Definition 2.1. We also tested variations where we include as independent variable not the individual reputation scores but the difference $\Pi(merchant) - \Pi(competitor)$. All regressions yielded qualitatively similar results, so due to space restrictions we only report results for the regressions that include all the control variables and all the text variables; we report results using the *price premium* as the dependent variable. Our regressions in this setting contain 107,922 observations, and a total of 547 independent variables.

5.2 Experimental Results

Recall of Extraction: The first step of our experimental evaluation is to examine whether the opinion extraction technique of Section 4.1 indeed captures all the reputation characteristics expressed in the feed-

Dimension	Human Recall	Computer Recall
Product Condition	0.76	0.76
Price	0.91	0.61
Package	0.96	0.66
Overall Experience	0.65	0.55
Delivery Speed	0.96	0.92
Item Description	0.22	0.43
Product Satisfaction	0.68	0.58
Problem Response	0.30	0.37
Customer Service	0.57	0.50
Average	**0.66**	**0.60**

Table 1: The recall of our technique compared to the recall of the human annotators

back (recall) and whether the dimensions that we capture are accurate (precision). To examine the recall question, we used two human annotators. The annotators read a random sample of 1,000 feedback postings, and identified the reputation dimensions mentioned in the text. Then, they examined the extracted modifier-dimension pairs for each posting and marked whether the modifier-dimension pairs captured the identified real reputation dimensions mentioned in the posting and which pairs were spurious, non-opinion phrases.

Both annotators identified nine reputation dimensions (see Table 1). Since the annotators did not agree in all annotations, we computed the average *human recall* $hRec_d = \frac{agreed_d}{all_d}$ for each dimension d, where $agreed_d$ is the number of postings for which both annotators identified the reputation dimension d, and all_d is the number of postings in which at least one annotator identified the dimension d. Based on the annotations, we computed the recall of our algorithm against each annotator. We report the average recall for each dimension, together with the human recall in Table 1. The recall of our technique is only slightly inferior to the performance of humans, indicating that the technique of Section 4.1 extracts the majority of the posted evaluations.[8]

Interestingly, precision is not an issue in our setting. In our framework, if an particular modifier-dimension pair is just noise, then it is almost impossible to have a statistically significant correlation with the price premiums. The noisy opinion phrases are statistically guaranteed to be filtered out by the regression.

Estimating Polarity and Strength: In Table 2, we present the modifier-dimension pairs (positive and negative) that had the strongest "dollar value" and were statistically significant across all regressions. (Due to space issues, we cannot list the values for all pairs.) These values reflect changes in the merchants's pricing power *after* taking their average numerical score and level of experience into account, and also highlight the *additional* the value contained in text-based reputation. The examples that we list here illustrate that our technique generates a natural ranking of the opinion phrases, inferring the strength of each modifier *within* the context in which this opinion is evaluated. This holds true even for misspelled evaluations that would break existing techniques based on annotation or on resources like WordNet. Furthermore, these values reflect the *context* in which the opinion is evaluated. For example, the pair *good packaging* has a dollar value of -$0.58. Even though this seems counterintuitive, it actually reflects the nature of an online marketplace where most of the positive evaluations contain superlatives, and a mere "good" is actually interpreted by the buyers as a lukewarm, slightly negative evaluation. Existing techniques cannot capture such phenomena.

Price Premiums vs. Ratings: One of the natural comparisons is to examine whether we could reach similar results by just using the average star rating associated with each feedback posting to infer the score of each opinion phrase. The underlying assumption behind using the ratings is that the review is perfectly summarized by the star rating, and hence the text plays mainly an explanatory role and carries no extra information, given the star rating. For this, we examined the R^2 fit of the regression, with and without the use of the text variables. Without the use of text variables, the R^2 was 0.35, while when using only the text-based regressors, the R^2 fit increased to 0.63. This result clearly indicates that the actual text contains significantly more information than the ratings.

We also experimented with predicting which merchant will make a sale, if they simultaneously sell the same product, based on their listed prices and on their numeric and text reputation. Our C4.5 classifier (Quinlan, 1992) takes a pair of merchants and decides which of the two will make a sale. We used as training set the transactions that took place in the first four months and as test set the transactions in the last two months of our data set. Table 3 summarizes the results for different sets of features used. The 55%

[8] In the case of "Item Description," where the computer recall was higher than the human recall, our technique identified almost all the phrases of one annotator, but the other annotator had a more liberal interpretation of "Item Description" dimension and annotated significantly more postings with the dimension "Item Description" than the other annotator, thus decreasing the human recall.

Modifier Dimension	Dollar Value
[wonderful experience]	$5.86
[outstanding seller]	$5.76
[excellant service]	$5.27
[lightning delivery]	$4.84
[highly recommended]	$4.15
[best seller]	$3.80
[perfectly packaged]	$3.74
[excellent condition]	$3.53
[excellent purchase]	$3.22
[excellent seller]	$2.70
[excellent communication]	$2.38
[perfect item]	$1.92
[terrific condition]	$1.87
[top quality]	$1.67
[awesome service]	$1.05
[A+++ seller]	$1.03
[great merchant]	$0.93
[friendly service]	$0.81
[easy service]	$0.78
[never received]	-$7.56
[defective product]	-$6.82
[horible experience]	-$6.79
[never sent]	-$6.69
[never recieved]	-$5.29
[bad experience]	-$5.26
[cancelled order]	-$5.01
[never responded]	-$4.87
[wrong product]	-$4.39
[not as advertised]	-$3.93
[poor packaging]	-$2.92
[late shipping]	-$2.89
[wrong item]	-$2.50
[not yet received]	-$2.35
[still waiting]	-$2.25
[wrong address]	-$1.54
[never buy]	-$1.48

Table 2: The highest scoring opinion phrases, as determined by the product $w_k \cdot a(\mu_j, d_k)$.

accuracy when using only prices as features indicates that customers rarely choose a product based solely on price. Rather, as indicated by the 74% accuracy, they also consider the reputation of the merchants. However, the real value of the postings relies on the text and not on the numeric ratings: the accuracy is 87%-89% when using the textual reputation variables. In fact, text subsumes the numeric variables but not vice versa, as indicated by the results in Table 3.

6 Related Work

To the best of our knowledge, our work is the first to use economics for measuring the effect of opinions and deriving their polarity and strength in an econometric manner. A few papers in the past tried to combine text analysis with economics (Das and Chen, 2006; Lewitt and Syverson, 2005), but the text analysis was limited to token counting and did not use any NLP techniques. The technique of Section 4.1 is based on existing research in sentiment analysis. For instance, (Hatzivassiloglou and McKeown, 1997; Nigam and Hurst, 2004) use annotated data to create a supervised learning technique to identify the semantic orientation of adjectives. We follow the approach by Turney (2002), who note that the semantic orientation of an adjective depends on the noun that it modifies and suggest using adjective-noun or adverb-verb pairs to extract semantic orientation. However, we do not rely on linguistic resources (Kamps and Marx, 2002) or on search engines (Turney and Littman, 2003) to determine the semantic orientation, but rather rely on econometrics for this task. Hu and Liu (2004), whose study is the closest to our work, use WordNet to compute the semantic orientation of product evaluations and try to summarize user reviews by extracting the positive and negative evaluations of the different product features. Similarly, Snyder and Barzilay (2007) decompose an opinion across several dimensions and capture the sentiment across each dimension. Other work in this area includes (Lee, 2004; Popescu and Etzioni, 2005) which uses text mining in the context product reviews, but none uses the economic context to evaluate the opinions.

Features	Accuracy on Test Set
Price	55%
Price + Numeric Reputation	74%
Price + Numeric Reputation + Text Reputation	89%
Price + Text Reputation	87%

Table 3: Predicting the merchant who makes the sale.

7 Conclusion and Further Applications

We demonstrated the value of using econometrics for extracting a *quantitative* interpretation of opinions. Our technique, additionally, takes into consideration the *context* within which these opinions are evaluated. Our experimental results show that our techniques can capture the pragmatic meaning of the expressed opinions using simple economic variables as a form of training data. The source code with our implementation together with the data set used in this paper are available from `http://economining.stern.nyu.edu`.

There are many other applications beyond reputation systems. For example, using sales rank data from Amazon.com, we can examine the effect of product reviews on product sales and detect the weight that

customers put on different product features; furthermore, we can discover how customer evaluations on individual product features affect product sales and extract the pragmatic meaning of these evaluations. Another application is the analysis of the effect of news stories on stock prices: we can examine what news topics are important for the stock market and see how the views of different opinion holders and the wording that they use can cause the market to move up or down. In a slightly different twist, we can analyze news stories and blogs in conjunction with results from prediction markets and extract the pragmatic effect of news and blogs on elections or other political events. Another research direction is to examine the effect of summarizing product descriptions on product sales: short descriptions reduce the cognitive load of consumers but increase their uncertainty about the underlying product characteristics; a longer description has the opposite effect. The optimum description length is the one that balances both effects and maximizes product sales.

Similar approaches can improve the state of art in both economics and computational linguistics. In economics and in social sciences in general, most researchers handle textual data manually or with simplistic token counting techniques; in the worst case they ignore text data altogether. In computational linguistics, researchers often rely on human annotators to generate training data, a laborious and error-prone task. We believe that cross-fertilization of ideas between the fields of computational linguistics and econometrics can be beneficial for both fields.

PageRanking WordNet Synsets: An Application to Opinion Mining*

Andrea Esuli and Fabrizio Sebastiani

Abstract

This paper presents an application of PageRank, a random-walk model originally devised for ranking Web search results, to ranking WordNet synsets in terms of how strongly they possess a given semantic property. The semantic properties we use for exemplifying the approach are positivity and negativity, two properties of central importance in sentiment analysis. The idea derives from the observation that WordNet may be seen as a graph in which synsets are connected through the binary relation "a term belonging to synset s_k occurs in the gloss of synset s_i", and on the hypothesis that this relation may be viewed as a transmitter of such semantic properties. The data for this relation can be obtained from eXtended WordNet, a publicly available sense-disambiguated version of WordNet. We argue that this relation is structurally akin to the relation between hyperlinked Web pages, and thus lends itself to PageRank analysis. We report experimental results supporting our intuitions.

1 Introduction

Recent years have witnessed an explosion of work on *opinion mining* (aka *sentiment analysis*), the discipline that deals with the quantitative and qualitative analysis of text for the purpose of determining its opinion-related properties (ORPs). An important part of this research has been the work on the automatic determination of the ORPs of *terms*, as e.g., in determining whether an adjective tends to give a positive, a negative, or a neutral nature to the noun phrase it appears in. While many works (Esuli and Sebastiani, 2005; Hatzivassiloglou and McKeown, 1997; Kamps et al., 2004; Takamura et al., 2005; Turney and Littman, 2003) view the properties of positivity and negativity as categorical (i.e., a term is either positive or it is not), others (Andreevskaia and Bergler, 2006b; Grefenstette et al., 2006; Kim and Hovy, 2004; Subasic and Huettner, 2001) view them as *graded* (i.e., a term may be positive to a certain degree), with the underlying interpretation varying from fuzzy to probabilistic.

Some authors go a step further and attach these properties not to terms but to term *senses* (typically: WordNet synsets), on the assumption that different senses of the same term may have different opinion-related properties (Andreevskaia and Bergler, 2006a; Esuli and Sebastiani, 2006b; Ide, 2006; Wiebe and Mihalcea, 2006).

In this paper we contribute to this latter literature with a novel method for ranking the *entire* set of WordNet synsets, irrespectively of POS, according to their ORPs. Two rankings are produced, one according to positivity and one according to negativity. The two rankings are independent, i.e., it is *not* the case that one is the inverse of the other, since e.g., the least positive synsets may be negative or neutral synsets alike.

This work was partially supported by Project ONTOTEXT "From Text to Knowledge for the Semantic Web", funded by the Provincia Autonoma di Trento under the 2004–2006 "Fondo Unico per la Ricerca" funding scheme.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 424–431,
Prague, Czech Republic, June 2007.

The main hypothesis underlying our method is that the positivity and negativity of WordNet synsets can be determined by mining their glosses. It crucially relies on the observation that the gloss of a WordNet synset contains terms *that themselves belong to synsets*, and on the hypothesis that the glosses of positive (resp. negative) synsets will mostly contain terms belonging to positive (negative) synsets. This means that the binary relation $s_i \blacktriangleright s_k$ ("the gloss of synset s_i contains a term belonging to synset s_k"), which induces a directed graph on the set of WordNet synsets, may be thought of as a channel through which positivity and negativity flow, from the *definiendum* (the synset s_i being defined) to the *definiens* (a synset s_k that contributes to the definition of s_i by virtue of its member terms occurring in the gloss of s_i). In other words, if a synset s_i is known to be positive (negative), this can be viewed as an indication that the synsets s_k to which the terms occurring in the gloss of s_i belong, are themselves positive (negative).

We obtain the data of the $\blacktriangleright$ relation from eXtended WordNet (Harabagiu et al., 1999), an automatically sense-disambiguated version of WordNet in which every term occurrence in every gloss is linked to the synset it is deemed to belong to.

In order to compute how polarity flows in the graph of WordNet synsets we use the well known PageRank algorithm (Brin and Page, 1998). PageRank, a random-walk model for ranking Web search results which lies at the basis of the Google search engine, is probably the most important single contribution to the fields of information retrieval and Web search of the last ten years, and was originally devised in order to detect how authoritativeness flows in the Web graph and how it is conferred onto Web sites. The advantages of PageRank are its strong theoretical foundations, its fast convergence properties, and the effectiveness of its results. The reason why PageRank, among all random-walk algorithms, is particularly suited to our application will be discussed in the rest of the paper.

Note however that our method is not limited to ranking synsets *by positivity and negativity*, and could in principle be applied to the determination of other semantic properties of synsets, such as membership in a domain, since for many other properties we may hypothesize the existence of a similar "hydraulics" between synsets. We thus see positivity and negativity only as proofs-of-concept for the potential of the method.

The rest of the paper is organized as follows. Section 2 reports on related work on the ORPs of lexical items, highlighting the similarities and differences between the discussed methods and our own. In Section 3 we turn to discussing our method; in order to make the paper self-contained, we start with a brief introduction of PageRank (Section 3.1) and of the structure of eXtended WordNet (Section 3.2). Section 4 describes the structure of our experiments, while Section 5 discusses the results we have obtained, comparing them with other results from the literature. Section 6 concludes.

2 Related work

Several works have recently tackled the automated determination of term polarity. Hatzivassiloglou and McKeown (1997) determine the polarity of adjectives by mining pairs of conjoined adjectives from text, and observing that conjunctions such as and tend to conjoin adjectives of the same polarity while conjunctions such as but tend to conjoin adjectives of opposite polarity. Turney and Littman (2003) determine the polarity of generic terms by computing the pointwise mutual information (PMI) between the target term and each of a set of "seed" terms of known positivity or negativity, where the marginal and joint probabilities needed for PMI computation are equated to the fractions of documents from a given corpus that contain the terms, individually or jointly. Kamps et al. (2004) determine the polarity of adjectives by checking whether the target adjective is closer to the term good or to the term bad in the graph induced on WordNet by the synonymy relation. Kim and Hovy (2004) determine the polarity of generic terms by means of two alternative learning-free methods that use two sets of seed terms of known positivity and negativity, and are based on the frequency with which synonyms of the target term also appear in the respective seed sets. Among these works, (Turney and Littman, 2003) has proven by far the most effective, but it is also by far the most computationally intensive.

Some recent works have employed, as in the present paper, the glosses from online dictionar-

ies for term polarity detection. Andreevskaia and Berger (2006a) extend a set of terms of known positivity/negativity by adding to them all the terms whose glosses contain them; this algorithm does not view glosses as a source for a graph of terms, and is based on a different intuition than ours. Esuli and Sebastiani (2005; 2006a) determine the ORPs of generic terms by learning, in a semi-supervised way, a binary term classifier from a set of training terms that have been given vectorial representations by indexing their WordNet glosses. The same authors later extend their work to determining the ORPs of WordNet synsets (Esuli and Sebastiani, 2006b). However, there is a substantial difference between these works and the present one, in that the former simply view the glosses as sources of textual representations for the terms/synsets, and not as inducing a graph of synsets as we instead view them here.

The work closest in spirit to the present one is probably that by Takamura et al. (2005), who determine the polarity of terms by applying intuitions from the theory of electron spins: two terms that appear one in the gloss of the other are viewed as akin to two neighbouring electrons, which tend to acquire the same "spin" (a notion viewed as akin to polarity) due to their being neighbours. This work is similar to ours since a graph between terms is generated from dictionary glosses, and since an iterative algorithm that converges to a stable state is used, but the algorithm is very different, and based on intuitions from very different walks of life.

Some recent works have tackled the attribution of opinion-related properties to word senses or synsets (Ide, 2006; Wiebe and Mihalcea, 2006)[1]; however, they do not use glosses in any significant way, and are thus very different from our method.

The interested reader may also consult (Mihalcea, 2006) for other applications of random-walk models to computational linguistics.

3 Ranking WordNet synsets by PageRank

3.1 The PageRank algorithm

Let $G = \langle N, L \rangle$ be a directed graph, with N its set of nodes and L its set of directed links; let $\mathbf{W_0}$ be the $|N| \times |N|$ *adjacency matrix* of G, i.e., the matrix such that $\mathbf{W}_0[i,j] = 1$ iff there is a link from node n_i to node n_j. We will denote by $B(i) = \{n_j \mid \mathbf{W_0}[j,i] = 1\}$ the set of the *backward neighbours* of n_i, and by $F(i) = \{n_j \mid \mathbf{W_0}[i,j] = 1\}$ the set of the *forward neighbours* of n_i. Let $\mathbf{W}$ be the *row-normalized adjacency matrix* of G, i.e., the matrix such that $\mathbf{W}[i,j] = \frac{1}{|F(i)|}$ iff $\mathbf{W_0}[i,j] = 1$ and $\mathbf{W}[i,j] = 0$ otherwise.

The input to PageRank is the row-normalized adjacency matrix $\mathbf{W}$, and its output is a vector $\mathbf{a} = \langle a_1, \ldots, a_{|N|} \rangle$, where a_i represents the "score" of node n_i. When using PageRank for search results ranking, n_i is a Web site and a_i measures its computed authoritativeness; in our application n_i is instead a synset and a_i measures the degree to which n_i has the semantic property of interest. PageRank iteratively computes vector $\mathbf{a}$ based on the formula

$$a_i^{(k)} \leftarrow \alpha \sum_{j \in B(i)} \frac{a_j^{(k-1)}}{|F(j)|} + (1-\alpha)e_i \qquad (1)$$

where $a_i^{(k)}$ denotes the value of the i-th entry of vector $\mathbf{a}$ at the k-th iteration, e_i is a constant such that $\sum_i e_{i=1}^{|N|} = 1$, and $0 \leq \alpha \leq 1$ is a control parameter. In vectorial form, Equation 1 can be written as

$$\mathbf{a}^{(k)} = \alpha \mathbf{a}^{(k-1)} \mathbf{W} + (1-\alpha)\mathbf{e} \qquad (2)$$

The underlying intuition is that a node n_i has a high score when (recursively) it has many high-scoring backward neighbours with few forward neighbours each; a node n_j thus passes its score a_j along to its forward neighbours $F(j)$, but this score is subdivided equally among the members of $F(j)$. This mechanism (that is represented by the summation in Equation 1) is then "smoothed" by the e_i constants, whose role is (see (Bianchini et al., 2005) for details) to avoid that scores flow and get trapped into so-called "rank sinks" (i.e., cliques with backward neighbours but no forward neighbours).

The computational properties of the PageRank algorithm, and how to compute it efficiently, have been widely studied; the interested reader may consult (Bianchini et al., 2005).

In the original application of PageRank for ranking Web search results the elements of $\mathbf{e}$ are usually taken to be all equal to $\frac{1}{|N|}$. However, it is possible

[1] Andreevskaia and Berger (2006a) also work on term senses, rather than terms, but they evaluate their work on terms only. This is the reason why they are listed in the preceding paragraph and not here.

to give different values to different elements in $\mathbf{e}$. In fact, the value of e_i amounts to an *internal source of score* for n_i that is constant across the iterations and independent from its backward neighbours. For instance, attributing a null e_i value to all but a few Web pages that are about a given topic can be used in order to bias the ranking of Web pages in favour of this topic (Haveliwala, 2003).

In this work we use the e_i values as internal sources of a given ORP (positivity *or* negativity), by attributing a null e_i value to all but a few "seed" synsets known to possess that ORP. PageRank will thus make the ORP flow from the seed synsets, at a rate constant throughout the iterations, into other synsets along the ▶ relation, until a stable state is reached; the final a_i values can be used to rank the synsets in terms of that ORP. Our method thus requires *two* runs of PageRank; in the first $\mathbf{e}$ has non-null scores for the positive seed synsets, while in the second the same happens for the negative ones.

3.2 eXtended WordNet

The transformation of WordNet into a graph based on the ▶ relation would of course be non-trivial, but is luckily provided by *eXtended WordNet* (Harabagiu et al., 1999), a publicly available version of WordNet in which (among other things) each term s_k occurring in a WordNet gloss (except those in example phrases) is lemmatized and mapped to the synset in which it belongs[2]. We use eXtended WordNet version 2.0-1.1, which refers to WordNet version 2.0. The eXtended WordNet resource has been automatically generated, which means that the associations between terms and synsets are likely to be sometimes incorrect, and this of course introduces noise in our method.

3.3 PageRank, (eXtended) WordNet, and ORP flow

We now discuss the application of PageRank to ranking WordNet synsets by positivity and negativity. Our algorithm consists in the following steps:

1. The graph $G = \langle N, L \rangle$ on which PageRank will be applied is generated. We define N to be the set of all WordNet synsets; in WordNet 2.0 there are 115,424 of them. We define L to contain a link from synset s_i to synset s_k iff the gloss of s_i contains *at least* a term belonging to s_k (terms occurring in the examples phrases and terms occurring after a term that expresses negation are not considered). Numbers, articles and prepositions occurring in the glosses are discarded, since they can be assumed to carry no positivity and negativity, and since they do not belong to a synset of their own. This leaves only nouns, adjectives, verbs, and adverbs.

2. The graph $G = \langle N, L \rangle$ is "pruned" by removing "self-loops", i.e., links going from a synset s_i into itself (since we assume that there is no flow of semantics from a concept unto itself). The row-normalized adjacency matrix $\mathbf{W}$ of G is derived.

3. The e_i values are loaded into the $\mathbf{e}$ vector; all synsets other than the seed synsets of renowned positivity (negativity) are given a value of 0. The α control parameter is set to a fixed value. We experiment with several different versions of the $\mathbf{e}$ vector and several different values of α; see Section 4.3 for details.

4. PageRank is executed using $\mathbf{W}$ and $\mathbf{e}$, iterating until a predefined termination condition is reached. The termination condition we use in this work consists in the fact that the cosine of the angle between $\mathbf{a}^{(k)}$ and $\mathbf{a}^{(k+1)}$ is above a predefined threshold χ (here we have set $\chi = 1 - 10^{-9}$).

5. We rank all the synsets of WordNet in descending order of their a_i score.

The process is run twice, once for positivity and once for negativity.

The last question to be answered is: "why PageRank?" Are the characteristics of PageRank more suitable to the problem of ranking synsets than other random-walk algorithms? The answer is yes, since it seems reasonable that:

1. If terms contained in synset s_k occur in the glosses of many positive synsets, and if the positivity scores of these synsets are high, then it is likely that s_k is itself positive (the same happens for negativity). This justifies the summation of Equation 1.

[2] http://xwn.hlt.utdallas.edu/

2. If the gloss of a positive synset that contains a term in synset s_k also contains many other terms, then this is a weaker indication that s_k is itself positive (this justifies dividing by $|F(j)|$ in Equation 1).

3. The ranking resulting from the algorithm needs to be biased in favour of a specific ORP; this justifies the presence of the $(1-\alpha)e_i$ factor in Equation 1).

The fact that PageRank is the "right" random-walk algorithm for our application is also confirmed by some experiments (not reported here for reasons of space) we have run with slightly different variants of the model (e.g., one in which we challenge intuition 2 above and thus avoid dividing by $|F(j)|$ in Equation 1). These experiments have always returned inferior results with respect to standard PageRank, thereby confirming the correctness of our intuitions.

4 Experiments

4.1 The benchmark

To evaluate the quality of the rankings produced by our experiments we have used the Micro-WNOp corpus (Cerini et al., 2007) as a benchmark[3]. Micro-WNOp consists in a set of 1,105 WordNet synsets, each of which was manually assigned a triplet of scores, one of positivity, one of negativity, one of neutrality. The evaluation was performed by five MSc students of linguistics, proficient second-language speakers of English. Micro-WNOp is representative of WordNet with respect to the different parts of speech, in the sense that it contains synsets of the different parts of speech in the same proportions as in the entire WordNet. However, it is not representative of WordNet with respect to ORPs, since this would have brought about a corpus largely composed of neutral synsets, which would be pretty useless as a benchmark for testing automatically derived lexical resources *for opinion mining*. It was thus generated by randomly selecting 100 positive + 100 negative + 100 neutral terms from the General Inquirer lexicon (see (Turney and Littman, 2003) for details) and including all the synsets that contained at least one such term, without paying attention to POS. See (Cerini et al., 2007) for more details.

The corpus is divided into three parts:

- Common: 110 synsets which all the evaluators evaluated by working together, so as to align their evaluation criteria.
- Group1: 496 synsets which were each independently evaluated by three evaluators.
- Group2: 499 synsets which were each independently evaluated by the other two evaluators.

Each of these three parts has the same balance, in terms of both parts of speech and ORPs, of Micro-WNOp as a whole. We obtain the positivity (negativity) ranking from Micro-WNOp by averaging the positivity (negativity) scores assigned by the evaluators of each group into a single score, and by sorting the synsets according to the resulting score. We use Group1 as a validation set, i.e., in order to fine-tune our method, and Group2 as a test set, i.e., in order to evaluate our method once all the parameters have been optimized on the validation set.

The result of applying PageRank to the graph G induced by the $\blacktriangleright$ relation, given a vector $\mathbf{e}$ of internal sources of positivity (negativity) score and a value for the α parameter, is a ranking of all the WordNet synsets in terms of positivity (negativity). By using different $\mathbf{e}$ vectors and different values of α we obtain different rankings, whose quality we evaluate by comparing them against the ranking obtained from Micro-WNOp.

4.2 The effectiveness measure

A ranking $\preceq$ is a partial order on a set of objects $N = \{o_1 \dots o_{|N|}\}$. Given a pair (o_i, o_j) of objects, o_i may precede o_j ($o_i \preceq o_j$), it may follow o_i ($o_i \succeq o_j$), or it may be tied with o_j ($o_i \approx o_j$).

To evaluate the rankings produced by PageRank we have used the *p-normalized Kendall τ distance* (noted τ_p – see e.g., (Fagin et al., 2004)) between the Micro-WNOp rankings and those predicted by PageRank. A standard function for the evaluation of rankings with ties, τ_p is defined as

$$\tau_p = \frac{n_d + p \cdot n_u}{Z} \quad (3)$$

[3] http://www.unipv.it/wnop/

where n_d is the number of *discordant pairs*, i.e., pairs of objects ordered one way in the gold standard and the other way in the prediction; n_u is the number of pairs ordered (i.e., not tied) in the gold standard and tied in the prediction, and p is a penalization to be attributed to each such pair; and Z is a normalization factor (equal to the number of pairs that are ordered in the gold standard) whose aim is to make the range of τ_p coincide with the $[0, 1]$ interval. Note that pairs tied in the gold standard are not considered in the evaluation.

The penalization factor is set to $p = \frac{1}{2}$, which is equal to the probability that a ranking algorithm correctly orders the pair by random guessing; there is thus no advantage to be gained from either random guessing or assigning ties between objects. For a prediction which perfectly coincides with the gold standard τ_p equals 0; for a prediction which is exactly the inverse of the gold standard τ_p equals 1.

4.3 Setup

In order to produce a ranking by positivity (negativity) we need to provide an $\mathbf{e}$ vector as input to PageRank. We have experimented with several different definitions of $\mathbf{e}$, each for both positivity and negativity. For reasons of space, we only report results from the five most significant ones.

We have first tested a vector (hereafter dubbed $\mathbf{e}1$) with all values uniformly set to $\frac{1}{|N|}$. This is the $\mathbf{e}$ vector originally used in (Brin and Page, 1998) for Web page ranking, and brings about an unbiased (that is, with respect to particular properties) ranking of WordNet. Of course, it is not meant to be used for ranking by positivity or negativity; we have used it as a baseline in order to evaluate the impact of property-biased vectors.

The first sensible, albeit minimalistic, definition of $\mathbf{e}$ we have used (dubbed $\mathbf{e}2$) is that of a vector with uniform non-null e_i scores assigned to the synsets that contain the adjective good (bad), and null scores for all other synsets. A further, still fairly minimalistic definition we have used (dubbed $\mathbf{e}3$) is that of a vector with uniform non-null e_i scores assigned to the synsets that contain at least one of the seven "paradigmatic" positive (negative) adjectives used as seeds in (Turney and Littman, 2003)[4], and null scores for all other synsets.

We have also tested a more complex version of $\mathbf{e}$, with e_i scores obtained from release 1.0 of SentiWordNet (Esuli and Sebastiani, 2006b)[5]. This latter is a lexical resource in which each WordNet synset is given a positivity score, a negativity score, and a neutrality score. We produced an $\mathbf{e}$ vector (dubbed $\mathbf{e}4$) in which the score assigned to a synset is proportional to the positivity (negativity) score assigned to it by SentiWordNet, and in which all entries sum up to 1. In a similar way we also produced a further $\mathbf{e}$ vector (dubbed $\mathbf{e}5$) through the scores of a newer release of SentiWordNet (release 1.1), resulting from a slight modification of the approach that had brought about release 1.0 (Esuli and Sebastiani, 2007b).

PageRank is parametric on α, which determines the balance between the contributions of the $\mathbf{a}^{(k-1)}$ vector and the $\mathbf{e}$ vector. A value of $\alpha = 0$ makes the $\mathbf{a}^{(k)}$ vector coincide with $\mathbf{e}$, and corresponds to discarding the contribution of the random-walk algorithm. Conversely, setting $\alpha = 1$ corresponds to discarding the contribution of $\mathbf{e}$, and makes $\mathbf{a}^{(k)}$ uniquely depend on the topology of the graph; the result is an "unbiased" ranking. The desirable cases are, of course, in between. As first hinted in Section 4.1, we thus optimize the α parameter on the synsets in Group1, and then test the algorithm with the optimal value of α on the synsets in Group2. All the 101 values of α from 0.0 to 1.0 with a step of .01 have been tested in the optimization phase. Optimization is performed anew for each experiment, which means that different values of α may be eventually selected for different $\mathbf{e}$ vectors.

5 Results

The results show that the use of PageRank in combination with suitable vectors $\mathbf{e}$ almost always improves the ranking, sometimes significantly so, with respect to the original ranking embodied by the $\mathbf{e}$ vector.

For positivity, the rankings produced using PageRank and any of the vectors from $\mathbf{e}2$ to $\mathbf{e}5$ all improve on the original rankings, with a relative improvement, measured as the relative decrease in τ_p,

[4]The seven positive adjectives are good, nice, excellent, positive, fortunate, correct, superior, and the seven negative ones are bad, nasty, poor, negative, unfortunate, wrong, inferior.

[5]http://sentiwordnet.isti.cnr.it/

ranging from -4.88% ($\mathbf{e}5$) to -6.75% ($\mathbf{e}4$). These rankings are also all better than the rankings produced by using PageRank and the uniform-valued vector $\mathbf{e}1$, with a minimum relative improvement of -5.04% ($\mathbf{e}3$) and a maximum of -34.47% ($\mathbf{e}4$). This suggests that the key to good performance is indeed a combination of positivity flow *and* internal source of score.

For the negativity rankings, the performance of both SentiWordNet-based vectors is still good, producing a -4.31% ($\mathbf{e}4$) and a -3.45% ($\mathbf{e}5$) improvement with respect to the original rankings. The "minimalistic" vectors (i.e., $\mathbf{e}2$ and $\mathbf{e}3$) are not as good as their positive counterparts. The reason seems to be that the generation of a ranking by negativity seems a somehow harder task than the generation of a ranking by positivity; this is also shown by the results obtained with the uniform-valued vector $\mathbf{e}1$, in which the application of PageRank improves with respect to $\mathbf{e}1$ for positivity but deteriorates for negativity. However, against the baseline constituted by the results obtained with the uniform-valued vector $\mathbf{e}1$ for negativity, our rankings show a relevant improvement, ranging from -8.56% ($\mathbf{e}2$) to -48.27% ($\mathbf{e}4$).

Our results are particularly significant for the $\mathbf{e}4$ vectors, derived by SentiWordNet 1.0, for a number of reasons. First, $\mathbf{e}4$ brings about the best value of τ_p obtained in all our experiments (.325 for positivity, .284 for negativity). Second, the relative improvement with respect to $\mathbf{e}4$ is the most marked among the various choices for $\mathbf{e}$ (6.75% for positivity, 4.31% for negativity). Third, the improvement is obtained with respect to an already high-quality resource, obtained by the same techniques that, at the term level, are still the best performers for polarity detection on the widely used General Inquirer benchmark (Esuli and Sebastiani, 2005).

Finally, observe that the fact that $\mathbf{e}4$ outperforms all other choices for $\mathbf{e}$ (and $\mathbf{e}2$ in particular) was not necessarily to be expected. In fact, SentiWordNet 1.0 was built by a semi-supervised learning method that uses vectors $\mathbf{e}2$ as its only initial training data. This paper thus shows that, starting from $\mathbf{e}2$ as the only manually annotated data, the best results are obtained neither by the semi-supervised method that generated SentiWordNet 1.0, nor by PageRank, but by the concatenation of the former with the latter.

		Positivity		Negativity	
$\mathbf{e}$	PageRank?	τ_p	Δ	τ_p	Δ
$\mathbf{e}1$	before	.500		.500	
	after	.496	(-0.81%)	.549	(9.83%)
$\mathbf{e}2$	before	.500		.500	
	after	.467	(-6.65%)	.502	(0.31%)
$\mathbf{e}3$	before	.500		.500	
	after	.471	(-5.79%)	.495	(-0.92%)
$\mathbf{e}4$	before	.349		.296	
	after	**.325**	(-6.75%)	**.284**	(-4.31%)
$\mathbf{e}5$	before	.400		.407	
	after	.380	(-4.88%)	.393	(-3.45%)

Table 1: Values of τ_p between predicted rankings and gold standard rankings (smaller is better). For each experiment the first line indicates the ranking obtained from the original $\mathbf{e}$ vector (before the application of PageRank), while the second line indicates the ranking obtained after the application of PageRank, with the relative improvement (a negative percentage indicates improvement).

6 Conclusions

We have investigated the applicability of a random-walk model to the problem of ranking synsets according to positivity and negativity. However, we conjecture that this model can be of more general use, i.e., for the determination of other properties of term senses, such as membership in a domain. This paper thus presents a proof-of-concept of the model, and the results of experiments support our intuitions.

Also, we see this work as a proof of concept for the applicability of general random-walk algorithms (and not just PageRank) to the determination of the semantic properties of synsets. In a more recent paper (Esuli and Sebastiani, 2007a) we have investigated a related random-walk model, one in which, symmetrically to the intuitions of the model presented in this paper, semantics flows from the *definiens* to the *definiendum*; a metaphor that proves no less powerful than the one we have championed in this paper.

Abstract

In this paper we investigate a structured model for jointly classifying the sentiment of text at varying levels of granularity. Inference in the model is based on standard sequence classification techniques using constrained Viterbi to ensure consistent solutions. The primary advantage of such a model is that it allows classification decisions from one level in the text to influence decisions at another. Experiments show that this method can significantly reduce classification error relative to models trained in isolation.

1 Introduction

Extracting sentiment from text is a challenging problem with applications throughout Natural Language Processing and Information Retrieval. Previous work on sentiment analysis has covered a wide range of tasks, including polarity classification (Pang et al., 2002; Turney, 2002), opinion extraction (Pang and Lee, 2004), and opinion source assignment (Choi et al., 2005; Choi et al., 2006). Furthermore, these systems have tackled the problem at different levels of granularity, from the document level (Pang et al., 2002), sentence level (Pang and Lee, 2004; Mao and Lebanon, 2006), phrase level (Turney, 2002; Choi et al., 2005), as well as the speaker level in debates (Thomas et al., 2006). The ability to classify sentiment on multiple levels is important since different applications have different needs. For example, a summarization system for product reviews might require polarity classification at the sentence or phrase level; a question answering system would most likely require the sentiment of paragraphs; and a system that determines which articles from an online news source are editorial in nature would require a document level analysis.

This work focuses on models that jointly classify sentiment on multiple levels of granularity. Consider the following example,

> *This is the first Mp3 player that I have used ... I thought it sounded great ... After only a few weeks, it started having trouble with the earphone connection ... I won't be buying another.*
>
> Mp3 player review from Amazon.com

This excerpt expresses an overall negative opinion of the product being reviewed. However, not all parts of the review are negative. The first sentence merely provides some context on the reviewer's experience with such devices and the second sentence indicates that, at least in one regard, the product performed well. We call the problem of identifying the sentiment of the document and of all its subcomponents, whether at the paragraph, sentence, phrase or word level, *fine-to-coarse sentiment analysis*.

The simplest approach to fine-to-coarse sentiment analysis would be to create a separate system for each level of granularity. There are, however, obvious advantages to building a single model that classifies each level in tandem. Consider the sentence,

> *My 11 year old daughter has also been using it and it is a lot harder than it looks.*

In isolation, this sentence appears to convey negative sentiment. However, it is part of a favorable review

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 432–439,
Prague, Czech Republic, June 2007.

for a piece of fitness equipment, where *hard* essentially means *good workout*. In this domain, *hard*'s sentiment can only be determined in context (i.e., *hard* to assemble versus a *hard* workout). If the classifier knew the overall sentiment of a document, then disambiguating such cases would be easier.

Conversely, document level analysis can benefit from finer level classification by taking advantage of common discourse cues, such as the last sentence being a reliable indicator for overall sentiment in reviews. Furthermore, during training, the model will not need to modify its parameters to explain phenomena like the typically positive word *great* appearing in a negative text (as is the case above). The model can also avoid overfitting to features derived from neutral or objective sentences. In fact, it has already been established that sentence level classification can improve document level analysis (Pang and Lee, 2004). This line of reasoning suggests that a cascaded approach would also be insufficient. Valuable information is passed in both directions, which means any model of fine-to-coarse analysis should account for this.

In Section 2 we describe a simple structured model that jointly learns and infers sentiment on different levels of granularity. In particular, we reduce the problem of joint sentence and document level analysis to a sequential classification problem using constrained Viterbi inference. Extensions to the model that move beyond just two-levels of analysis are also presented. In Section 3 an empirical evaluation of the model is given that shows significant gains in accuracy over both single level classifiers and cascaded systems.

1.1 Related Work

The models in this work fall into the broad class of global structured models, which are typically trained with structured learning algorithms. Hidden Markov models (Rabiner, 1989) are one of the earliest structured learning algorithms, which have recently been followed by discriminative learning approaches such as conditional random fields (CRFs) (Lafferty et al., 2001; Sutton and McCallum, 2006), the structured perceptron (Collins, 2002) and its large-margin variants (Taskar et al., 2003; Tsochantaridis et al., 2004; McDonald et al., 2005; Daumé III et al., 2006). These algorithms are usually applied to sequential labeling or chunking, but have also been applied to parsing (Taskar et al., 2004; McDonald et al., 2005), machine translation (Liang et al., 2006) and summarization (Daumé III et al., 2006).

Structured models have previously been used for sentiment analysis. Choi et al. (2005, 2006) use CRFs to learn a global sequence model to classify and assign sources to opinions. Mao and Lebanon (2006) used a sequential CRF regression model to measure polarity on the sentence level in order to determine the *sentiment flow* of authors in reviews. Here we show that fine-to-coarse models of sentiment can often be reduced to the sequential case.

Cascaded models for fine-to-coarse sentiment analysis were studied by Pang and Lee (2004). In that work an initial model classified each sentence as being subjective or objective using a global min-cut inference algorithm that considered local labeling consistencies. The top subjective sentences are then input into a standard document level polarity classifier with improved results. The current work differs from that in Pang and Lee through the use of a single joint structured model for both sentence and document level analysis.

Many problems in natural language processing can be improved by learning and/or predicting multiple outputs jointly. This includes parsing and relation extraction (Miller et al., 2000), entity labeling and relation extraction (Roth and Yih, 2004), and part-of-speech tagging and chunking (Sutton et al., 2004). One interesting work on sentiment analysis is that of Popescu and Etzioni (2005) which attempts to classify the sentiment of phrases with respect to possible product features. To do this an iterative algorithm is used that attempts to globally maximize the classification of all phrases while satisfying local consistency constraints.

2 Structured Model

In this section we present a structured model for fine-to-coarse sentiment analysis. We start by examining the simple case with two-levels of granularity – the sentence and document – and show that the problem can be reduced to sequential classification with constrained inference. We then discuss the feature space and give an algorithm for learning the parameters based on large-margin structured learning.

Extensions to the model are also examined.

2.1 A Sentence-Document Model

Let $\mathcal{Y}(d)$ be a discrete set of sentiment labels at the document level and $\mathcal{Y}(s)$ be a discrete set of sentiment labels at the sentence level. As input a system is given a document containing sentences $\boldsymbol{s} = s_1, \ldots, s_n$ and must produce sentiment labels for the document, $y^d \in \mathcal{Y}(d)$, and each individual sentence, $\boldsymbol{y}^s = y^s_1, \ldots, y^s_n$, where $y^s_i \in \mathcal{Y}(s)\ \forall\ 1 \leq i \leq n$. Define $\boldsymbol{y} = (y^d, \boldsymbol{y}^s) = (y^d, y^s_1, \ldots, y^s_n)$ as the joint labeling of the document and sentences. For instance, in Pang and Lee (2004), y^d would be the polarity of the document and y^s_i would indicate whether sentence s_i is subjective or objective. The models presented here are compatible with arbitrary sets of discrete output labels.

Figure 1 presents a model for jointly classifying the sentiment of both the sentences and the document. In this undirected graphical model, the label of each sentence is dependent on the labels of its neighbouring sentences plus the label of the document. The label of the document is dependent on the label of every sentence. Note that the edges between the input (each sentence) and the output labels are not solid, indicating that they are given as input and are not being modeled. The fact that the sentiment of sentences is dependent not only on the local sentiment of other sentences, but also the global document sentiment – and vice versa – allows the model to directly capture the importance of classification decisions across levels in fine-to-coarse sentiment analysis. The local dependencies between sentiment labels on sentences is similar to the work of Pang and Lee (2004) where soft local consistency constraints were created between every sentence in a document and inference was solved using a min-cut algorithm. However, jointly modeling the document label and allowing for non-binary labels complicates min-cut style solutions as inference becomes intractable.

Learning and inference in undirected graphical models is a well studied problem in machine learning and NLP. For example, CRFs define the probability over the labels conditioned on the input using the property that the joint probability distribution over the labels factors over clique potentials in undirected graphical models (Lafferty et al., 2001).

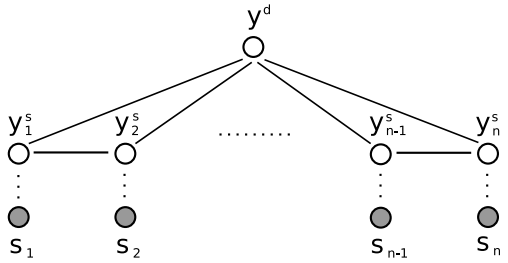

Figure 1: Sentence and document level model.

In this work we will use structured linear classifiers (Collins, 2002). We denote the score of a labeling $\boldsymbol{y}$ for an input $\boldsymbol{s}$ as $score(\boldsymbol{y}, \boldsymbol{s})$ and define this score as the sum of scores over each clique,

$$\begin{aligned} score(\boldsymbol{y}, \boldsymbol{s}) &= score((y^d, \boldsymbol{y}^s), \boldsymbol{s}) \\ &= score((y^d, y^s_1, \ldots, y^s_n), \boldsymbol{s}) \\ &= \sum_{i=2}^{n} score(y^d, y^s_{i-1}, y^s_i, \boldsymbol{s}) \end{aligned}$$

where each clique score is a linear combination of features and their weights,

$$score(y^d, y^s_{i-1}, y^s_i, \boldsymbol{s}) = \mathbf{w} \cdot \mathbf{f}(y^d, y^s_{i-1}, y^s_i, \boldsymbol{s}) \quad (1)$$

and $\mathbf{f}$ is a high dimensional feature representation of the clique and $\mathbf{w}$ a corresponding weight vector. Note that $\boldsymbol{s}$ is included in each score since it is given as input and can always be conditioned on.

In general, inference in undirected graphical models is intractable. However, for the common case of sequences (a.k.a. linear-chain models) the Viterbi algorithm can be used (Rabiner, 1989; Lafferty et al., 2001). Fortunately there is a simple technique that reduces inference in the above model to sequence classification with a constrained version of Viterbi.

2.1.1 Inference as Sequential Labeling

The inference problem is to find the highest scoring labeling $\boldsymbol{y}$ for an input $\boldsymbol{s}$, i.e.,

$$\arg\max_{\boldsymbol{y}} \ score(\boldsymbol{y}, \boldsymbol{s})$$

If the document label y^d is fixed, then inference in the model from Figure 1 reduces to the sequential case. This is because the search space is only over the sentence labels y^s_i, whose graphical structure forms a chain. Thus the problem of finding the

Input: $\boldsymbol{s} = s_1, \ldots, s_n$
1. $\boldsymbol{y}$ = null
2. for each $y^d \in \mathcal{Y}(d)$
3. $\quad \boldsymbol{y}^s = \arg\max_{\boldsymbol{y}^s} \; score((y^d, \boldsymbol{y}^s), \boldsymbol{s})$
4. $\quad \boldsymbol{y}' = (y^d, \boldsymbol{y}^s)$
5. $\quad$ if $score(\boldsymbol{y}', \boldsymbol{s}) > score(\boldsymbol{y}, \boldsymbol{s})$ or $\boldsymbol{y}$ = null
6. $\quad\quad \boldsymbol{y} = \boldsymbol{y}'$
7. return $\boldsymbol{y}$

Figure 2: Inference algorithm for model in Figure 1. The argmax in line 3 can be solved using Viterbi's algorithm since y^d is fixed.

highest scoring sentiment labels for all sentences, given a particular document label y^d, can be solved efficiently using Viterbi's algorithm.

The general inference problem can then be solved by iterating over each possible y^d, finding $\boldsymbol{y^s}$ maximizing $score((y^d, \boldsymbol{y^s}), \boldsymbol{s})$ and keeping the single best $\boldsymbol{y} = (y^d, \boldsymbol{y^s})$. This algorithm is outlined in Figure 2 and has a runtime of $O(|\mathcal{Y}(d)||\mathcal{Y}(s)|^2 n)$, due to running Viterbi $|\mathcal{Y}(d)|$ times over a label space of size $|\mathcal{Y}(s)|$. The algorithm can be extended to produce exact k-best lists. This is achieved by using k-best Viterbi techniques to return the k-best global labelings for each document label in line 3. Merging these sets will produce the final k-best list.

It is possible to view the inference algorithm in Figure 2 as a constrained Viterbi search since it is equivalent to flattening the model in Figure 1 to a sequential model with sentence labels from the set $\mathcal{Y}(s) \times \mathcal{Y}(d)$. The resulting Viterbi search would then need to be constrained to ensure consistent solutions, i.e., the label assignments agree on the document label over all sentences. If viewed this way, it is also possible to run a constrained forward-backward algorithm and learn the parameters for CRFs as well.

2.1.2 Feature Space

In this section we define the feature representation for each clique, $\mathbf{f}(y^d, y^s_{i-1}, y^s_i, \boldsymbol{s})$. Assume that each sentence s_i is represented by a set of binary predicates $\mathcal{P}(s_i)$. This set can contain any predicate over the input $\boldsymbol{s}$, but for the present purposes it will include all the unigram, bigram and trigrams in the sentence s_i conjoined with their part-of-speech (obtained from an automatic classifier). Back-offs of each predicate are also included where one or more word is discarded. For instance, if $\mathcal{P}(s_i)$ contains the predicate *a:DT_great:JJ_product:NN*, then it would also have the predicates *a:DT_great:JJ_*:NN*, *a:DT_*:JJ_product:NN*, **:DT_great:JJ_product:NN*, *a:DT_*:JJ_*:NN*, etc. Each predicate, p, is then conjoined with the label information to construct a binary feature. For example, if the sentence label set is $\mathcal{Y}(s) = \{\text{subj}, \text{obj}\}$ and the document set is $\mathcal{Y}(d) = \{\text{pos}, \text{neg}\}$, then the system might contain the following feature,

$$\mathbf{f}_{(j)}(y^d, y^s_{i-1}, y^s_i, \boldsymbol{s}) = \begin{cases} 1 & \text{if } p \in \mathcal{P}(s_i) \\ & \text{and } y^s_{i-1} = \text{obj} \\ & \text{and } y^s_i = \text{subj} \\ & \text{and } y^d = \text{neg} \\ 0 & \text{otherwise} \end{cases}$$

Where $\mathbf{f}_{(j)}$ is the j^{th} dimension of the feature space. For each feature, a set of back-off features are included that only consider the document label y^d, the current sentence label y^s_i, the current sentence and document label y^s_i and y^d, and the current and previous sentence labels y^s_i and y^s_{i-1}. Note that through these back-off features the joint models feature set will subsume the feature set of any individual level model. Only features observed in the training data were considered. Depending on the data set, the dimension of the feature vector $\mathbf{f}$ ranged from 350K to 500K. Though the feature vectors can be sparse, the feature weights will be learned using large-margin techniques that are well known to be robust to large and sparse feature representations.

2.1.3 Training the Model

Let $\mathcal{Y} = \mathcal{Y}(d) \times \mathcal{Y}(s)^n$ be the set of all valid sentence-document labelings for an input $\boldsymbol{s}$. The weights, $\mathbf{w}$, are set using the MIRA learning algorithm, which is an inference based online large-margin learning technique (Crammer and Singer, 2003; McDonald et al., 2005). An advantage of this algorithm is that it relies only on inference to learn the weight vector (see Section 2.1.1). MIRA has been shown to provide state-of-the-art accuracy for many language processing tasks including parsing, chunking and entity extraction (McDonald, 2006).

The basic algorithm is outlined in Figure 3. The algorithm works by considering a single training instance during each iteration. The weight vector $\mathbf{w}$ is updated in line 4 through a quadratic programming problem. This update modifies the weight vector so

Training data: $\mathcal{T} = \{(\boldsymbol{y}_t, \boldsymbol{s}_t)\}_{t=1}^{T}$

1. $\mathbf{w}^{(0)} = 0;\ i = 0$
2. for $n : 1..N$
3. for $t : 1..T$
4. $\mathbf{w}^{(i+1)} = \arg\min_{\mathbf{w}^*} \left\|\mathbf{w}^* - \mathbf{w}^{(i)}\right\|$
   s.t. $score(\boldsymbol{y}_t, \boldsymbol{s}_t) - score(\boldsymbol{y}', \boldsymbol{s}) \geq L(\boldsymbol{y}_t, \boldsymbol{y}')$
   relative to $\mathbf{w}^*$
   $\forall \boldsymbol{y}' \in \mathcal{C} \subset \mathcal{Y}$, where $|\mathcal{C}| = k$
5. $i = i + 1$
6. return $\mathbf{w}^{(N \times T)}$

Figure 3: MIRA learning algorithm.

that the score of the correct labeling is larger than the score of every labeling in a constraint set $\mathcal{C}$ with a margin proportional to the loss. The constraint set $\mathcal{C}$ can be chosen arbitrarily, but it is usually taken to be the k labelings that have the highest score under the old weight vector $\mathbf{w}^{(i)}$ (McDonald et al., 2005). In this manner, the learning algorithm can update its parameters relative to those labelings closest to the decision boundary. Of all the weight vectors that satisfy these constraints, MIRA chooses the one that is as close as possible to the previous weight vector in order to retain information about previous updates.

The loss function $L(\boldsymbol{y}, \boldsymbol{y}')$ is a positive real valued function and is equal to zero when $\boldsymbol{y} = \boldsymbol{y}'$. This function is task specific and is usually the hamming loss for sequence classification problems (Taskar et al., 2003). Experiments with different loss functions for the joint sentence-document model on a development data set indicated that the hamming loss over sentence labels multiplied by the 0-1 loss over document labels worked best.

An important modification that was made to the learning algorithm deals with how the k constraints are chosen for the optimization. Typically these constraints are the k highest scoring labelings under the current weight vector. However, early experiments showed that the model quickly learned to discard any labeling with an incorrect document label for the instances in the training set. As a result, the constraints were dominated by labelings that only differed over sentence labels. This did not allow the algorithm adequate opportunity to set parameters relative to incorrect document labeling decisions. To combat this, k was divided by the number of document labels, to get a new value k'. For each document label, the k' highest scoring labelings were

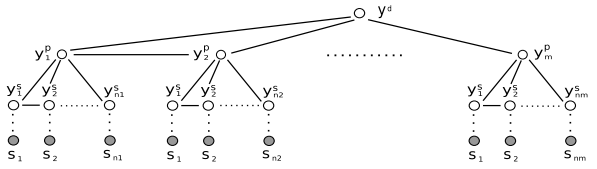

Figure 4: An extension to the model from Figure 1 incorporating paragraph level analysis.

extracted. Each of these sets were then combined to produce the final constraint set. This allowed constraints to be equally distributed amongst different document labels.

Based on performance on the development data set the number of training iterations was set to $N = 5$ and the number of constraints to $k = 10$. Weight averaging was also employed (Collins, 2002), which helped improve performance.

2.2 Beyond Two-Level Models

To this point, we have focused solely on a model for two-level fine-to-coarse sentiment analysis not only for simplicity, but because the experiments in Section 3 deal exclusively with this scenario. In this section, we briefly discuss possible extensions for more complex situations. For example, longer documents might benefit from an analysis on the paragraph level as well as the sentence and document levels. One possible model for this case is given in Figure 4, which essentially inserts an additional layer between the sentence and document level from the original model. Sentence level analysis is dependent on neighbouring sentences as well as the paragraph level analysis, and the paragraph analysis is dependent on each of the sentences within it, the neighbouring paragraphs, and the document level analysis. This can be extended to an arbitrary level of fine-to-coarse sentiment analysis by simply inserting new layers in this fashion to create more complex hierarchical models.

The advantage of using hierarchical models of this form is that they are nested, which keeps inference tractable. Observe that each pair of adjacent levels in the model is equivalent to the original model from Figure 1. As a result, the scores of the every label at each node in the graph can be calculated with a straight-forward bottom-up dynamic programming algorithm. Details are omitted

	Sentence Stats				Document Stats		
	Pos	Neg	Neu	Tot	Pos	Neg	Tot
Car	472	443	264	1179	98	80	178
Fit	568	635	371	1574	92	97	189
Mp3	485	464	214	1163	98	89	187
Tot	1525	1542	849	3916	288	266	554

Table 1: Data statistics for corpus. Pos = positive polarity, Neg = negative polarity, Neu = no polarity.

for space reasons.

Other models are possible where dependencies occur across non-neighbouring levels, e.g., by inserting edges between the sentence level nodes and the document level node. In the general case, inference is exponential in the size of each clique. Both the models in Figure 1 and Figure 4 have maximum clique sizes of three.

3 Experiments

3.1 Data

To test the model we compiled a corpus of 600 online product reviews from three domains: car seats for children, fitness equipment, and Mp3 players. Of the original 600 reviews that were gathered, we discarded duplicate reviews, reviews with insufficient text, and spam. All reviews were labeled by online customers as having a positive or negative polarity on the document level, i.e., $\mathcal{Y}(d) = \{\text{pos}, \text{neg}\}$. Each review was then split into sentences and every sentence annotated by a single annotator as either being positive, negative or neutral, i.e., $\mathcal{Y}(s) = \{\text{pos}, \text{neg}, \text{neu}\}$. Data statistics for the corpus are given in Table 1.

All sentences were annotated based on their context within the document. Sentences were annotated as neutral if they conveyed no sentiment or had indeterminate sentiment from their context. Many neutral sentences pertain to the circumstances under which the product was purchased. A common class of sentences were those containing product features. These sentences were annotated as having positive or negative polarity if the context supported it. This could include punctuation such as exclamation points, smiley/frowny faces, question marks, etc. The supporting evidence could also come from another sentence, e.g., *"I love it. It has 64Mb of memory and comes with a set of earphones"*.

3.2 Results

Three baseline systems were created,

- **Document-Classifier** is a classifier that learns to predict the document label only.
- **Sentence-Classifier** is a classifier that learns to predict sentence labels in isolation of one another, i.e., without consideration for either the document or neighbouring sentences sentiment.
- **Sentence-Structured** is another sentence classifier, but this classifier uses a sequential chain model to learn and classify sentences. The third baseline is essentially the model from Figure 1 without the top level document node. This baseline will help to gage the empirical gains of the different components of the joint structured model on sentence level classification.

The model described in Section 2 will be called **Joint-Structured**. All models use the same basic predicate space: unigram, bigram, trigram conjoined with part-of-speech, plus back-offs of these (see Section 2.1.2 for more). However, due to the structure of the model and its label space, the feature space of each might be different, e.g., the document classifier will only conjoin predicates with the document label to create the feature set. All models are trained using the MIRA learning algorithm.

Results for each model are given in the first four rows of Table 2. These results were gathered using 10-fold cross validation with one fold for development and the other nine folds for evaluation. This table shows that classifying sentences in isolation from one another is inferior to accounting for a more global context. A significant increase in performance can be obtained when labeling decisions between sentences are modeled (Sentence-Structured). More interestingly, even further gains can be had when document level decisions are modeled (Joint-Structured). In many cases, these improvements are highly statistically significant.

On the document level, performance can also be improved by incorporating sentence level decisions – though these improvements are not consistent. This inconsistency may be a result of the model overfitting on the small set of training data. We

suspect this because the document level error rate on the Mp3 training set converges to zero much more rapidly for the Joint-Structured model than the Document-Classifier. This suggests that the Joint-Structured model might be relying too much on the sentence level sentiment features – in order to minimize its error rate – instead of distributing the weights across all features more evenly.

One interesting application of sentence level sentiment analysis is summarizing product reviews on retail websites like Amazon.com or review aggregators like Yelp.com. In this setting the correct polarity of a document is often known, but we wish to label sentiment on the sentence or phrase level to aid in generating a cohesive and informative summary. The joint model can be used to classify sentences in this setting by constraining inference to the known fixed document label for a review. If this is done, then sentiment accuracy on the sentence level increases substantially from 62.6% to 70.3%.

Finally we should note that experiments using CRFs to train the structured models and logistic regression to train the local models yielded similar results to those in Table 2.

3.2.1 Cascaded Models

Another approach to fine-to-coarse sentiment analysis is to use a cascaded system. In such a system, a sentence level classifier might first be run on the data, and then the results input into a document level classifier – or vice-versa.[1] Two cascaded systems were built. The first uses the Sentence-Structured classifier to classify all the sentences from a review, then passes this information to the document classifier as input. In particular, for every predicate in the original document classifier, an additional predicate that specifies the polarity of the sentence in which this predicate occurred was created. The second cascaded system uses the document classifier to determine the global polarity, then passes this information as input into the Sentence-Structured model, constructing predicates in a similar manner.

The results for these two systems can be seen in the last two rows of Table 2. In both cases there is a slight improvement in performance suggesting that an iterative approach might be beneficial. That is, a system could start by classifying documents, use the document information to classify sentences, use the sentence information to classify documents, and repeat until convergence. However, experiments showed that this did not improve accuracy over a single iteration and often hurt performance.

Improvements from the cascaded models are far less consistent than those given from the joint structure model. This is because decisions in the cascaded system are passed to the next layer as the "gold" standard at test time, which results in errors from the first classifier propagating to errors in the second. This could be improved by passing a lattice of possibilities from the first classifier to the second with corresponding confidences. However, solutions such as these are really just approximations of the joint structured model that was presented here.

4 Future Work

One important extension to this work is to augment the models for partially labeled data. It is realistic to imagine a training set where many examples do not have every level of sentiment annotated. For example, there are thousands of online product reviews with labeled document sentiment, but a much smaller amount where sentences are also labeled. Work on learning with hidden variables can be used for both CRFs (Quattoni et al., 2004) and for inference based learning algorithms like those used in this work (Liang et al., 2006).

Another area of future work is to empirically investigate the use of these models on longer documents that require more levels of sentiment analysis than product reviews. In particular, the relative position of a phrase to a contrastive discourse connective or a cue phrase like "in conclusion" or "to summarize" may lead to improved performance since higher level classifications can learn to weigh information passed from these lower level components more heavily.

5 Discussion

In this paper we have investigated the use of a global structured model that learns to predict sentiment on different levels of granularity for a text. We de-

[1] Alternatively, decisions from the sentence classifier can guide which input is seen by the document level classifier (Pang and Lee, 2004).

	Sentence Accuracy				Document Accuracy			
	Car	Fit	Mp3	Total	Car	Fit	Mp3	Total
Document-Classifier	-	-	-	-	72.8	80.1	**87.2**	80.3
Sentence-Classifier	54.8	56.8	49.4	53.1	-	-	-	-

scribed a simple model for sentence-document analysis and showed that inference in it is tractable. Experiments show that this model obtains higher accuracy than classifiers trained in isolation as well as cascaded systems that pass information from one level to another at test time. Furthermore, extensions to the sentence-document model were discussed and it was argued that a nested hierarchical structure would be beneficial since it would allow for efficient inference algorithms.

Abstract

Automatic sentiment classification has been extensively studied and applied in recent years. However, sentiment is expressed differently in different domains, and annotating corpora for every possible domain of interest is impractical. We investigate domain adaptation for sentiment classifiers, focusing on online reviews for different types of products. First, we extend to sentiment classification the recently-proposed structural correspondence learning (SCL) algorithm, reducing the relative error due to adaptation between domains by an average of 30% over the original SCL algorithm and 46% over a supervised baseline. Second, we identify a measure of domain similarity that correlates well with the potential for adaptation of a classifier from one domain to another. This measure could for instance be used to select a small set of domains to annotate whose trained classifiers would transfer well to many other domains.

1 Introduction

Sentiment detection and classification has received considerable attention recently (Pang et al., 2002; Turney, 2002; Goldberg and Zhu, 2004). While movie reviews have been the most studied domain, sentiment analysis has extended to a number of new domains, ranging from stock message boards to congressional floor debates (Das and Chen, 2001; Thomas et al., 2006). Research results have been deployed industrially in systems that gauge market reaction and summarize opinion from Web pages, discussion boards, and blogs.

With such widely-varying domains, researchers and engineers who build sentiment classification systems need to collect and curate data for each new domain they encounter. Even in the case of market analysis, if automatic sentiment classification were to be used across a wide range of domains, the effort to annotate corpora for each domain may become prohibitive, especially since product features change over time. We envision a scenario in which developers annotate corpora for a small number of domains, train classifiers on those corpora, and then apply them to other similar corpora. However, this approach raises two important questions. First, it is well known that trained classifiers lose accuracy when the test data distribution is significantly different from the training data distribution [1]. Second, it is not clear which notion of domain similarity should be used to select domains to annotate that would be good proxies for many other domains.

We propose solutions to these two questions and evaluate them on a corpus of reviews for four different types of products from Amazon: books, DVDs, electronics, and kitchen appliances[2]. First, we show how to extend the recently proposed structural cor-

respondence learning (SCL) domain adaptation algorithm (Blitzer et al., 2006) for use in sentiment classification. A key step in SCL is the selection of *pivot features* that are used to link the source and target domains. We suggest selecting pivots based not only on their common frequency but also according to their mutual information with the source labels. For data as diverse as product reviews, SCL can sometimes misalign features, resulting in degradation when we adapt between domains. In our second extension we show how to correct misalignments using a very small number of labeled instances.

Second, we evaluate the $\mathcal{A}$-distance (Ben-David et al., 2006) between domains as measure of the loss due to adaptation from one to the other. The $\mathcal{A}$-distance can be measured from unlabeled data, and it was designed to take into account only divergences which affect classification accuracy. We show that it correlates well with adaptation loss, indicating that we can use the $\mathcal{A}$-distance to select a subset of domains to label as sources.

In the next section we briefly review SCL and introduce our new pivot selection method. Section 3 describes datasets and experimental method. Section 4 gives results for SCL and the mutual information method for selecting pivot features. Section 5 shows how to correct feature misalignments using a small amount of labeled target domain data. Section 6 motivates the $\mathcal{A}$-distance and shows that it correlates well with adaptability. We discuss related work in Section 7 and conclude in Section 8.

2 Structural Correspondence Learning

Before reviewing SCL, we give a brief illustrative example. Suppose that we are adapting from reviews of computers to reviews of cell phones. While many of the features of a good cell phone review are the same as a computer review – the words "excellent" and "awful" for example – many words are totally new, like "reception". At the same time, many features which were useful for computers, such as "dual-core" are no longer useful for cell phones.

Our key intuition is that even when "good-quality reception" and "fast dual-core" are completely distinct for each domain, if they both have high correlation with "excellent" and low correlation with "awful" on *unlabeled* data, then we can tentatively align them. After learning a classifier for computer reviews, when we see a cell-phone feature like "good-quality reception", we know it should behave in a roughly similar manner to "fast dual-core".

2.1 Algorithm Overview

Given labeled data from a source domain and unlabeled data from both source and target domains, SCL first chooses a set of m pivot features which occur frequently in both domains. Then, it models the correlations between the pivot features and all other features by training linear pivot predictors to predict occurrences of each pivot in the unlabeled data from both domains (Ando and Zhang, 2005; Blitzer et al., 2006). The ℓth pivot predictor is characterized by its weight vector $\mathbf{w}_\ell$; positive entries in that weight vector mean that a non-pivot feature (like "fast dual-core") is highly correlated with the corresponding pivot (like "excellent").

The pivot predictor column weight vectors can be arranged into a matrix $W = [\mathbf{w}_\ell]_{\ell=1}^{n}$. Let $\theta \in \mathbb{R}^{k \times d}$ be the top k left singular vectors of W (here d indicates the total number of features). These vectors are the principal predictors for our weight space. If we chose our pivot features well, then we expect these principal predictors to discriminate among positive and negative words in both domains.

At training and test time, suppose we observe a feature vector $\mathbf{x}$. We apply the projection $\theta\mathbf{x}$ to obtain k new real-valued features. Now we learn a predictor for the augmented instance $\langle \mathbf{x}, \theta\mathbf{x} \rangle$. If θ contains meaningful correspondences, then the predictor which uses θ will perform well in both source and target domains.

2.2 Selecting Pivots with Mutual Information

The efficacy of SCL depends on the choice of pivot features. For the part of speech tagging problem studied by Blitzer et al. (2006), frequently-occurring words in both domains were good choices, since they often correspond to function words such as prepositions and determiners, which are good indicators of parts of speech. This is not the case for sentiment classification, however. Therefore, we require that pivot features also be good predictors of the source label. Among those features, we then choose the ones with highest mutual information to the source label. Table 1 shows the set-symmetric

differences between the two methods for pivot selection when adapting a classifier from books to kitchen appliances. We refer throughout the rest of this work to our method for selecting pivots as SCL-MI.

3 Dataset and Baseline

We constructed a new dataset for sentiment domain adaptation by selecting Amazon product reviews for four different product types: books, DVDs, electronics and kitchen appliances. Each review consists of a rating (0-5 stars), a reviewer name and location, a product name, a review title and date, and the review text. Reviews with rating > 3 were labeled positive, those with rating < 3 were labeled negative, and the rest discarded because their polarity was ambiguous. After this conversion, we had 1000 positive and 1000 negative examples for each domain, the same balanced composition as the polarity dataset (Pang et al., 2002). In addition to the labeled data, we included between 3685 (DVDs) and 5945 (kitchen) instances of unlabeled data. The size of the unlabeled data was limited primarily by the number of reviews we could crawl and download from the Amazon website. Since we were able to obtain labels for all of the reviews, we also ensured that they were balanced between positive and negative examples, as well.

While the polarity dataset is a popular choice in the literature, we were unable to use it for our task. Our method requires many unlabeled reviews and despite a large number of IMDB reviews available online, the extensive curation requirements made preparing a large amount of data difficult [3].

For classification, we use linear predictors on unigram and bigram features, trained to minimize the Huber loss with stochastic gradient descent (Zhang, 2004). On the polarity dataset, this model matches the results reported by Pang et al. (2002). When we report results with SCL and SCL-MI, we require that pivots occur in more than five documents in each domain. We set k, the number of singular vectors of the weight matrix, to 50.

[3]For a description of the construction of the polarity dataset, see `http://www.cs.cornell.edu/people/pabo/movie-review-data/`.

4 Experiments with SCL and SCL-MI

Each labeled dataset was split into a training set of 1600 instances and a test set of 400 instances. All the experiments use a classifier trained on the training set of one domain and tested on the test set of a possibly different domain. The baseline is a linear classifier trained without adaptation, while the gold standard is an in-domain classifier trained on the same domain as it is tested.

Figure 1 gives accuracies for all pairs of domain adaptation. The domains are ordered clockwise from the top left: books, DVDs, electronics, and kitchen. For each set of bars, the first letter is the source domain and the second letter is the target domain. The thick horizontal bars are the accuracies of the in-domain classifiers for these domains. Thus the first set of bars shows that the baseline achieves 72.8% accuracy adapting from DVDs to books. SCL-MI achieves 79.7% and the in-domain gold standard is 80.4%. We say that the *adaptation loss* for the baseline model is 7.6% and the adaptation loss for the SCL-MI model is 0.7%. The *relative reduction in error due to adaptation* of SCL-MI for this test is 90.8%.

We can observe from these results that there is a rough grouping of our domains. Books and DVDs are similar, as are kitchen appliances and electronics, but the two groups are different from one another. Adapting classifiers from books to DVDs, for instance, is easier than adapting them from books to kitchen appliances. We note that when transferring from kitchen to electronics, SCL-MI actually outperforms the in-domain classifier. This is possible since the unlabeled data may contain information that the in-domain classifier does not have access to.

At the beginning of Section 2 we gave examples of how features can change behavior across domains. The first type of behavior is when predictive features from the source domain are not predictive or do not appear in the target domain. The second is

Table 2: Correspondences discovered by SCL for books and kitchen appliances. The top row shows features that only appear in books and the bottom features that only appear in kitchen appliances. The left and right columns show negative and positive features in correspondence, respectively.

when predictive features from the target domain do not appear in the source domain. To show how SCL deals with those domain mismatches, we look at the adaptation from book reviews to reviews of kitchen appliances. We selected the top 1000 most informative features in both domains. In both cases, between 85 and 90% of the informative features from one domain were not among the most informative of the other domain[4]. SCL addresses both of these issues simultaneously by aligning features from the two domains.

Table 2 illustrates one row of the projection matrix θ for adapting from books to kitchen appliances; the features on each row appear only in the corresponding domain. A supervised classifier trained on book reviews cannot assign weight to the kitchen features in the second row of table 2. In contrast, SCL assigns weight to these features indirectly through the projection matrix. When we observe the feature "predictable" with a negative book review, we update parameters corresponding to the entire projection, including the kitchen-specific features "poorly_designed" and "awkward_to".

While some rows of the projection matrix θ are

[4]There is a third type, features which are positive in one domain but negative in another, but they appear very infrequently in our datasets.

useful for classification, SCL can also misalign features. This causes problems when a projection is discriminative in the source domain but not in the target. This is the case for adapting from kitchen appliances to books. Since the book domain is quite broad, many projections in books model topic distinctions such as between religious and political books. These projections, which are uninformative as to the target label, are put into correspondence with the fewer discriminating projections in the much narrower kitchen domain. When we adapt from kitchen to books, we assign weight to these uninformative projections, degrading target classification accuracy.

5 Correcting Misalignments

We now show how to use a small amount of target domain labeled data to learn to ignore misaligned projections from SCL-MI. Using the notation of Ando and Zhang (2005), we can write the supervised training objective of SCL on the source domain as

$$\min_{\mathbf{w},\mathbf{v}} \sum_i L\left(\mathbf{w}'\mathbf{x}_i + \mathbf{v}'\theta\mathbf{x}_i, y_i\right) + \lambda||\mathbf{w}||^2 + \mu||\mathbf{v}||^2 \,,$$

where y is the label. The weight vector $\mathbf{w} \in \mathbb{R}^d$ weighs the original features, while $\mathbf{v} \in \mathbb{R}^k$ weighs the projected features. Ando and Zhang (2005) and Blitzer et al. (2006) suggest $\lambda = 10^{-4}, \mu = 0$, which we have used in our results so far.

Suppose now that we have trained source model weight vectors $\mathbf{w}_s$ and $\mathbf{v}_s$. A small amount of target domain data is probably insufficient to significantly change $\mathbf{w}$, but we can correct $\mathbf{v}$, which is much smaller. We augment each labeled target instance $\mathbf{x}_j$ with the label assigned by the source domain classifier (Florian et al., 2004; Blitzer et al., 2006). Then we solve

$$\min_{\mathbf{w},\mathbf{v}} \sum_j L\left(\mathbf{w}'\mathbf{x}_j + \mathbf{v}'\theta\mathbf{x}_j, y_j\right) + \lambda||\mathbf{w}||^2 + \mu||\mathbf{v} - \mathbf{v}_s||^2 \,.$$

Since we don't want to deviate significantly from the source parameters, we set $\lambda = \mu = 10^{-1}$.

Figure 2 shows the corrected SCL-MI model using 50 target domain labeled instances. We chose this number since we believe it to be a reasonable amount for a single engineer to label with minimal effort. For reasons of space, for each target domain we show adaptation from only the two domains on which SCL-MI performed the worst relative to the supervised baseline. For example, the book domain shows only results from electronics and kitchen, but not DVDs. As a baseline, we used the label of the source domain classifier as a feature in the target, but did not use any SCL features. We note that the baseline is very close to just using the source domain classifier, because with only 50 target domain instances we do not have enough data to relearn all of the parameters in $\mathbf{w}$. As we can see, though, relearning the 50 parameters in $\mathbf{v}$ is quite helpful. The corrected model *always* improves over the baseline for every possible transfer, including those not shown in the figure.

dom \ model	base	base +targ	scl	scl-mi	scl-mi +targ
books	8.9	9.0	7.4	5.8	**4.4**
dvd	8.9	8.9	7.8	6.1	**5.3**
electron	8.3	8.5	6.0	5.5	**4.8**
kitchen	10.2	9.9	7.0	5.6	**5.1**
average	9.1	9.1	7.1	5.8	**4.9**

Table 3: For each domain, we show the loss due to transfer for each method, averaged over all domains. The bottom row shows the average loss over all runs.

The idea of using the regularizer of a linear model to encourage the target parameters to be close to the source parameters has been used previously in domain adaptation. In particular, Chelba and Acero (2004) showed how this technique can be effective for capitalization adaptation. The major difference between our approach and theirs is that we only penalize deviation from the source parameters for the weights $\mathbf{v}$ of projected features, while they work with the weights of the original features only. For our small amount of labeled target data, attempting to penalize $\mathbf{w}$ using $\mathbf{w}_s$ performed no better than our baseline. Because we only need to learn to ignore projections that misalign features, we can make much better use of our labeled data by adapting only 50 parameters, rather than 200,000.

Table 3 summarizes the results of sections 4 and 5. Structural correspondence learning reduces the error due to transfer by 21%. Choosing pivots by mutual information allows us to further reduce the error to 36%. Finally, by adding 50 instances of target domain data and using this to correct the misaligned projections, we achieve an average relative

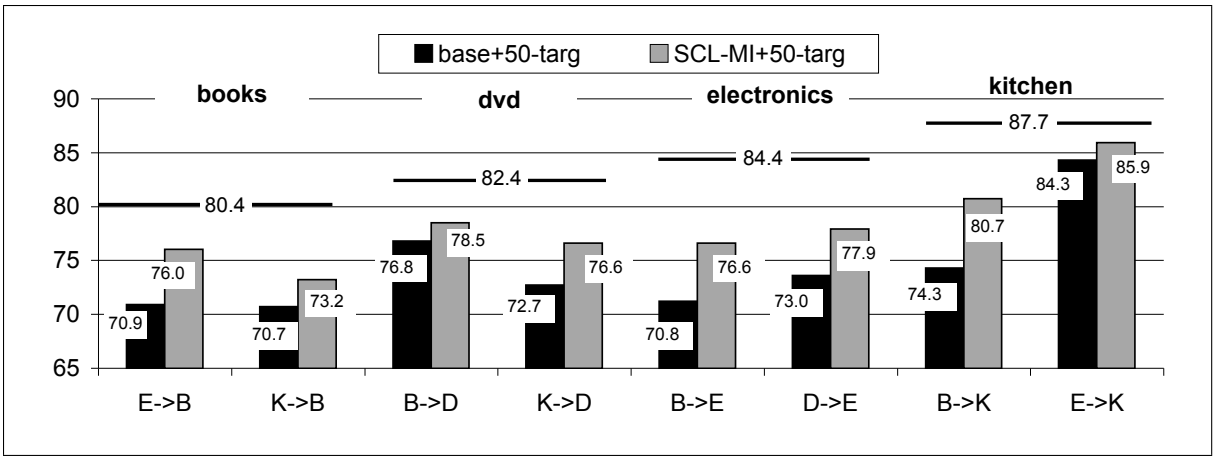

Figure 2: Accuracy results for domain adaptation with 50 labeled target domain instances.

reduction in error of 46%.

6 Measuring Adaptability

Sections 2-5 focused on how to adapt to a target domain when you had a labeled source dataset. We now take a step back to look at the problem of selecting source domain data to label. We study a setting where an engineer knows roughly her domains of interest but does not have any labeled data yet. In that case, she can ask the question "Which sources should I label to obtain the best performance over all my domains?" On our product domains, for example, if we are interested in classifying reviews of kitchen appliances, we know from sections 4-5 that it would be foolish to label reviews of books or DVDs rather than electronics. Here we show how to select source domains using only unlabeled data and the SCL representation.

6.1 The $\mathcal{A}$-distance

We propose to measure domain adaptability by using the divergence of two domains after the SCL projection. We can characterize domains by their induced distributions on instance space: the more different the domains, the more divergent the distributions. Here we make use of the $\mathcal{A}$-distance (Ben-David et al., 2006). The key intuition behind the $\mathcal{A}$-distance is that while two domains can differ in arbitrary ways, we are only interested in the differences that affect classification accuracy.

Let $\mathcal{A}$ be the family of subsets of $\mathbb{R}^k$ corresponding to characteristic functions of linear classifiers (sets on which a linear classifier returns positive value). Then the $\mathcal{A}$ distance between two probability distributions is

$$d_{\mathcal{A}}(\mathcal{D}, \mathcal{D}') = 2 \sup_{A \in \mathcal{A}} |\Pr_{\mathcal{D}}[A] - \Pr_{\mathcal{D}'}[A]| \ .$$

That is, we find the subset in $\mathcal{A}$ on which the distributions differ the most in the L_1 sense. Ben-David et al. (2006) show that computing the $\mathcal{A}$-distance for a finite sample is exactly the problem of minimizing the empirical risk of a classifier that discriminates between instances drawn from $\mathcal{D}$ and instances drawn from $\mathcal{D}'$. This is convenient for us, since it allows us to use classification machinery to compute the $\mathcal{A}$-distance.

6.2 Unlabeled Adaptability Measurements

We follow Ben-David et al. (2006) and use the Huber loss as a proxy for the $\mathcal{A}$-distance. Our procedure is as follows: Given two domains, we compute the SCL representation. Then we create a data set where each instance $\theta\mathbf{x}$ is labeled with the identity of the domain from which it came and train a linear classifier. For each pair of domains we compute the empirical average per-instance Huber loss, subtract it from 1, and multiply the result by 100. We refer to this quantity as the proxy $\mathcal{A}$-distance. When it is 100, the two domains are completely distinct. When it is 0, the two domains are indistinguishable using a linear classifier.

Figure 3 is a correlation plot between the proxy $\mathcal{A}$-distance and the adaptation error. Suppose we wanted to label two domains out of the four in such a

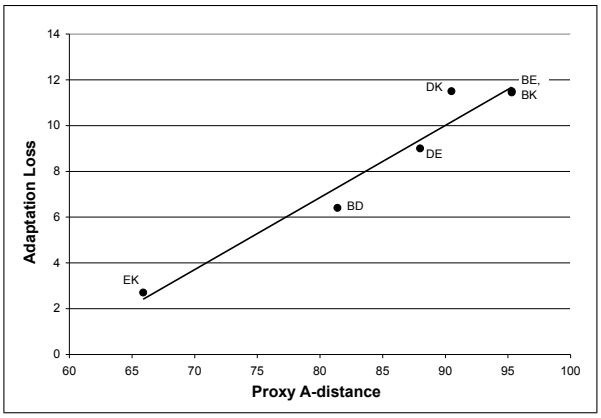

Figure 3: The proxy $\mathcal{A}$-distance between each domain pair plotted against the average adaptation loss of as measured by our baseline system. Each pair of domains is labeled by their first letters: EK indicates the pair electronics and kitchen.

way as to minimize our error on all the domains. Using the proxy $\mathcal{A}$-distance as a criterion, we observe that we would choose one domain from either books or DVDs, but not both, since then we would not be able to adequately cover electronics or kitchen appliances. Similarly we would also choose one domain from either electronics or kitchen appliances, but not both.

7 Related Work

Sentiment classification has advanced considerably since the work of Pang et al. (2002), which we use as our baseline. Thomas et al. (2006) use discourse structure present in congressional records to perform more accurate sentiment classification. Pang and Lee (2005) treat sentiment analysis as an ordinal ranking problem. In our work we only show improvement for the basic model, but all of these new techniques also make use of lexical features. Thus we believe that our adaptation methods could be also applied to those more refined models.

While work on domain adaptation for sentiment classifiers is sparse, it is worth noting that other researchers have investigated unsupervised and semisupervised methods for domain adaptation. The work most similar in spirit to ours that of Turney (2002). He used the difference in mutual information with two human-selected features (the words "excellent" and "poor") to score features in a completely unsupervised manner. Then he classified documents according to various functions of these mutual information scores. We stress that our method improves a supervised baseline. While we do not have a direct comparison, we note that Turney (2002) performs worse on movie reviews than on his other datasets, the same type of data as the polarity dataset.

We also note the work of Aue and Gamon (2005), who performed a number of empirical tests on domain adaptation of sentiment classifiers. Most of these tests were unsuccessful. We briefly note their results on combining a number of source domains. They observed that source domains closer to the target helped more. In preliminary experiments we confirmed these results. Adding more labeled data always helps, but diversifying training data does not. When classifying kitchen appliances, for any fixed amount of labeled data, it is always better to draw from electronics as a source than use some combination of all three other domains.

Domain adaptation alone is a generally well-studied area, and we cannot possibly hope to cover all of it here. As we noted in Section 5, we are able to significantly outperform basic structural correspondence learning (Blitzer et al., 2006). We also note that while Florian et al. (2004) and Blitzer et al. (2006) observe that including the label of a source classifier as a feature on small amounts of target data tends to improve over using either the source alone or the target alone, we did not observe that for our data. We believe the most important reason for this is that they explore structured prediction problems, where labels of surrounding words from the source classifier may be very informative, even if the current label is not. In contrast our simple binary prediction problem does not exhibit such behavior. This may also be the reason that the model of Chelba and Acero (2004) did not aid in adaptation.

Finally we note that while Blitzer et al. (2006) did combine SCL with labeled target domain data, they only compared using the label of SCL or non-SCL source classifiers as features, following the work of Florian et al. (2004). By only adapting the SCL-related part of the weight vector $\mathbf{v}$, we are able to make better use of our small amount of unlabeled data than these previous techniques.

8 Conclusion

Sentiment classification has seen a great deal of attention. Its application to many different domains of discourse makes it an ideal candidate for domain adaptation. This work addressed two important questions of domain adaptation. First, we showed that for a given source and target domain, we can significantly improve for sentiment classification the structural correspondence learning model of Blitzer et al. (2006). We chose pivot features using not only common frequency among domains but also mutual information with the source labels. We also showed how to correct structural correspondence misalignments by using a small amount of labeled target domain data.

Second, we provided a method for selecting those source domains most likely to adapt well to given target domains. The unsupervised $\mathcal{A}$-distance measure of divergence between domains correlates well with loss due to adaptation. Thus we can use the $\mathcal{A}$-distance to select source domains to label which will give low target domain error.

In the future, we wish to include some of the more recent advances in sentiment classification, as well as addressing the more realistic problem of ranking. We are also actively searching for a larger and more varied set of domains on which to test our techniques.

Clustering Clauses for High-Level Relation Detection: An Information-theoretic Approach

Samuel Brody
School of Informatics
University of Edinburgh
s.brody@sms.ed.ac.uk

Abstract

Recently, there has been a rise of interest in unsupervised detection of high-level semantic relations involving complex units, such as phrases and whole sentences. Typically such approaches are faced with two main obstacles: data sparseness and correctly generalizing from the examples. In this work, we describe the *Clustered Clause* representation, which utilizes information-based clustering and inter-sentence dependencies to create a simplified and generalized representation of the grammatical clause. We implement an algorithm which uses this representation to detect a predefined set of high-level relations, and demonstrate our model's effectiveness in overcoming both the problems mentioned.

1 Introduction

The semantic relationship between words, and the extraction of meaning from syntactic data has been one of the main points of research in the field of computational linguistics (see Section 5 and references therein). Until recently, the focus has remained largely either at the single word or sentence level (for instance: dependency extraction, word-to-word semantic similarity from syntax, etc.) or on relations between units at a very high context level such as the entire paragraph or document (e.g. categorizing documents by topic).

Recently there have been several attempts to define frameworks for detecting and studying interactions at an intermediate context level, and involving whole clauses or sentences. Dagan et al. (2005) have emphasized the importance of detecting textual-entailment/implication between two sentences, and its place as a key component in many real-world applications, such as Information Retrieval and Question Answering.

When designing such a framework, one is faced with several obstacles. As we approach higher levels of complexity, the problem of defining the basic units we study (e.g. words, sentences etc.) and the increasing amount of interactions make the task very difficult. In addition, the data sparseness problem becomes more acute as the data units become more complex and have an increasing number of possible values, despite the fact that many of these values have similar or identical meaning.

In this paper we demonstrate an approach to solving the complexity and data sparseness problems in the task of detecting relations between sentences or clauses. We present the *Clustered Clause* structure, which utilizes information-based clustering and dependencies within the sentence to create a simplified and generalized representation of the grammatical clause and is designed to overcome both these problems.

The clustering method we employ is an integral part of the model. We evaluate our clusters against semantic similarity measures defined on the human-annotated WordNet structure (Fellbaum, 1998). The results of these comparisons show that our cluster members are very similar semantically. We also define a high-level relation detection task involving relations between clauses, evaluate our results, and demonstrate

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 448–455,
Prague, Czech Republic, June 2007.

the effectiveness of using our model in this task.

This work extends selected parts of Brody (2005), where further details can be found.

2 Model Construction

When designing our framework, we must address the complexity and sparseness problems encountered when dealing with whole sentences. Our solution to these issues combines two elements. First, to reduce complexity, we simplify a grammatical clause to its primary components - the subject, verb and object. Secondly, to provide a generalization framework which will enable us to overcome data-sparseness, we cluster each part of the clause using data from within the clause itself. By combining the simplified clause structure and the clustering we produce our *Clustered Clause* model - a triplet of clusters representing a generalized clause.

The Simplified Clause: In order to extract clauses from the text, we use Lin's parser MINIPAR (Lin, 1994). The output of the parser is a dependency tree of each sentence, also containing lemmatized versions of the component words. We extract the verb, subject and object of every clause (including subordinate clauses), and use this triplet of values, the simplified clause, in place of the original complete clause. As seen in Figure 1, these components make up the top (root) triangle of the clause parse tree. We also use the lemmatized form of the words provided by the parser, to further reduce complexity.

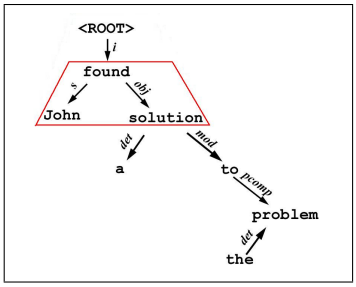

Figure 1: The parse tree for the sentence "John found a solution to the problem". The subject-verb-object triplet is marked with a border.

Clustering Clause Components: For our model, we cluster the data to provide both generalization, by using a cluster to represent a more generalized concept shared by its component words, and a form of dimensionality reduction, by using fewer units (clusters) to represent a much larger amount of words.

We chose to use the Sequential Information Bottleneck algorithm (Slonim et al., 2002) for our clustering tasks. The information Bottleneck principle views the clustering task as an optimization problem, where the clustering algorithm attempts to group together values of one variable while retaining as much information as possible regarding the values of another (target) variable. There is a trade-off between the compactness of the clustering and the amount of retained information. This algorithm (and others based on the IB principle) is especially suited for use with graphical models or dependency structures, since the distance measure it employs in the clustering is defined solely by the dependency relation between two variables, and therefore required no external parameters. The values of one variable are clustered using their co-occurrence distribution with regard to the values of the second (target) variable in the dependency relation. As an example, consider the following subject-verb co-occurrence matrix:

S \ V	**tell**	**scratch**	**drink**
dog	0	4	5
John	4	0	9
cat	0	6	3
man	6	1	2

The value in cell (i, j) indicates the number of times the noun i occurred as the subject of the verb j. Calculating the Mutual Information between the subjects variable (S) and verbs variable (V) in this table, we get $MI(S, V) = 0.52$ bits. Suppose we wish to cluster the subject nouns into two clusters while preserving the highest Mutual Information with regard to the verbs. The following co-occurrence matrix is the optimal clustering, and retains a M.I. value of 0.4 bits (77% of original):

Clustered S \ V	**tell**	**scratch**	**drink**
{dog,cat}	0	10	8
{John,man}	10	1	11

Notice that although the values in the *drink* column are higher than in others, and we may be

tempted to cluster together *dog* and *John* based on this column, the informativeness of this verb is smaller - if we know the verb is *tell* we can be sure the noun is not *dog* or *cat*, whereas if we know it is *drink*, we can only say it is slightly more probable that the noun is *John* or *dog*.

Our dependency structure consists of three variables: subject, verb, and object, and we take advantage of the subject-verb and verb-object dependencies in our clustering. The clustering was performed on each variable separately, in a two phase procedure (see Figure 2). In the first stage, we clustered the subject variable into 200 clusters[1], using the subject-verb dependency (i.e. the verb variable was the target). The same was done with the object variable, using the verb-object dependency. In the second phase, we wish to cluster the verb values with regard to both the subject and object variables. We could not use all pairs of subjects and objects values as the target variable in this task, since too many such combinations exist. Instead, we used a variable composed of all the pairs of subject and object *clusters* as the target for the verb clustering. In this fashion we produced 100 verb clusters.

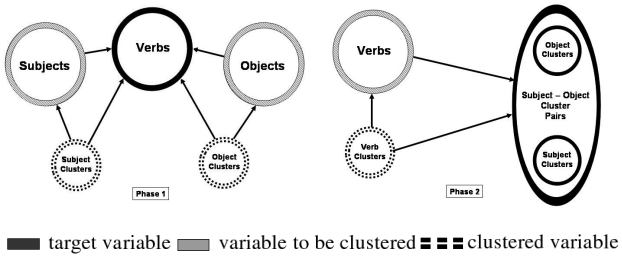

Figure 2: The two clustering phases. Arrows represent dependencies between the variables which are used in the clustering.

Combining the Model Elements: Having obtained our three clustered variables, our original simplified clause triplet can now be used to produce the *Clustered Clause* model. This model represents a clause in the data by a triplet of cluster indexes, one cluster index for each clustered variable. In order to map a clause in the text to its corresponding clustered clause, it is first parsed and lemmatized to obtain the subject, verb and object values, as described above, and then assigned to the clustered clause in which the subject cluster index is that of the cluster containing the subject word of the clause, and the same for the verb and object words. For example, the sentence "The terrorist threw the grenade" would be converted to the triplet (terrorist, throw, grenade) and assigned to the clustered clause composed of the three clusters to which these words belong. Other triplets assigned to this clustered clause might include (fundamentalist, throw, bomb) or (militant, toss, explosive). Applying this procedure to the entire text corpus results in a distillation of the text into a series of clustered clauses containing the essential information about the actions described in the text.

Technical Specifications: For this work we chose to use the entire Reuters Corpus (English, release 2000), containing 800,000 news articles collected uniformly from 20/8/1996 to 19/8/1997. Before clustering, several preprocessing steps were taken. We had a very large amount of word values for each of the Subject (85,563), Verb (4,593) and Object (74,842) grammatical categories. Many of the words were infrequent proper nouns or rare verbs and were of little interest in the pattern recognition task. We therefore removed the less frequent words - those appearing in their category less than one hundred times. We also cleaned our data by removing all words that were one letter in length, other than the word 'I'. These were mostly initials in names of people or companies, which were uninformative without the surrounding context. This processing step brought us to the final count of 2,874,763 clause triplets (75.8% of the original number), containing 3,153 distinct subjects, 1,716 distinct verbs, and 3,312 distinct objects. These values were clustered as described above. The clusters were used to convert the simplified clauses into clustered clauses.

3 Evaluating Cluster Quality

Examples of some of the resulting clusters are provided in Table 1. When manually examin-

[1]The chosen numbers of clusters are such that each the resulting clustered variables preserved approximately half of the co-occurrence mutual information that existed between the original (unclustered) variable and its target.

"Technical Developements" (Subject Cluster 160): treatment, drug, method, tactic, version, technology, software, design, device, vaccine, ending, tool, mechanism, technique, instrument, therapy, concept, model
"Ideals/Virtues" (Object Cluster 14): sovereignty, dominance, logic, validity, legitimacy, freedom, discipline, viability, referendum, wisdom, innocence, credential, integrity, independence
"Emphasis Verbs" (Verb Cluster 92): imply, signify, highlight, mirror, exacerbate, mark, signal, underscore, compound, precipitate, mask, illustrate, herald, reinforce, suggest, underline, aggravate, reflect, demonstrate, spell, indicate, deepen
"Plans" (Object Cluster 33): journey, arrangement, trip, effort, attempt, revolution, pullout, handover, sweep, preparation, filing, start, play, repatriation, redeployment, landing, visit, push, transition, process

Table 1: Example clusters (labeled manually).

ing the clusters, we noticed the "fine-tuning" of some of the clusters. For instance, we had a cluster of countries involved in military conflicts, and another for other countries; a cluster for winning game scores, and another for ties; etc. The fact that the algorithm separated these clusters indicates that the distinction between them is important with regard to the interactions within the clause. For instance, in the first example, the context in which countries from the first cluster appear is very different from that involving countries in the second cluster.

The effect of the dependencies we use is also strongly felt. Many clusters can be described by labels such as "things that are thrown" (*rock, flower, bottle, grenade* and others), or "verbs describing attacks" (*spearhead, foil, intensify, mount, repulse* and others). While such criteria may not be the first choice of someone who is asked to cluster verbs or nouns, they represent unifying themes which are very appropriate to pattern detection tasks, in which we wish to detect connections between actions described in the clauses. For instance, we would like to detect the relation between throwing and military/police action (much of the throwing described in the news reports fits this relation). In order to do this, we must have clusters which unite the words relevant to those actions. Other criteria for clustering would most likely not be suitable, since they would probably not put *egg, bottle* and *rock* in the same category. In this respect, our clustering method provides a more effective modeling of the domain knowledge.

3.1 Evaluation via Semantic Resource

Since the success of our pattern detection task depends to a large extent on the quality of our clusters, we performed an experiment designed to evaluate semantic similarity between members of our clusters. For this purpose we made use of the WordNet Similarity package (Pedersen et al., 2004). This package contains many similarity measures, and we selected three of them (Resnik (1995), Leacock and Chodorow (1997), Hirst and St-Onge (1997)), which make use of different aspects of WordNet (hierarchy and graph structure). We measured the average pairwise similarity between any two words appearing in the same cluster. We then performed the same calculation on a random grouping of the words, and compared the two scores. The results (Fig. 3) show that our clustering, based on co-occurrence statistics and dependencies within the sentence, correlates with a purely semantic similarity as represented by the WordNet structure, and cannot be attributed to chance.

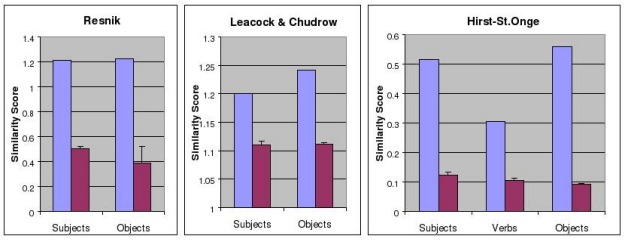

Figure 3: Inter-cluster similarity (average pairwise similarity between cluster members) in our clustering (light) and a random one (dark). Random clustering was performed 10 times. Average values are shown with error bars to indicate standard deviation. Only Hirst & St-Onge measure verb similarity.

4 Relation Detection Task

Motivation: In order to demonstrate the use of our model, we chose a relation detection task. The workshop on entailment mentioned in the introduction was mainly focused on detecting whether or not an entailment relation exists between two texts. In this work we present a com-

plementary approach - a method designed to automatically detect relations between portions of text and generate a knowledge base of the detected relations in a generalized form. As stated by (Dagan et al., 2005), such relations are important for IR applications. In addition, the patterns we employ are likely to be useful in other linguistic tasks involving whole clauses, such as paraphrase acquisition.

Pattern Definition: For our relation detection task, we searched for instances of predefined patterns indicating a relation between two clustered clauses. We restricted the search to clause pairs which co-occur within a distance of ten clauses[2] from each other. In addition to the distance restriction, we required an *anchor*: a noun that appears in both clauses, to further strengthen the relation between them. Noun anchors establish the fact that the two component actions described by the pattern involve the same entities, implying a direct connection between them. The use of verb anchors was also tested, but found to be less helpful in detecting significant patterns, since in most cases it simply found verbs which tend to repeat themselves frequently in a context. The method we describe assumes that statistically significant co-occurrences indicate a relationship between the clauses, but does not attempt to determine the type of relation.

Significance Calculation: The patterns detected by the system were scored using the statistical *p-value* measure. This value represents the probability of detecting a certain number of occurrences of a given pattern in the data under the independence assumption, i.e. assuming there is no connection between the two halves of the pattern. If the system has detected k instances of a certain pattern, we calculate the probability of encountering this number of instances under the independence assumption. The smaller the probability, the higher the significance. We consider patterns with a chance probability lower than 5% to be significant.

We assume a Gaussian-like distribution of occurrence probability for each pattern[3]. In order to estimate the mean and standard deviation values, we created 100 simulated sequences of triplets (representing clustered clauses) which were independently distributed and varied only in their overall probability of occurrence. We then estimated the mean and standard deviation for any pair of clauses in the actual data using the simulated sequences.

(X, VC_{36}, OC_7)	$\rightarrow_{10}$ (X, VC_{57}, OC_{85})
storm, lash, province	... storm, cross, Cuba
quake, shake, city	... quake, hit, Iran
earthquake, jolt, city	... earthquake, hit, Iran

cyclone, near, coast	... cyclone, cause, damage
earthquake,hit,northwest	... earthquake,cause,damage
quake , hit, northwest	... quake, cause, casualty
earthquake,hit,city	... earthquake,cause,damage

Table 2: Example Patterns

4.1 Pattern Detection Results

In Table 2 we present several examples of high ranking (i.e. significance) patterns with different anchorings detected by our method. The detected patterns are represented using the notation of the form $(SC_i, VC_j, X) \rightarrow_n (X, VC_{i'}, OC_{j'})$. X indicates the anchoring word. In the example notation, the anchoring word is the object of the first clause and the subject of the second (O-S for short). n indicates the maximal distance between the two clauses. The terms SC, VC or OC with a subscripted index represent the cluster containing the subject, verb or object (respectively) of the appropriate clause. For instance, in the first example in Table 2, VC_{36} indicates verb cluster no. 36, containing the verbs *lash, shake* and *jolt*, among others.

[2]Our experiments showed that increasing the distance beyond this point did not result in significant increase in the number of detected patterns.

[3]Based on Gwadera et al. (2003), dealing with a similar, though simpler, case.

[4]In two of the patterns, instead of a cluster for the verb, we have a single word - *beat* or *cause*. This is the result of an automatic post-processing stage intended to prevent over-generalization. If all the instances of the pat-

Anchoring System	Number of Patterns Found
Subject-Subject	428
Object-Object	291
Subject-Object	180
Object-Subject	178

Table 3: Numbers of patterns found ($p < 5\%$)

Table 3 lists the number of patterns found, for each anchoring system. The different anchoring systems produce quantitatively different results. Anchoring between the same categories produces more patterns than between the same noun in different grammatical roles. This is expected, since many nouns can only play a certain part in the clause (for instance, many verbs cannot have an inanimate entity as their subject).

The number of instances of patterns we found for the anchored template might be considered low, and it is likely that some patterns were missed simply because their occurrence probability was very low and not enough instances of the pattern occurred in the text. In Section 4 we stated that in this task, we were more interested in precision than in recall. In order to detect a wider range of patterns, a less restricted definition of the patterns, or a different significance indicator, should be used (see Sec. 6).

Human Evaluation: In order to better determine the quality of patterns detected by our system, and confirm that the statistical significance testing is consistent with human judgment, we performed an evaluation experiment with the help of 22 human judges. We presented each of the judges with 60 example groups, 15 for each type of anchoring. Each example group contained three clause pairs conforming to the anchoring relation. The clauses were presented in a normalized form consisting only of a subject, object and verb converted to past tense, with the addition of necessary determiners and prepositions. For example, the triplet *(police, detain, leader)* was converted to *"The police detained the leader"*. In half the cases (randomly selected), these clause pairs were actual examples (instances) of a pattern detected by our system (instances group), such as those appearing in Table 2. In the other half, we listed three clause pairs, each of which conformed to the anchoring specification listed in Section 4, but which were randomly sampled from the data, and so had no connection to one another (baseline group). We asked the judges to rate on a scale of 1-5 whether they thought the clause pairs were a good set of examples of a common relation linking the first clause in each pair to the second one.

	Instances Score	Instances StdDev	Baseline Score	Baseline StdDev
All	3.5461	0.4780	2.6341	0.4244
O-S	3.9266	0.6058	2.8761	0.5096
O-O	3.4938	0.5144	2.7464	0.6205
S-O	3.4746	0.7340	2.5758	0.6314
S-S	3.2398	0.4892	2.3584	0.5645

Table 4: Results for human evaluation

Table 4 reports the overall average scores for baseline and instances groups, and for each of the four anchoring types individually. The scores were averaged over all examples and all judges. An ANOVA showed the difference in scores between the baseline and instance groups to be significant ($p < 0.001$) in all four cases.

Achievement of Model Goals: We employed clustering in our model to overcome data-sparseness. The importance of this decision was evident in our results. For example, the second pattern shown in Table 2 appeared only four times in the text. In these instances, verb cluster 40 was represented twice by the verb *arrest* and twice by *detain*. Two appearances are within the statistical deviation of all but the rarest words, and would not have been detected as significant without the clustering effect. This means the pattern would have been overlooked, despite the strongly intuitive connection it represents. The system detected several such patterns.

The other reason for clustering was generalization. Even in cases where patterns involving single words could have been detected, it would have been impossible to unify similar patterns into generalized ones. In addition, when encountering a new clause which differs slightly from

tern in the text contained the same word in a certain position (in these examples - the verb position in the second clause), this word was placed in that position in the generalized pattern, rather than the cluster it belonged to. Since we have no evidence for the fact that other words in the cluster can fit that position, using the cluster indicator would be over-generalizing.

the ones we recognized in the original data, there would be no way to recognize it and draw the appropriate conclusions. For example, there would be no way to relate the sentence *"The typhoon approached the coast"* to the fourth example pattern, and the connection with the resulting damage would not be recognized.

5 Comparison with Previous Work

The relationship between textual features and semantics and the use of syntax as an indicator of semantics has been widespread. Following the idea proposed in Harris' Distributional Hypothesis (Harris, 1985), that words occurring in similar contexts are semantically similar, many works have used different definitions of context to identify various types of semantic similarity. Hindle (1990) uses a mutual-information based metric derived from the distribution of subject, verb and object in a large corpus to classify nouns. Pereira et al. (1993) cluster nouns according to their distribution as direct objects of verbs, using information-theoretic tools (the predecessors of the tools we use in this work). They suggest that information theoretic measures can also measure semantic relatedness.

These works focus only on relatedness of individual words and do not describe how the automatic estimation of semantic similarity can be useful in real-world tasks. In our work we demonstrate that using clusters as generalized word units helps overcome the sparseness and generalization problems typically encountered when attempting to extract high-level patterns from text, as required for many applications.

The DIRT system (Lin and Pantel, 2001) deals with inference rules, and employs the notion of paths between two nouns in a sentence's parse tree. The system extracts such path structures from text, and provides a similarity measure between two such paths by comparing the words which fill the same slots in the two paths. After extracting the paths, the system finds groups of similar paths. This approach bears several similarities to the ideas described in this paper, since our structure can be seen as a specific path in the parse tree (probably the most basic one, see Fig. 1). In our setup, similar clauses are clustered together in the same *Clustered-Clause*, which could be compared to clustering DIRT's paths using its similarity measure. Despite these similarities, there are several important differences between the two systems. Our method uses only the relationships inside the path or clause in the clustering procedure, so the similarity is based on the structure itself. Furthermore, Lin and Pantel did not create path clusters or generalized paths, so that while their method allowed them to compare phrases for similarity, there is no convenient way to identify high level contextual relationships between two nearby sentences. This is one of the significant advantages that clustering has over similarity measures - it allows a group of similar objects to be represented by a single unit.

There have been several attempts to formulate and detect relationships at a higher context level. The VerbOcean project (Chklovski and Pantel, 2004) deals with relations between verbs. It presents an automatically acquired network of such relations, similar to the WordNet framework. Though the patterns used to acquire the relations are usually parts of a single sentence, the relationships themselves can also be used to describe connections between different sentences, especially the enablement and *happens-before* relations. Since verbs are the central part of the clause, VerbOcean can be viewed as detecting relations between clauses as whole units, as well as those between individual words. As a solution to the data sparseness problem, web queries are used. Torisawa (2006) addresses a similar problem, but focuses on temporal relations, and makes use of the phenomena of Japanese coordinate sentences. Neither of these approaches attempt to create generalized relations or group verbs into clusters, though in the case of VerbOcean this could presumably be done using the *similarity* and *strength* values which are defined and detected by the system.

6 Future Work

The clustered clause model presents many directions for further research. It may be productive to extend the model further, and include other parts of the sentence, such as adjectives

and adverbs. Clustering nouns by the adjectives that describe them may provide a more intuitive grouping. The addition of further elements to the structure may also allow the detection of new kinds of relations.

The news-oriented domain of the corpus we used strongly influenced our results. If we were interested in more mundane relations, involving day-to-day actions of individuals, a literary corpus would probably be more suitable.

In defining our pattern template, several elements were tailored specifically to our task. We limited ourselves to a very restricted set of patterns in order to better demonstrate the effectiveness of our model. For a more general knowledge acquisition task, several of these restrictions may be relaxed, allowing a much larger set of relations to be detected. For example, a less strict significance filter, such as the *support* and *confidence* measures commonly used in data mining, may be preferable. These can be set to different thresholds, according to the user's preference.

In our current work, in order to prevent overgeneralization, we employed a single step post-processing algorithm which detected the incorrect use of an entire cluster in place of a single word (see footnote for Table 2). This method allows only two levels of generalization - single words and whole clusters. A more appropriate way to handle generalization would be to use a hierarchical clustering algorithm. The Agglomerative Information Bottleneck (Slonim and Tishby, 1999) is an example of such an algorithm, and could be employed for this task. Use of a hierarchical method would result in several levels of clusters, representing different levels of generalization. It would be relatively easy to modify our procedure to reduce generalization to the level indicated by the pattern examples in the text, producing a more accurate description of the patterns detected.

Abstract

Obtaining large volumes of inference knowledge, such as entailment rules, has become a major factor in achieving robust semantic processing. While there has been substantial research on learning algorithms for such knowledge, their evaluation methodology has been problematic, hindering further research. We propose a novel evaluation methodology for entailment rules which explicitly addresses their semantic properties and yields satisfactory human agreement levels. The methodology is used to compare two state of the art learning algorithms, exposing critical issues for future progress.

1 Introduction

In many NLP applications, such as Question Answering (QA) and Information Extraction (IE), it is crucial to recognize that a particular target meaning can be inferred from different text variants. For example, a QA system needs to identify that "*Aspirin lowers the risk of heart attacks*" can be inferred from "*Aspirin prevents heart attacks*" in order to answer the question "*What lowers the risk of heart attacks?*". This type of reasoning has been recognized as a core semantic inference task by the generic *textual entailment* framework (Dagan et al., 2006).

A major obstacle for further progress in semantic inference is the lack of broad-scale knowledge-bases for semantic variability patterns (Bar-Haim et al., 2006). One prominent type of inference knowledge representation is inference rules such as paraphrases and *entailment rules*. We define an entailment rule to be a directional relation between two *templates*, text patterns with variables, e.g. 'X prevent $Y \rightarrow X$ lower the risk of Y'. The left-hand-side template is assumed to entail the right-hand-side template in certain contexts, under the same variable instantiation. Paraphrases can be viewed as bidirectional entailment rules. Such rules capture basic inferences and are used as building blocks for more complex entailment inference. For example, given the above rule, the answer "*Aspirin*" can be identified in the example above.

The need for large-scale inference knowledge-bases triggered extensive research on automatic acquisition of paraphrase and entailment rules. Yet the current precision of acquisition algorithms is typically still mediocre, as illustrated in Table 1 for DIRT (Lin and Pantel, 2001) and TEASE (Szpektor et al., 2004), two prominent acquisition algorithms whose outputs are publicly available. The current performance level only stresses the obvious need for satisfactory evaluation methodologies that would drive future research.

The prominent approach in the literature for evaluating rules, termed here the *rule-based* approach, is to present the rules to human judges asking whether each rule is correct or not. However, it is difficult to explicitly define when a learned rule should be considered correct under this methodology, and this was mainly left undefined in previous works. As the criterion for evaluating a rule is not well defined, using this approach often caused low agreement between human judges. Indeed, the standards for evaluation in this field are lower than other fields: many papers

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 456–463,
Prague, Czech Republic, June 2007.

don't report on human agreement at all and those that do report rather low agreement levels. Yet it is crucial to reliably assess rule correctness in order to measure and compare the performance of different algorithms in a replicable manner. Lacking a good evaluation methodology has become a barrier for further advances in the field.

In order to provide a well-defined evaluation methodology we first explicitly specify when entailment rules should be considered correct, following the spirit of their usage in applications. We then propose a new *instance-based* evaluation approach. Under this scheme, judges are not presented only with the rule but rather with a sample of sentences that match its left hand side. The judges then assess whether the rule holds under each specific example. A rule is considered correct only if the percentage of examples assessed as correct is sufficiently high.

We have experimented with a sample of input verbs for both DIRT and TEASE. Our results show significant improvement in human agreement over the rule-based approach. It is also the first comparison between such two state-of-the-art algorithms, which showed that they are comparable in precision but largely complementary in their coverage.

Additionally, the evaluation showed that both algorithms learn mostly one-directional rules rather than (symmetric) paraphrases. While most NLP applications need directional inference, previous acquisition works typically expected that the learned rules would be paraphrases. Under such an expectation, unidirectional rules were assessed as incorrect, underestimating the true potential of these algorithms. In addition, we observed that many learned rules are context sensitive, stressing the need to learn contextual constraints for rule applications.

2 Background: Entailment Rules and their Evaluation

2.1 Entailment Rules

An entailment rule '$L \rightarrow R$' is a directional relation between two templates, L and R. For example, 'X acquire $Y \rightarrow X$ own Y' or 'X beat $Y \rightarrow X$ play against Y'. Templates correspond to text fragments with variables, and are typically either linear phrases or parse sub-trees.

The goal of entailment rules is to help applications infer one text variant from another. A rule can be applied to a given text only when L can be inferred from it, with appropriate variable instantiation. Then, using the rule, the application deduces that R can also be inferred from the text under the same variable instantiation. For example, the rule 'X lose to $Y \rightarrow Y$ beat X' can be used to infer "*Liverpool beat Chelsea*" from "*Chelsea lost to Liverpool in the semifinals*".

Input	Correct	Incorrect
X change Y (DIRT)	($\leftrightarrow$) X modify Y ($\leftarrow$) X amend Y ($\leftarrow$) X revise Y	X adopt Y X create Y X stick to Y
X change Y (TEASE)	($\leftrightarrow$) X alter Y ($\rightarrow$) X affect Y ($\leftarrow$) X extend Y	X maintain Y X follow Y X use Y

Table 1: Examples of templates suggested by DIRT and TEASE as having an entailment relation, in some direction, with the input template 'X change Y'. The entailment direction arrows were judged manually and added for readability.

Entailment rules should typically be applied only in specific contexts, which we term *relevant contexts*. For example, the rule 'X acquire $Y \rightarrow X$ buy Y' can be used in the context of 'buying' events. However, it shouldn't be applied for "*Students acquired a new language*". In the same manner, the rule 'X acquire $Y \rightarrow X$ learn Y' should be applied only when Y corresponds to some sort of knowledge, as in the latter example.

Some existing entailment acquisition algorithms can add contextual constraints to the learned rules (Sekine, 2005), but most don't. However, NLP applications usually implicitly incorporate some contextual constraints when applying a rule. For example, when answering the question "*Which companies did IBM buy?*" a QA system would apply the rule 'X acquire $Y \rightarrow X$ buy Y' correctly, since the phrase "IBM acquire X" is likely to be found mostly in relevant economic contexts. We thus expect that an evaluation methodology should consider context relevance for entailment rules. For example, we would like both 'X acquire $Y \rightarrow X$ buy Y' and 'X acquire $Y \rightarrow X$ learn Y' to be assessed as correct (the second rule should not be deemed incorrect

just because it is not applicable in frequent economic contexts).

Finally, we highlight that the common notion of "paraphrase rules" can be viewed as a special case of entailment rules: a paraphrase '$L \leftrightarrow R$' holds if both templates entail each other. Following the textual entailment formulation, we observe that many applied inference settings require only directional entailment, and a requirement for symmetric paraphrase is usually unnecessary. For example, in order to answer the question "*Who owns Overture?*" it suffices to use a directional entailment rule whose right hand side is 'X own Y', such as 'X acquire $Y \rightarrow X$ own Y', which is clearly not a paraphrase.

2.2 Evaluation of Acquisition Algorithms

Many methods for automatic acquisition of rules have been suggested in recent years, ranging from distributional similarity to finding shared contexts (Lin and Pantel, 2001; Ravichandran and Hovy, 2002; Shinyama et al., 2002; Barzilay and Lee, 2003; Szpektor et al., 2004; Sekine, 2005). However, there is still no common accepted framework for their evaluation. Furthermore, all these methods learn rules as pairs of templates $\{L, R\}$ in a symmetric manner, without addressing rule directionality. Accordingly, previous works (except (Szpektor et al., 2004)) evaluated the learned rules under the paraphrase criterion, which underestimates the practical utility of the learned rules (see Section 2.1).

One approach which was used for evaluating automatically acquired rules is to measure their contribution to the performance of specific systems, such as QA (Ravichandran and Hovy, 2002) or IE (Sudo et al., 2003; Romano et al., 2006). While measuring the impact of learned rules on applications is highly important, it cannot serve as the primary approach for evaluating acquisition algorithms for several reasons. First, developers of acquisition algorithms often do not have access to the different applications that will later use the learned rules as generic modules. Second, the learned rules may affect individual systems differently, thus making observations that are based on different systems incomparable. Third, within a complex system it is difficult to assess the exact quality of entailment rules independently of effects of other system components.

Thus, as in many other NLP learning settings, a direct evaluation is needed. Indeed, the prominent approach for evaluating the quality of rule acquisition algorithms is by human judgment of the learned rules (Lin and Pantel, 2001; Shinyama et al., 2002; Barzilay and Lee, 2003; Pang et al., 2003; Szpektor et al., 2004; Sekine, 2005). In this evaluation scheme, termed here the *rule-based* approach, a sample of the learned rules is presented to the judges who evaluate whether each rule is correct or not. The criterion for correctness is not explicitly described in most previous works. By the common view of context relevance for rules (see Section 2.1), a rule was considered correct if the judge could think of reasonable contexts under which it holds.

We have replicated the rule-based methodology but did not manage to reach a 0.6 Kappa agreement level between pairs of judges. This approach turns out to be problematic because the rule correctness criterion is not sufficiently well defined and is hard to apply. While some rules might obviously be judged as correct or incorrect (see Table 1), judgment is often more difficult due to context relevance. One judge might come up with a certain context that, to her opinion, justifies the rule, while another judge might not imagine that context or think that it doesn't sufficiently support rule correctness. For example, in our experiments one of the judges did not identify the valid "religious holidays" context for the correct rule 'X observe $Y \rightarrow X$ celebrate Y'. Indeed, only few earlier works reported inter-judge agreement level, and those that did reported rather low Kappa values, such as 0.54 (Barzilay and Lee, 2003) and 0.55 - 0.63 (Szpektor et al., 2004).

To conclude, the prominent rule-based methodology for entailment rule evaluation is not sufficiently well defined. It results in low inter-judge agreement which prevents reliable and consistent assessments of different algorithms.

3 Instance-based Evaluation Methodology

As discussed in Section 2.1, an evaluation methodology for entailment rules should reflect the expected validity of their application within NLP systems. Following that line, an entailment rule '$L \rightarrow R$' should be regarded as *correct* if in all (or at least most) relevant contexts in which the instantiated template L is inferred from the given text, the instan-

	Rule	Sentence	Judgment
1	X seek $Y \rightarrow X$ disclose Y	If he is arrested, **he** can immediately seek **bail**.	Left not entailed
2	X clarify $Y \rightarrow X$ prepare Y	**He** didn't clarify **his position on the subject**.	Left not entailed
3	X hit $Y \rightarrow X$ approach Y	**Other earthquakes** have hit **Lebanon** since '82.	Irrelevant context
4	X lose $Y \rightarrow X$ surrender Y	**Bread** has recently lost **its subsidy**.	Irrelevant context
5	X regulate $Y \rightarrow X$ reform Y	**The SRA** regulates **the sale of sugar**.	No entailment
6	X resign $Y \rightarrow X$ share Y	**Lopez** resigned **his post at VW** last week.	No entailment
7	X set $Y \rightarrow X$ allow Y	**The committee** set **the following refunds**.	Entailment holds
8	X stress $Y \rightarrow X$ state Y	**Ben Yahia** also stressed **the need for action**.	Entailment holds

Table 2: Rule evaluation examples and their judgment.

tiated template R is also inferred from the text. This reasoning corresponds to the common definition of entailment in semantics, which specifies that a text L entails another text R if R is true in every circumstance (possible world) in which L is true (Chierchia and McConnell-Ginet, 2000).

It follows that in order to assess if a rule is correct we should judge whether R is typically entailed from those sentences that entail L (within relevant contexts for the rule). We thus present a new evaluation scheme for entailment rules, termed the *instance-based* approach. At the heart of this approach, human judges are presented not only with a rule but rather with a sample of examples of the rule's usage. Instead of thinking up valid contexts for the rule the judges need to assess the rule's validity under the given context in each example. The essence of our proposal is a (apparently non-trivial) protocol of a sequence of questions, which determines rule validity in a given sentence.

We shall next describe how we collect a sample of examples for evaluation and the evaluation process.

3.1 Sampling Examples

Given a rule '$L \rightarrow R$', our goal is to generate evaluation examples by finding a sample of sentences from which L is entailed. We do that by automatically retrieving, from a given corpus, sentences that match L and are thus likely to entail it, as explained below.

For each example sentence, we automatically extract the arguments that instantiate L and generate two phrases, termed *left phrase* and *right phrase*, which are constructed by instantiating the left template L and the right template R with the extracted arguments. For example, the left and right phrases generated for example 1 in Table 2 are "*he seek bail*" and "*he disclose bail*", respectively.

Finding sentences that match L can be performed at different levels. In this paper we match lexical-syntactic templates by finding a sub-tree of the sentence parse that is identical to the template structure. Of course, this matching method is not perfect and will sometimes retrieve sentences that do not entail the left phrase for various reasons, such as incorrect sentence analysis or semantic aspects like negation, modality and conditionals. See examples 1-2 in Table 2 for sentences that syntactically match L but do not entail the instantiated left phrase. Since we should assess R's entailment only from sentences that entail L, such sentences should be ignored by the evaluation process.

3.2 Judgment Questions

For each example generated for a rule, the judges are presented with the given sentence and the left and right phrases. They primarily answer two questions that assess whether entailment holds in this example, following the semantics of entailment rule application as discussed above:

$\mathbf{Q_{le}}$: Is the left phrase entailed from the sentence? A positive/negative answer corresponds to a '**Left entailed/not entailed**' judgment.

$\mathbf{Q_{re}}$: Is the right phrase entailed from the sentence? A positive/negative answer corresponds to an '**Entailment holds/No entailment**' judgment.

The first question identifies sentences that do not entail the left phrase, and thus should be ignored when evaluating the rule's correctness. While inappropriate matches of the rule left-hand-side may happen

and harm an overall system precision, such errors should be accounted for a system's rule matching module rather than for the rules' precision. The second question assesses whether the rule application is valid or not for the current example. See examples 5-8 in Table 2 for cases where entailment does or doesn't hold.

Thus, the judges focus only on the given sentence in each example, so the task is actually to evaluate whether *textual entailment* holds between the sentence (*text*) and each of the left and right phrases (*hypotheses*). Following past experience in textual entailment evaluation (Dagan et al., 2006) we expect a reasonable agreement level between judges.

As discussed in Section 2.1, we may want to ignore examples whose context is irrelevant for the rule. To optionally capture this distinction, the judges are asked another question:

$\mathbf{Q_{rc}}$: Is the right phrase a likely phrase in English? A positive/negative answer corresponds to a '**Relevant/Irrelevant context**' evaluation.

If the right phrase is not likely in English then the given context is probably irrelevant for the rule, because it seems inherently incorrect to infer an implausible phrase. Examples 3-4 in Table 2 demonstrate cases of irrelevant contexts, which we may choose to ignore when assessing rule correctness.

3.3 Evaluation Process

For each example, the judges are presented with the three questions above in the following order: (1) $\mathbf{Q_{le}}$ (2) $\mathbf{Q_{rc}}$ (3) $\mathbf{Q_{re}}$. If the answer to a certain question is negative then we do not need to present the next questions to the judge: if the left phrase is not entailed then we ignore the sentence altogether; and if the context is irrelevant then the right phrase cannot be entailed from the sentence and so the answer to $\mathbf{Q_{re}}$ is already known as negative.

The above entailment judgments assume that we can actually ask whether the left or right phrases are correct given the sentence, that is, we assume that a truth value can be assigned to both phrases. This is the case when the left and right templates correspond, as expected, to semantic relations. Yet sometimes learned templates are (erroneously) not relational, e.g. 'X, Y, IBM' (representing a list). We therefore let the judges initially mark rules that include such templates as non-relational, in which case their examples are not evaluated at all.

3.4 Rule Precision

We compute the precision of a rule by the percentage of examples for which entailment holds out of all "relevant" examples. We can calculate the precision in two ways, as defined below, depending on whether we ignore irrelevant contexts or not (obtaining lower precision if we don't). When systems answer an information need, such as a query or question, irrelevant contexts are sometimes not encountered thanks to additional context which is present in the given input (see Section 2.1). Thus, the following two measures can be viewed as upper and lower bounds for the expected precision of the rule applications in actual systems:

upper bound precision: $$\frac{\#\textbf{Entailment holds}}{\#\textbf{Relevant context}}$$

lower bound precision: $$\frac{\#\textbf{Entailment holds}}{\#\textbf{Left entailed}}$$

where # denotes the number of examples with the corresponding judgment.

Finally, we consider a rule to be correct only if its precision is at least 80%, which seems sensible for typical applied settings. This yields two alternative sets of correct rules, corresponding to the upper bound and lower bound precision measures. Even though judges may disagree on specific examples for a rule, their judgments may still agree overall on the rule's correctness. We therefore expect the agreement level on rule correctness to be higher than the agreement on individual examples.

4 Experimental Settings

We applied the instance-based methodology to evaluate two state-of-the-art unsupervised acquisition algorithms, DIRT (Lin and Pantel, 2001) and TEASE (Szpektor et al., 2004), whose output is publicly available. DIRT identifies semantically related templates in a local corpus using distributional similarity over the templates' variable instantiations. TEASE acquires entailment relations from the Web for a given input template I by identifying characteristic variable instantiations shared by I and other templates.

For the experiment we used the published DIRT and TEASE knowledge-bases[1]. For every given input template I, each knowledge-base provides a list of learned output templates $\{O_j\}_1^{n_I}$, where n_I is the number of output templates learned for I. Each output template is suggested as holding an entailment relation with the input template I, but the algorithms do not specify the entailment direction(s). Thus, each pair $\{I, O_j\}$ induces two candidate directional entailment rules: '$I \rightarrow O_j$' and '$O_j \rightarrow I$'.

4.1 Test Set Construction

The test set construction consists of three sampling steps: selecting a set of input templates for the two algorithms, selecting a sample of output rules to be evaluated, and selecting a sample of sentences to be judged for each rule.

First, we randomly selected 30 transitive verbs out of the 1000 most frequent verbs in the Reuters RCV1 corpus[2]. For each verb we manually constructed a lexical-syntactic input template by adding subject and object variables. For example, for the verb 'seek' we constructed the template '$X \xleftarrow{subj}$ seek $\xrightarrow{obj} Y$'.

Next, for each input template I we considered the learned templates $\{O_j\}_1^{n_I}$ from each knowledge-base. Since DIRT has a long tail of templates with a low score and very low precision, DIRT templates whose score is below a threshold of 0.1 were filtered out[3]. We then sampled 10% of the templates in each output list, limiting the sample size to be between 5-20 templates for each list (thus balancing between sufficient evaluation data and judgment load). For each sampled template O we evaluated both directional rules, '$I \rightarrow O$' and '$O \rightarrow I$'. In total, we sampled 380 templates, inducing 760 directional rules out of which 754 rules were unique.

Last, we randomly extracted a sample of example sentences for each rule '$L \rightarrow R$' by utilizing a search engine over the first CD of Reuters RCV1. First, we retrieved all sentences containing all lexical terms within L. The retrieved sentences were parsed using the Minipar dependency parser (Lin, 1998), keeping only sentences that syntactically match L (as explained in Section 3.1). A sample of 15 matching sentences was randomly selected, or all matching sentences if less than 15 were found. Finally, an example for judgment was generated from each sampled sentence and its left and right phrases (see Section 3.1). We did not find sentences for 108 rules, and thus we ended up with 646 unique rules that could be evaluated (with 8945 examples to be judged).

4.2 Evaluating the Test-Set

Two human judges evaluated the examples. We randomly split the examples between the judges. 100 rules (1287 examples) were cross annotated for agreement measurement. The judges followed the procedure in Section 3.3 and the correctness of each rule was assessed based on both its upper and lower bound precision values (Section 3.4).

5 Methodology Evaluation Results

We assessed the instance-based methodology by measuring the agreement level between judges. The judges agreed on 75% of the 1287 shared examples, corresponding to a reasonable Kappa value of 0.64. A similar kappa value of 0.65 was obtained for the examples that were judged as either entailment holds/no entailment by both judges. Yet, our evaluation target is to assess rules, and the Kappa values for the final correctness judgments of the shared rules were 0.74 and 0.68 for the lower and upper bound evaluations. These Kappa scores are regarded as 'substantial agreement' and are substantially higher than published agreement scores and those we managed to obtain using the standard rule-based approach. As expected, the agreement on rules is higher than on examples, since judges may disagree on a certain example but their judgements would still yield the same rule assessment.

Table 3 illustrates some disagreements that were still exhibited within the instance-based evaluation. The primary reason for disagreements was the difficulty to decide whether a context is relevant for a rule or not, resulting in some confusion between 'Irrelevant context' and 'No entailment'. This may explain the lower agreement for the upper bound precision, for which examples judged as 'Irrelevant context' are ignored, while for the lower bound both

[2] http://about.reuters.com/researchandstandards/corpus/

[3] Following advice by Patrick Pantel, DIRT's co-author.

Rule	Sentence	Judge 1	Judge 2
X sign $Y \rightarrow X$ set Y	**Iraq and Turkey** sign **agreement** to increase trade cooperation	Entailment holds	Irrelevant context
X worsen $Y \rightarrow X$ slow Y	**News of the strike** worsened **the situation**	Irrelevant context	No entailment
X get $Y \rightarrow X$ want Y	**He** will get **his parade** on Tuesday	Entailment holds	No entailment

Table 3: Examples for disagreement between the two judges.

judgments are conflated and represent no entailment. Our findings suggest that better ways for distinguishing relevant contexts may be sought in future research for further refinement of the instance-based evaluation methodology.

About 43% of all examples were judged as 'Left not entailed'. The relatively low matching precision (57%) made us collect more examples than needed, since 'Left not entailed' examples are ignored. Better matching capabilities will allow collecting and judging fewer examples, thus improving the efficiency of the evaluation process.

6 DIRT and TEASE Evaluation Results

	DIRT		TEASE	
	P	Y	P	Y
Rules:				
Upper Bound	30.5%	33.5	28.4%	40.3
Lower Bound	18.6%	20.4	17%	24.1
Templates:				
Upper Bound	44%	22.6	38%	26.9
Lower Bound	27.3%	14.1	23.6%	16.8

Table 4: Average Precision (P) and Yield (Y) at the rule and template levels.

We evaluated the quality of the entailment rules produced by each algorithm using two scores: (1) micro average ***Precision***, the percentage of correct rules out of all learned rules, and (2) average ***Yield***, the average number of correct rules learned for each input template I, as extrapolated based on the sample[4]. Since DIRT and TEASE do not identify rule directionality, we also measured these scores at the template level, where an output template O is considered correct if at least one of the rules '$I \rightarrow O$' or '$O \rightarrow I$' is correct. The results are presented in Table 4. The major finding is that the overall quality of DIRT and TEASE is very similar. Under the specific DIRT cutoff threshold chosen, DIRT exhibits somewhat higher Precision while TEASE has somewhat higher Yield (recall that there is no particular natural cutoff point for DIRT's output).

Since applications typically apply rules in a specific direction, the Precision for rules reflects their expected performance better than the Precision for templates. Obviously, future improvement in precision is needed for rule learning algorithms. Meanwhile, manual filtering of the learned rules can prove effective within limited domains, where our evaluation approach can be utilized for reliable filtering as well. The substantial yield obtained by these algorithms suggest that they are indeed likely to be valuable for recall increase in semantic applications.

In addition, we found that only about 15% of the correct templates were learned by both algorithms, which implies that the two algorithms largely complement each other in terms of coverage. One explanation may be that DIRT is focused on the domain of the local corpus used (news articles for the published DIRT knowledge-base), whereas TEASE learns from the Web, extracting rules from multiple domains. Since Precision is comparable it may be best to use both algorithms in tandem.

We also measured whether O is a paraphrase of I, i.e. whether both '$I \rightarrow O$' and '$O \rightarrow I$' are correct. Only 20-25% of all correct templates were assessed as paraphrases. This stresses the significance of evaluating directional rules rather than only paraphrases. Furthermore, it shows that in order to improve precision, acquisition algorithms must identify rule directionality.

[4]Since the rules are matched against the full corpus (as in IR evaluations), it is difficult to evaluate their true recall.

About 28% of all 'Left entailed' examples were evaluated as 'Irrelevant context', yielding the large difference in precision between the upper and lower precision bounds. This result shows that in order to get closer to the upper bound precision, learning algorithms and applications need to identify the relevant contexts in which a rule should be applied.

Last, we note that the instance-based quality assessment corresponds to the corpus from which the example sentences were taken. It is therefore best to evaluate the rules using a corpus of the same domain from which they were learned, or the target application domain for which the rules will be applied.

7 Conclusions

Accurate learning of inference knowledge, such as entailment rules, has become critical for further progress of applied semantic systems. However, evaluation of such knowledge has been problematic, hindering further developments. The instance-based evaluation approach proposed in this paper obtained acceptable agreement levels, which are substantially higher than those obtained for the common rule-based approach.

We also conducted the first comparison between two state-of-the-art acquisition algorithms, DIRT and TEASE, using the new methodology. We found that their quality is comparable but they effectively complement each other in terms of rule coverage. Also, we found that most learned rules are not paraphrases but rather one-directional entailment rules, and that many of the rules are context sensitive. These findings suggest interesting directions for future research, in particular learning rule directionality and relevant contexts, issues that were hardly explored till now. Such developments can be then evaluated by the instance-based methodology, which was designed to capture these two important aspects of entailment rules.

Abstract

We present an approach to query expansion in answer retrieval that uses Statistical Machine Translation (SMT) techniques to bridge the lexical gap between questions and answers. SMT-based query expansion is done by i) using a full-sentence paraphraser to introduce synonyms in context of the entire query, and ii) by translating query terms into answer terms using a full-sentence SMT model trained on question-answer pairs. We evaluate these global, context-aware query expansion techniques on *tfidf* retrieval from 10 million question-answer pairs extracted from FAQ pages. Experimental results show that SMT-based expansion improves retrieval performance over local expansion and over retrieval without expansion.

1 Introduction

One of the fundamental problems in Question Answering (QA) has been recognized to be the "lexical chasm" (Berger et al., 2000) between question strings and answer strings. This problem is manifested in a mismatch between question and answer vocabularies, and is aggravated by the inherent ambiguity of natural language. Several approaches have been presented that apply natural language processing technology to close this gap. For example, syntactic information has been deployed to reformulate questions (Hermjakob et al., 2002) or to replace questions by syntactically similar ones (Lin and Pantel, 2001); lexical ontologies such as Wordnet[1] have been used to find synonyms for question words (Burke et al., 1997; Hovy et al., 2000; Prager et al., 2001; Harabagiu et al., 2001), and statistical machine translation (SMT) models trained on question-answer pairs have been used to rank candidate answers according to their translation probabilities (Berger et al., 2000; Echihabi and Marcu, 2003; Soricut and Brill, 2006). Information retrieval (IR) is faced by a similar fundamental problem of "term mismatch" between queries and documents. A standard IR solution, query expansion, attempts to increase the chances of matching words in relevant documents by adding terms with similar statistical properties to those in the original query (Voorhees, 1994; Qiu and Frei, 1993; Xu and Croft, 1996).

In this paper we will concentrate on the task of answer retrieval from FAQ pages, i.e., an IR problem where user queries are matched against documents consisting of question-answer pairs found in FAQ pages. Equivalently, this is a QA problem that concentrates on finding answers given FAQ documents that are known to contain the answers. Our approach to close the lexical gap in this setting attempts to marry QA and IR technology by deploying SMT methods for query expansion in answer retrieval. We present two approaches to SMT-based query expansion, both of which are implemented in the framework of phrase-based SMT (Och and Ney, 2004; Koehn et al., 2003).

Our first query expansion model trains an end-to-end phrase-based SMT model on 10 million question-answer pairs extracted from FAQ pages.

The goal of this system is to learn lexical correlations between words and phrases in questions and answers, for example by allowing for multiple unaligned words in automatic word alignment, and disregarding issues such as word order. The ability to translate phrases instead of words and the use of a large language model serve as rich context to make precise decisions in the case of ambiguous translations. Query expansion is performed by adding content words that have not been seen in the original query from the n-best translations of the query.

Our second query expansion model is based on the use of SMT technology for full-sentence paraphrasing. A phrase table of paraphrases is extracted from bilingual phrase tables (Bannard and Callison-Burch, 2005), and paraphrasing quality is improved by additional discriminative training on manually created paraphrases. This approach utilizes large bilingual phrase tables as information source to extract a table of para-phrases. Synonyms for query expansion are read off from the n-best paraphrases of full queries instead of from paraphrases of separate words or phrases. This allows the model to take advantage of the rich context of a large n-gram language model when adding terms from the n-best paraphrases to the original query.

In our experimental evaluation we deploy a database of question-answer pairs extracted from FAQ pages for both training a question-answer translation model, and for a comparative evaluation of different systems on the task of answer retrieval. Retrieval is based on the *tfidf* framework of Jijkoun and de Rijke (2005), and query expansion is done straightforwardly by adding expansion terms to the query for a second retrieval cycle. We compare our global, context-aware query expansion techniques with Jijkoun and de Rijke's (2005) *tfidf* model for answer retrieval and a local query expansion technique (Xu and Croft, 1996). Experimental results show a significant improvement of SMT-based query expansion over both baselines.

2 Related Work

QA has approached the problem of the lexical gap by various techniques for *question reformulation*, including rule-based syntactic and semantic reformulation patterns (Hermjakob et al., 2002), reformulations based on shared dependency parses (Lin and Pantel, 2001), or various uses of the WordNet ontology to close the lexical gap word-by-word (Hovy et al., 2000; Prager et al., 2001; Harabagiu et al., 2001). Another use of natural language processing has been the deployment of SMT models on question-answer pairs for *(re)ranking* candidate answers which were either assumed to be contained in FAQ pages (Berger et al., 2000) or retrieved by baseline systems (Echihabi and Marcu, 2003; Soricut and Brill, 2006).

IR has approached the term mismatch problem by various approaches to *query expansion* (Voorhees, 1994; Qiu and Frei, 1993; Xu and Croft, 1996). Inconclusive results have been reported for techniques that expand query terms separately by adding strongly related terms from an external thesaurus such as WordNet (Voorhees, 1994). Significant improvements in retrieval performance could be achieved by *global* expansion techniques that compute corpus-wide statistics and take the entire query, or query *concept* (Qiu and Frei, 1993), into account, or by *local* expansion techniques that select expansion terms from the top ranked documents retrieved by the original query (Xu and Croft, 1996).
