A similar picture emerges for query expansion in QA: Mixed results have been reported for word-by-word expansion based on WordNet (Burke et al., 1997; Hovy et al., 2000; Prager et al., 2001; Harabagiu et al., 2001). Considerable improvements have been reported for the use of the local context analysis model of Xu and Croft (1996) in the QA system of Ittycheriah et al. (2001), or for the systems of Agichtein et al. (2004) or Harabagiu and Lacatusu (2004) that use FAQ data to learn how to expand query terms by answer terms.

The SMT-based approaches presented in this paper can be seen as global query expansion techniques in that our question-answer translation model uses the whole question-answer corpus as information source, and our approach to paraphrasing deploys large amounts of bilingual phrases as high-coverage information source for synonym finding. Furthermore, both approaches take the entire query context into account when proposing to add new terms to the original query. The approaches that are closest to our models are the SMT approach of Radev et al. (2001) and the paraphrasing approach

	web pages	FAQ pages	QA pairs
count	4 billion	795,483	10,568,160

Table 1: Corpus statistics of QA pair data

of Duboue and Chu-Carroll (2006). None of these approaches defines the problem of the lexical gap as a query expansion problem, and both approaches use much simpler SMT models than our systems, e.g., Radev et al. (2001) neglect to use a language model to aid disambiguation of translation choices, and Duboue and Chu-Carroll (2006) use SMT as black box altogether.

In sum, our approach differs from previous work in QA and IR in the use SMT technology for query expansion, and should be applicable in both areas even though experimental results are only given for the restricted domain of retrieval from FAQ pages.

3 Question-Answer Pairs from FAQ Pages

Large-scale collection of question-answer pairs has been hampered in previous work by the small sizes of publicly available FAQ collections or by restricted access to retrieval results via public APIs of search engines. Jijkoun and de Rijke (2005) nevertheless managed to extract around 300,000 FAQ pages and 2.8 million question-answer pairs by repeatedly querying search engines with "`intitle:faq`" and "`inurl:faq`". Soricut and Brill (2006) could deploy a proprietary URL collection of 1 billion URLs to extract 2.3 million FAQ pages containing the uncased string "faq" in the url string. The extraction of question-answer pairs amounted to a database of 1 million pairs in their experiment. However, inspection of the publicly available WebFAQ collection provided by Jijkoun and de Rijke[2] showed a great amount of noise in the retrieved FAQ pages and question-answer pairs, and yet the indexed question-answer pairs showed a serious recall problem in that no answer could be retrieved for many well-formed queries. For our experiment, we decided to prefer precision over recall and to attempt a precision-oriented FAQ and question-answer pair extraction that benefits the training of question-answer translation models.

[2]http://ilps.science.uva.nl/Resources/WazDah/

As shown in Table 1, the FAQ pages used in our experiment were extracted from a 4 billion page subset of the web using the queries "`inurl:faq`" and "`inurl:faqs`" to match the tokens "faq" or "faqs" in the urls. This extraction resulted in 2.6 million web pages (0.07% of the crawl). Since not all those pages are actually FAQs, we manually labeled 1,000 of those pages to train an online passive-aggressive classificier (Crammer et al., 2006) in a 10-fold cross validation setup. Training was done using 20 feature functions on occurrences question marks and key words in different fields of web pages, and resulted in an F1 score of around 90% for FAQ classification. Application of the classifier to the extracted web pages resulted in a classification of 795,483 pages as FAQ pages.

The extraction of question-answer pairs from this database of FAQ pages was performed again in a precision-oriented manner. The goal of this step was to extract url, title, question, and answers fields from the question-answer pairs in FAQ pages. This was achieved by using feature functions on punctuations, HTML tags (e.g., `<p>, <BR>`), listing markers (e.g., `Q:, (1)`), and lexical cues (e.g., `What, How`), and an algorithm similar to Joachims (2003) to propagate initial labels across similar text pieces. The result of this extraction step is a database of about 10 million question answer pairs (13.3 pairs per FAQ page). A manual evaluation of 100 documents, containing 1,303 question-answer pairs, achieved a precision of 98% and a recall of 82% for extracting question-answer pairs.

4 SMT-Based Query Expansion

Our SMT-based query expansion techniques are based on a recent implementation of the phrase-based SMT framework (Koehn et al., 2003; Och and Ney, 2004). The probability of translating a foreign sentence **f** into English **e** is defined in the noisy channel model as

$$\arg\max_e p(\mathbf{e}|\mathbf{f}) \quad = \quad \arg\max_e p(\mathbf{f}|\mathbf{e})p(\mathbf{e}) \quad (1)$$

This allows for a separation of a language model $p(\mathbf{e})$, and a translation model $p(\mathbf{f}|\mathbf{e})$. Translation probabilities are calculated from relative frequencies of phrases, which are extracted via various heuristics as larger blocks of aligned words from best word

alignments. Word alignments are estimated by models similar to Brown et al. (1993). For a sequence of I phrases, the translation probability in equation (1) can be decomposed into

$$p(f_i^I|e_i^I) = \prod_{i=1}^{I} p(f_i|e_i) \quad (2)$$

Recent SMT models have shown significant improvements in translation quality by improved modeling of local word order and idiomatic expressions through the use of phrases, and by the deployment of large n-gram language models to model fluency and lexical choice.

4.1 Question-Answer Translation

Our first approach to query expansion treats the questions and answers in the question-answer corpus as two distinct languages. That is, the 10 million question-answer pairs extracted from FAQ pages are fed as parallel training data into an SMT training pipeline. This training procedure includes various standard procedures such as preprocessing, sentence and chunk alignment, word alignment, and phrase extraction. The goal of question-answer translation is to learn associations between question words and synonymous answer words, rather than the translation of questions into fluent answers. Thus we did not conduct discriminative training of feature weights for translation probabilities or language model probabilities, but we held out 4,000 question-answer pairs for manual development and testing of the system. For example, the system was adjusted to account for the difference in sentence length between questions and answers by setting the null-word probability parameter in word alignment to 0.9. This allowed us to concentrate the word alignments to a small number of key words. Furthermore, extraction of phrases was based on the intersection of alignments from both translation directions, thus favoring precision over recall also in phrase alignment.

Table 2 shows unique translations of the query "how to live with cat allergies" on the phrase-level, with corresponding source and target phrases shown in brackets. Expansion terms are taken from phrase terms that have not been seen in the original query, and are highlighted in bold face.

4.2 SMT-Based Paraphrasing

Our SMT-based paraphrasing system is based on the approach presented in Bannard and Callison-Burch (2005). The central idea in this approach is to identify paraphrases or synonyms at the phrase level by pivoting on another language. For example, given a table of Chinese-to-English phrase translations, phrasal synonyms in the target language are defined as those English phrases that are aligned to the same Chinese source phrases. Translation probabilities for extracted para-phrases can be inferred from bilingual translation probabilities as follows: Given an English para-phrase pair (trg, syn), the probability $p(syn|trg)$ that trg translates into syn is defined as the joint probability that the English phrase trg translates into the foreign phrase src, and that the foreign phrase src translates into the English phrase syn. Under an independence assumption of those two events, this probability and the reverse translation direction $p(trg|syn)$ can be defined as follows:

$$p(syn|trg) = \max_{src} p(src|trg)p(syn|src) \quad (3)$$
$$p(trg|syn) = \max_{src} p(src|syn)p(trg|src)$$

Since the same para-phrase pair can be obtained by pivoting on multiple foreign language phrases, a summation or maximization over foreign language phrases is necessary. In order not to put too much probability mass onto para-phrase translations that can be obtained from multiple foreign language phrases, we maximize instead of summing over src.

In our experiments, we employed equation (3) to infer for each para-phrase pair translation model probabilities $p_\phi(syn|trg)$ and $p_{\phi'}(trg|syn)$ from relative frequencies of phrases in bilingual tables. In contrast to Bannard and Callison-Burch (2005), we applied the same inference step to infer also lexical translation probabilities $p_w(syn|trg)$ and $p_{w'}(trg|syn)$ as defined in Koehn et al. (2003) for para-phrases. Furthermore, we deployed features for the number of words l_w, number of phrases c_ϕ , a reordering score p_d , and a score for a 6-gram language model p_{LM} trained on English web data. The final model combines these features in a log-linear model that defines the probability of paraphrasing a full sentence, consisting of a sequence of I phrases

qa-translation	(how, how) (to, to) (live, live) (with, with) (cat, **pet**) (allergies, allergies) (how, how) (to, to) (live, live) (with, with) (cat, cat) (allergies, **allergy**) (how, how) (to, to) (live, live) (with, with) (cat, cat) (allergies, **food**) (how, how) (to, to) (live, live) (with, with) (cat, **cats**) (allergies, allergies)
paraphrasing	(how, how) (to live, to live) (with cat, with cat) (allergies, **allergy**) (how, **ways**) (to live, to live) (with cat, with cat) (allergies, allergies) (how, how) (to live with, to live with) (cat, **feline**) (allergies, allergies) (how to, how to) (live, **living**) (with cat, with cat) (allergies, allergies) (how to, how to) (live, **life**) (with cat, with cat) (allergies, allergies) (how, **way**) (to live, to live) (with cat, with cat) (allergies, allergies) (how, how) (to live, to live) (with cat, with cat) (allergies, **allergens**) (how, how) (to live, to live) (with cat, with cat) (allergies, **allergen**)

Table 2: Unique n-best phrase-level translations of query "how to live with cat allergies".

as follows:

$$
\begin{aligned}
p(syn_1^I|trg_1^I) &= (\prod_{i=1}^{I} p_\phi(syn_i|trg_i)^{\lambda_\phi} \quad (4)\\
&\times\ p_{\phi'}(trg_i|syn_i)^{\lambda_{\phi'}}\\
&\times\ p_w(syn_i|trg_i)^{\lambda_w}\\
&\times\ p_{w'}(trg_i|syn_i)^{\lambda_{w'}}\\
&\times\ p_d(syn_i, trg_i)^{\lambda_d})\\
&\times\ l_w(syn_1^I)^{\lambda_l}\\
&\times\ c_\phi(syn_1^I)^{\lambda_c}\\
&\times\ p_{LM}(syn_1^I)^{\lambda_{LM}}
\end{aligned}
$$

For estimation of the feature weights $\vec{\lambda}$ defined in equation (4) we employed minimum error rate (MER) training under the BLEU measure (Och, 2003). Training data for MER training were taken from multiple manual English translations of Chinese sources from the NIST 2006 evaluation data. The first of four reference translations for each Chinese sentence was taken as source paraphrase, the rest as reference paraphrases. Discriminative training was conducted on 1,820 sentences; final evaluation on 2,390 sentences. A baseline paraphrase table consisting of 33 million English para-phrase pairs was extracted from 1 billion phrase pairs from three different languages, at a cutoff of para-phrase probabilities of 0.0025.

Query expansion is done by adding terms introduced in n-best paraphrases of the query. Table 2 shows example paraphrases for the query "how to live with cat allergies" with newly introduced terms highlighted in bold face.

5 Experimental Evaluation

Our baseline answer retrieval system is modeled after the *tfidf* retrieval model of Jijkoun and de Rijke (2005). Their model calculates a linear combination of vector similarity scores between the user query and several fields in the question-answer pair. We used the cosine similarity metric with logarithmically weighted term and document frequency weights in order to reproduce the Lucene[3] model used in Jijkoun and de Rijke (2005). For indexing of fields, we adopted the settings that were reported to be optimal in Jijkoun and de Rijke (2005). These settings comprise the use of 8 question-answer pair fields, and a weight vector $\langle 0.0, 1.0, 0.0, 0.0, 0.5, 0.5, 0.2, 0.3\rangle$ for fields ordered as follows: (1) full FAQ document text, (2) question text, (3) answer text, (4) title text, (5)-(8) each of the above without stopwords. The second field thus takes takes wh-words, which would typically be filtered out, into account. All other fields are matched without stopwords, with higher weight assigned to document and question than to answer and title fields. We did not use phrase-matching or stemming in our experiments, similar to Jijkoun and de Rijke (2005), who could not find positive effects for these features in their experiments.

Expansion terms are taken from those terms in the n-best translations of the query that have not been seen in the original query string. For paraphrasing-based query expansion, a 50-best list of paraphrases of the original query was used. For the noisier question-answer translation, expansion terms and phrases were extracted from a 10-

[3] http://lucene.apache.org

	S_2@10	S_2@20	$S_{1,2}$@10	$S_{1,2}$@20
baseline *tfidf*	27	35	58	65
local expansion	30 (+ 11.1)	40 (+ 14.2)	57 (- 1)	63 (- 3)
SMT-based expansion	38 (+ 40.7)	43 (+ 22.8)	58	65

Table 3: Success rate at 10 or 20 results for retrieval of adequate (2) or material (1) answers; relative change in brackets.

best list of query translations. Terms taken from query paraphrases were matched with the same field weight vector $\langle 0.0, 1.0, 0.0, 0.0, 0.5, 0.5, 0.2, 0.3\rangle$ as above. Terms taken from question-answer translation were matched with the weight vector $\langle 0.0, 1.0, 0.0, 0.0, 0.5, 0.2, 0.5, 0.3\rangle$, preferring answer fields over question fields. After stopword removal, the average number of expansion terms produced was 7.8 for paraphrasing, and 3.1 for question-answer translation.

The local expansion technique used in our experiments follows Xu and Croft (1996) in taking expansion terms from the top n answers that were retrieved by the baseline *tfidf* system, and by incorporating cooccurrence information with query terms. This is done by calculating term frequencies for expansion terms by summing up the *tfidf* weights of the answers in which they occur, thus giving higher weight to terms that occur in answers that receive a higher similarity score to the original query. In our experiments, expansion terms are ranked according to this modified *tfidf* calculation over the top 20 answers retrieved by the baseline retrieval run, and matched a second time with the field weight vector $\langle 0.0, 1.0, 0.0, 0.0, 0.5, 0.2, 0.5, 0.3\rangle$ that prefers answer fields over question fields. After stopword removal, the average number of expansion terms produced by the local expansion technique was 9.25.

The test queries we used for retrieval are taken from query logs of the MetaCrawler search engine[4] and were provided to us by Valentin Jijkoun. In order to maximize recall for the comparative evaluation of systems, we selected 60 queries that were well-formed natural language questions without metacharacters and spelling errors. However, for one third of these well-formed queries none of the five compared systems could retrieve an answer. Examples are *"how do you make a cornhusk doll"*, *"what is the idea of materialization"*, or *"what does 8x certified mean"*, pointing to a severe recall problem of the question-answer database.

Evaluation was performed by manual labeling of top 20 answers retrieved for each of 60 queries for each system by two independent judges. For the sake of consistency, we chose not to use the assessments provided by Jijkoun and de Rijke. Instead, the judges were asked to find agreement on the examples on which they disagreed after each evaluation round. The ratings together with the question-answer pair id were stored and merged into the retrieval results for the next system evaluation. In this way consistency across system evaluations could be ensured, and the effort of manual labeling could be substantially reduced. The quality of retrieval results was assessed according to Jijkoun and de Rijke's (2005) three point scale:

- adequate (2): answer is contained
- material (1): no exact answer, but important information given
- unsatisfactory (0): user's information need is not addressed

The evaluation measure used in Jijkoun and de Rijke (2005) is the success rate at 10 or 20 answers, i.e., $S_2@n$ is the percentage of queries with at least one adequate answer in the top n retrieved question-answer pairs, and $S_{1,2}@n$ is the percentage of queries with at least one adequate or material answer in the top n results. This evaluation measure accounts for improvements in coverage, i.e., it rewards cases where answers are found for queries that did not have an adequate or material answer before. In contrast, the mean reciprocal rank (MRR) measure standardly used in QA can have the effect of preferring systems that find answers only for a small set of queries, but rank them higher than systems with

Table 4: Examples for queries and expansion terms yielding improved (+), decreased (-), or unchanged (0) retrieval performance compared to retrieval without expansion.

higher coverage. This makes MRR less adequate for the low-recall setup of FAQ retrieval.

Table 3 shows success rates at 10 and 20 retrieved question-answer pairs for five different systems. The results for the *baseline tfidf* system, following Jijkoun and de Rijke (2005), are shown in row 2. Row 3 presents results for our variant of *local expansion* by pseudo-relevance feedback (Xu and Croft, 1996). Results for *SMT-based expansion* are given in row 4. A comparison of success rates for retrieving at least one adequate answer in the top 10 results shows relative improvements over the baseline of 11.1% for local query expansion, and of 40.7% for combined SMT-based expansion. Success rates at top 20 results show similar relative improvements of 14.2% for local query expansion, and of 22.8% for combined SMT-based expansion. On the easier task of retrieving a material or adequate answer, success rates drop by a small amount for local expansion, and stay unchanged for SMT-based expansion.

These results can be explained by inspecting a few sample query expansions. Examples (1)-(3) in Table 4 illustrate cases where SMT-based query expansion improves results over baseline performance, but local expansion decreases performance by introducing irrelevant terms. In (4) retrieval performance is improved over the baseline for both expansion techniques. In (5) both local and SMT-based expansion introduce terms that decrease retrieval performance compared to retrieval without expansion.

6 Conclusion

We presented two techniques for query expansion in answer retrieval that are based on SMT technology. Our method for question-answer translation uses a large corpus of question-answer pairs extracted from FAQ pages to learn a translation model from questions to answers. SMT-based paraphrasing utilizes large amounts of bilingual data as a new information source to extract phrase-level synonyms. Both SMT-based techniques take the entire query context into account when adding new terms to the original query. In an experimental comparison with a baseline *tfidf* approach and a local query expansion technique on the task of answer retrieval from FAQ pages, we showed a significant improvement of both SMT-based query expansion over both baselines.

Despite the small-scale nature of our current experimental results, we hope to apply the presented techniques to general web retrieval in future work. Another task for future work is to scale up the extraction of question-answer pair data in order to provide an improved resource for question-answer translation.

A Computational Model of Text Reuse in Ancient Literary Texts

John Lee

jsylee@csail.mit.edu

Abstract

We propose a computational model of text reuse tailored for ancient literary texts, available to us often only in small and noisy samples. The model takes into account source alternation patterns, so as to be able to align even sentences with low surface similarity. We demonstrate its ability to characterize text reuse in the Greek New Testament.

1 Introduction

Text reuse is the transformation of a source text into a target text in order to serve a different purpose. Past research has addressed a variety of text-reuse applications, including: journalists turning a news agency text into a newspaper story (Clough et al., 2002); editors adapting an encyclopedia entry to an abridged version (Barzilay and Elhadad, 2003); and plagiarizers disguising their sources by removing surface similarities (Uzuner et al., 2005).

A common assumption in the recovery of text reuse is the conservation of some degree of lexical similarity from the *source sentence* to the *derived sentence*. A simple approach, then, is to define a lexical similarity measure and estimate a score threshold; given a sentence in the target text, if the highest-scoring sentence in the source text is above the threshold, then the former is considered to be derived from the latter. Obviously, the effectiveness of this basic approach depends on the degree of lexical similarity: source sentences that are quoted verbatim are easier to identify than those that have been transformed by a skillful plagiarizer.

The crux of the question, therefore, is how to identify source sentences despite their lack of surface similarity to the derived sentences. Ancient literary texts, which are the focus of this paper, present some distinctive challenges in this respect.

1.1 Ancient Literary Texts

"Borrowed material embedded in the flow of a writer's text is a common phenomenon in Antiquity." (van den Hoek, 1996). Ancient writers rarely acknowledged their sources. Due to the scarcity of books, they often needed to quote from memory, resulting in inexact quotations. Furthermore, they combined multiple sources, sometimes inserting new material or substantially paraphrasing their sources to suit their purpose. To compound the noise, the version of the source text available to us today might not be the same as the one originally consulted by the author. Before the age of the printing press, documents were susceptible to corruptions introduced by copyists.

Identifying the sources of ancient texts is useful in many ways. It helps establish their relative dates. It traces the evolution of ideas. The material quoted, left out or altered in a composition provides much insight into the agenda of its author. Among the more frequently quoted ancient books are the gospels in the New Testament. Three of them — the gospels of Matthew, Mark, and Luke — are called the Synoptic Gospels because of the substantial text reuse among them.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 472–479,

Table 1: Luke 9:30-33 and their source verses in the Gospel of Mark. The Greek words with common stems in the target and source verses are bolded. The King James Version English translation is included for reference. §1.2 comments on the text reuse in these verses.

1.2 Synoptic Gospels

The nature of text reuse among the Synoptics spans a wide spectrum. On the one hand, some revered verses, such as the sayings of Jesus or the apostles, were preserved verbatim. Such is the case with Peter's short speech in the second half of Luke 9:33 (see Table 1). On the other hand, unimportant details may be deleted, and new information weaved in from other sources or oral traditions. For example, "Luke often edits the introductions to new sections with the greatest independence" (Taylor, 1972). To complicate matters, it is believed by some researchers that the version of the Gospel of Mark used by Luke was a more primitive version, customarily called *Proto-Mark*, which is no longer extant (Boismard, 1972). Continuing our example in Table 1, verses 9:31-32 have no obvious counterparts in the Gospel of Mark. Some researchers have attributed them to an earlier version of Mark (Boismard, 1972) or to Luke's "redactional tendencies" (Bovon, 2002).

The result is that some verses bear little resemblance to their sources, due to extensive redaction, or to discrepancies between different versions of the source text. In the first case, any surface similarity score alone is unlikely to be effective. In the second, even deep semantic analysis might not suffice.

1.3 Goals

One property of text reuse that has not been explored in past research is *source alternation patterns*. For example, "it is well known that sections of Luke derived from Mark and those of other origins are arranged in continuous blocks" (Cadbury, 1920). This notion can be formalized with features on the blocks and order of the source sentences. The first goal of this paper is to *leverage source alternation patterns to optimize the global text reuse hypothesis.*

Scholars of ancient texts tend to express their analyses qualitatively. We attempt to translate their insights into a quantitative model. To our best knowledge, this is the first sentence-level, quantitative text-reuse model proposed for ancient texts. Our second goal is thus to *bring a quantitative approach to source analysis of ancient texts.*

2 Previous Work

Text reuse is analyzed at the document level in (Clough et al., 2002), which classifies newspaper articles as wholly, partially, or non-derived from a news agency text. The hapax legomena, and sentence alignment based on N-gram overlap, are found to be the most useful features. Considering a document as a whole mitigates the problem of low similarity scores for some of the derived sentences.

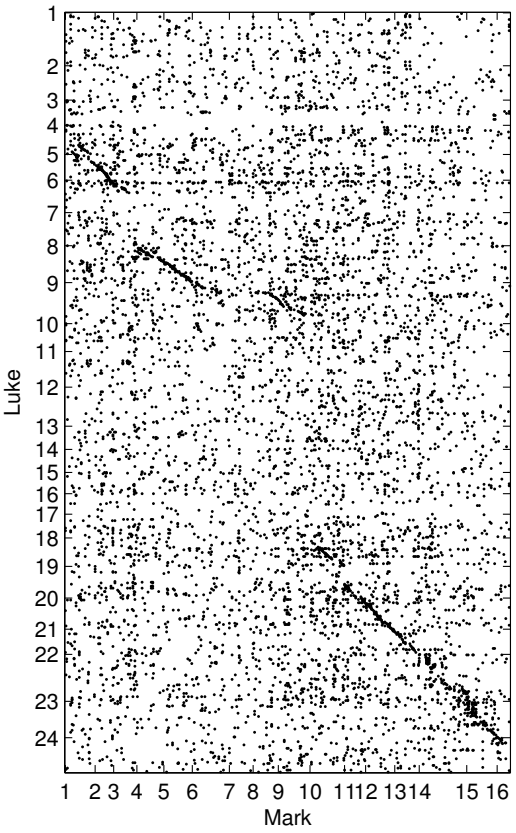

Figure 1: A dot-plot of the cosine similarity measure between the Gospel of Luke and the Gospel of Mark. The number on the axes represent chapters. The thick diagonal lines reflect regions of high lexical similarity between the two gospels.

At the level of short passages or sentences, (Hatzivassiloglou et al., 1999) goes beyond N-gram, taking advantage of WordNet synonyms, as well as ordering and distance between shared words. (Barzilay and Elhadad, 2003) shows that the simple cosine similarity score can be effective when used in conjunction with paragraph clustering. A more detailed comparison with this work follows in §4.2.

In the humanities, reused material in the writings of Plutarch (Helmbold and O'Neil, 1959) and Clement (van den Hoek, 1996) have been manually classified as quotations, reminiscences, references or paraphrases. Studies on the Synoptics have been limited to N-gram overlap, notably (Honoré, 1968) and (Miyake et al., 2004).

Text	Hypothesis	Researcher	Model
L_{train}	$L_{train.B}$	(Bovon, 2002)	*B*
	$L_{train.J}$	(Jeremias, 1966)	*J*
L_{test}	$L_{test.B}$	(Bovon, 2003)	
	$L_{test.J}$	(Jeremias, 1966)	

Table 2: Two models of text reuse of Mark in L_{train} are trained on two different text-reuse hypotheses: The *B* model is on the hypothesis in (Bovon, 2002), and the *J* model, on (Jeremias, 1966). These two models then predict the text-reuse in L_{test}.

3 Data

We assume the Two-Document Theory[1], which hypothesizes that the Gospel of Luke and the Gospel of Matthew have as their common sources two documents: the Gospel of Mark, and a lost text customarily denoted *Q*. In particular, we will consider the Gospel of Luke[2] as the target text, and the Gospel of Mark as the source text.

We use a Greek New Testament corpus prepared by the Center for Computer Analysis of Texts at the University of Pennsylvania[3], based on the text variant from the United Bible Society. The text-reuse hypotheses (i.e., lists of verses deemed to be derived from Mark) of François Bovon (Bovon, 2002; Bovon, 2003) and Joachim Jeremias (Jeremias, 1966) are used. Table 2 presents our notations.

Luke 1:1 to 9:50 (L_{train}, 458 verses) Chapters 1 and 2, narratives of the births of Jesus and John the Baptist, are based on non-Markan sources. Verses 3:1 to 9:50 describe Jesus' activities in Galilee, a substantial part of which is derived from Mark.

Luke Chapters 22 to 24 (L_{test}, 179 verses) These chapters, known as the Passion Narrative, serve as our test text. Markan sources were behind 38% of the verses, according to Bovon, and 7% according to Jeremias.

[1]This theory (Streeter, 1930) is currently accepted by a majority of researchers. It guides our choice of experimental data, but our model does not depend on its validity.

[2]We do not consider the Gospel of Matthew or *Q* in this study. Verses from Luke 9:51 to the end of chapter 21 are also not considered, since their sources are difficult to ascertain (Bovon, 2002).

[3]Obtained through Peter Ballard (personal communication)

4 Approach

For each verse in the target text (a "target verse"), we would like to determine whether it is derived from a verse in the source text (a "source verse") and, if so, which one.

Following the framework of global linear models in (Collins, 2002), we cast this task as learning a mapping F from input verses $\mathbf{x} \in \mathcal{X}$ to a text-reuse hypothesis $\mathbf{y} \in \mathcal{Y} \cup \{\epsilon\}$. $\mathcal{X}$ is the set of verses in the target text. In our case, $\mathbf{x}_{train} = (x_1, \ldots, x_{458})$ is the sequence of verses in L_{train}, and $\mathbf{x}_{test}$ is that of L_{test}. $\mathcal{Y}$ is the set of verses in the source text. Say the sequence $\mathbf{y} = (y_1, \ldots, y_n)$ is the text-reuse hypothesis for $\mathbf{x} = (x_1, \ldots, x_n)$. If y_i is ϵ, then x_i is not derived from the source text; otherwise, y_i is the source verse for x_i. The set of candidates $\mathbf{GEN}(\mathbf{x})$ contains all possible sequences for $\mathbf{y}$, and Θ is the parameter vector. The mapping F is thus:

$$F(\mathbf{x}) = \arg \max_{\mathbf{y} \in \mathbf{GEN}(\mathbf{x})} \Phi(\mathbf{x}, \mathbf{y}) \cdot \Theta$$

4.1 Features

Given the small amount of training data available[4], the feature space must be kept small to avoid overfitting. Starting with the cosine similarity score as the baseline feature, we progressively enrich the model with the following features:

Cosine Similarity [Sim] Treating a target verse as a query to the set of source verses, we compute the cosine similarity, weighted with tf.idf, for each pair of source verse and target verse[5]. This standard bag-of-words approach is appropriate for Greek, a relatively free word-order language. Figure 1 plots this feature on Luke and Mark.

Non-derived verses are assigned a constant score in lieu of the cosine similarity. We will refer to this constant as the *cosine threshold* (C): when the Sim feature alone is used, the constant effectively acts as the threshold above which target verses are considered to be derived. If w_i, w_j are the vectors of words of a target verse and a candidate source verse, then:

$$sim(i,j) = \begin{cases} \frac{w_i \cdot w_j}{\|w_i\| \cdot \|w_j\|} & \text{if derived} \\ C & \text{otherwise} \end{cases}$$

Number of Blocks [Block] Luke can be viewed as alternating between Mark and non-Markan material, and he "prefers to pick up alternatively entire blocks rather than isolated units." (Bovon, 2002) We will use the term *Markan block* to refer to a sequence of verses that are derived from Mark. A verse with a low cosine score, but positioned in the middle of a Markan block, is likely to be derived. Conversely, an isolated verse in the middle of a non-Markan block, even with a high cosine score, is unlikely to be so. The heavier the weight of this feature, the fewer blocks are preferred.

Source Proximity [Prox] When two derived verses are close to one another, their respective source verses are also likely to be close to one another; in other words, derived verses tend to form "continuous blocks" (Cadbury, 1920).

We define *distance* as the number of verses separating two verses. For each pair of consecutive target verses, we take the inverse of the distance between their source verses. This feature is thus intended to discourage a derived verse from being aligned with a source verse that shares some lexical similarities by chance, but is far away from other source verses in the Markan block.

Source Order [Order] "Whenever Luke follows the Markan narrative in his own gospel he follows painstakingly the Markan order", and hence "deviations in the order of the material must therefore be regarded as indications that Luke is not following Mark." (Jeremias, 1966). This feature is a binary function on two consecutive derived verses, indicating whether their source verses are in order. A positive weight for this feature would favor an alignment that respects the order of the source text.

In cases where there are no obvious source verses, such as Luke 9:30-31 in Table 1, the source order

[4]Note that the training set consists of only one $\mathbf{x}_{train}$ — the Gospel of Luke. Luke's only other book, the *Acts of the Apostles*, contains few identifiable reused material.

[5]A targert verse is also allowed to match two consecutive source verses.

and proximity would be disrupted. To mitigate this issue, we allow the `Prox` and `Order` features the option of skipping up to two verses within a Markan block in the target text. In our example, Luke 9:30 can skip to 9:32, preserving the source proximity and order between their source verses, Mark 9:4 and 9:5.

Another potential feature is the occurrence of function words characteristic of Luke (Rehkopf, 1959), along the same lines as in the study of the Federalist Papers (Mosteller and Wallace, 1964). These stylistic indicators, however, are unlikely to be as helpful on the sentence level as on the document level. Furthermore, Luke "reworks [his sources] to an extent that, within his entire composition, the sources rarely come to light in their original independent form" (Bovon, 2002). The significance of the presence of these indicators, therefore, is diminished.

4.2 Discussion

This model is both a simplification of and an extension to the one advocated in (Barzilay and Elhadad, 2003). On the one hand, we perform no paragraph clustering or mapping before sentence alignment. Ancient texts are rarely divided into paragraphs, nor are they likely to be large enough for statistical methods on clustering. Instead, we rely on the `Prox` feature to encourage source verses to stay close to each other in the alignment.

On the other hand, our model makes two extensions to the "Micro Alignment" step in (Barzilay and Elhadad, 2003). First, we add the `Block` and `Prox` features to capture source alternation patterns. Second, we place no hard restrictions on the reordering of the source text, opting instead for a soft preference for maintaining the source order through the `Order` feature. In contrast, deviation from the source order is limited to "flips" between two sentences in (Barzilay and Elhadad, 2003), an assumption that is not valid in the Synoptics[6].

4.3 Evaluation Metric

Our model can make two types of errors: *source error*, when it predicts a non-derived target verse to be derived, or vice versa; and *alignment error*, when it correctly predicts a target verse to be derived, but aligns it to the wrong source verse.

Correspondingly, we interpret the output of our model at two levels: as a binary output, i.e., the target verse is either "derived" or "non-derived"; or, as an alignment of the target verse to a source verse. We measure the precision and recall of the target verses at both levels, yielding two F-measures, F_{source} and F_{align}[7].

Literary dependencies in the Synoptics are typically expressed as pairs of *pericopes* (short, coherent passages), for example, "Luke 22:47-53 // Mark 14:43-52". Likewise, for F_{align}, we consider the output correct if the hypothesized source verse lies within the pericope[8].

5 Experiments

This section presents experiments for evaluating our text-reuse model. §5.1 gives some implementation details. §5.2 describes the training process, which uses text-reuse hypotheses of two different researchers ($L_{train.B}$ and $L_{train.J}$) on the same training text. The two resulting models thus represent two different opinions on how Luke re-used Mark; they then produce two hypotheses on the test text ($\hat{L}_{test.B}$ and $\hat{L}_{test.J}$).

Evaluations of these hypotheses follow. In §5.3, we compare them with the hypotheses of the same two researchers on the test text ($L_{test.B}$ and $L_{test.J}$). In §5.3, we compare them with the hypotheses of seven other representative researchers (Neirynck, 1973). Ideally, when the model is trained on a particular researcher's hypothesis on the train text, its hypothesis on the test text should be closest to the one proposed by the same researcher.

5.1 Implementation

Suppose we align the i^{th} target verse to the k^{th} source verse or to ϵ. Using dynamic programming, their score is the cosine similarity score $sim(i, k)$, added to the best alignment state up to the $(i - 1 - skip)^{th}$ target verse, where $skip$ can vary from 0 to 2 (see §4.1). If the j^{th} source verse is the aligned

[6]For example, Luke 6:12-19 transposes Mark 3:7-12 and Mark 3:13-19 (Bovon, 2002).

[7]Note that F_{align} is never higher than F_{source} since it penalizes both source and alignment errors.

[8]A more fine-grained metric is individual verse alignment. This is unfortunately difficult to measure. As discussed in §1.2, many derived verses have no clear source verses.

Model	*B*		*J*	
Train Hyp	$L_{train.B}$		$L_{train.J}$	
Metric	F_{source}	F_{align}	F_{source}	F_{align}
`Sim`	0.760	0.646	0.748	0.635
`+Block`	0.961	0.728	0.977	0.743
`All`	**0.985**	**0.949**	**0.983**	**0.936**

Table 3: Performance on the training text, L_{train}. The features are accumulative; `All` refers to the full feature set.

verse in this state, then $score(i, k)$ is:

$$sim(i,k) + \max_{j,skip}\{score(i-1-skip, j) + w_{prox} \cdot prox(j,k) + w_{order} \cdot order(j,k) - w_{block} \cdot block(j,k)\}$$

If both j and k are aligned (i.e., not ϵ), then:

$$\begin{aligned} prox(j,k) &= \frac{1}{dist(j,k)} \\ order(j,k) &= 1 \text{ if } j \geq k \\ block(j,k) &= 1 \text{ if starting new block} \end{aligned}$$

Otherwise these are set to zero.

5.2 Training Results

The model takes only four parameters: the weights for the `Block`, `Prox` and `Order` features, as well as the cosine threshold (C). They are empirically optimized, accurate to 0.01, on the two training hypotheses listed in Table 2, yielding two models, *B* and *J*.

Table 3 shows the increasing accuracy of both models in describing the text reuse in L_{train} as more features are incorporated. The `Block` feature contributes most in predicting the block boundaries, as seen in the jump of F_{source} from `Sim` to `+Block`. The `Prox` and `Order` features substantially improve the alignment, boosting the F_{align} from `+Block` to `All`.

Both models *B* and *J* fit their respective hypotheses to very high degrees. For *B*, the only significant source error occurs in Luke 8:1-4, which are derived verses with low similarity scores. They are transitional verses at the beginning of a Markan block. For *J*, the pericope Luke 6:12-16 is wrongly predicted as derived.

Most alignment errors are misalignments to a neighboring pericope, typically for verses located near the boundary between two pericopes. Due to their low similarity scores, the model was unable to decide if they belong to the end of the preceding pericope or to the beginning of the following one.

Model	*B*		*J*	
Test Hyp	$L_{test.B}$		$L_{test.J}$	
Metric	F_{source}	F_{align}	F_{source}	F_{align}
`Sim`	0.579	0.382	0.186	0.144
`+Block`	0.671	0.329	0.743	0.400
`All`	**0.779**	**0.565**	**0.839**	**0.839**

Table 5: Performance on the test text, L_{test}.

5.3 Test Results

The two models trained in §5.2, *B* and *J*, are intended to capture the characteristics of text reuse in L_{train} according to two different researchers. When applied on the test text, L_{test}, they produce two hypotheses, $\hat{L}_{test.B}$ and $\hat{L}_{test.J}$. Ideally, they should be similar to the hypotheses offered by the same researchers (namely, $L_{test.B}$ and $L_{test.J}$), and dissimilar to those by other researchers. We analyze the first aspect in §5.3, and the second aspect in §5.3.

Comparison with Bovon and Jeremias

Table 4 shows the output of *B* and *J* on L_{test}. As more features are added, their output increasingly resemble $L_{test.B}$ and $L_{test.J}$, as shown in Table 5.

Both $\hat{L}_{test.B}$ and $\hat{L}_{test.J}$ contain the same number of Markan blocks as the "reference" hypotheses proposed by the respective scholars. In both cases, the pericope Luke 22:24-30 is correctly assigned as non-derived, despite their relatively high cosine scores. This illustrates the effect of the `Block` feature.

As for source errors, both *B* and *J* mistakenly assign Luke 22:15-18 as Markan, attracted by the high similarity score of Luke 22:18 with Mark 14:25. *B*, in addition, attributes another pericope to Mark where Bovon does not. Despite the penalty of lower source proximity, it wrongly aligned Luke 23:37-38 to Mark 15:2, misled by a specific title of Jesus that happens to be present in both.

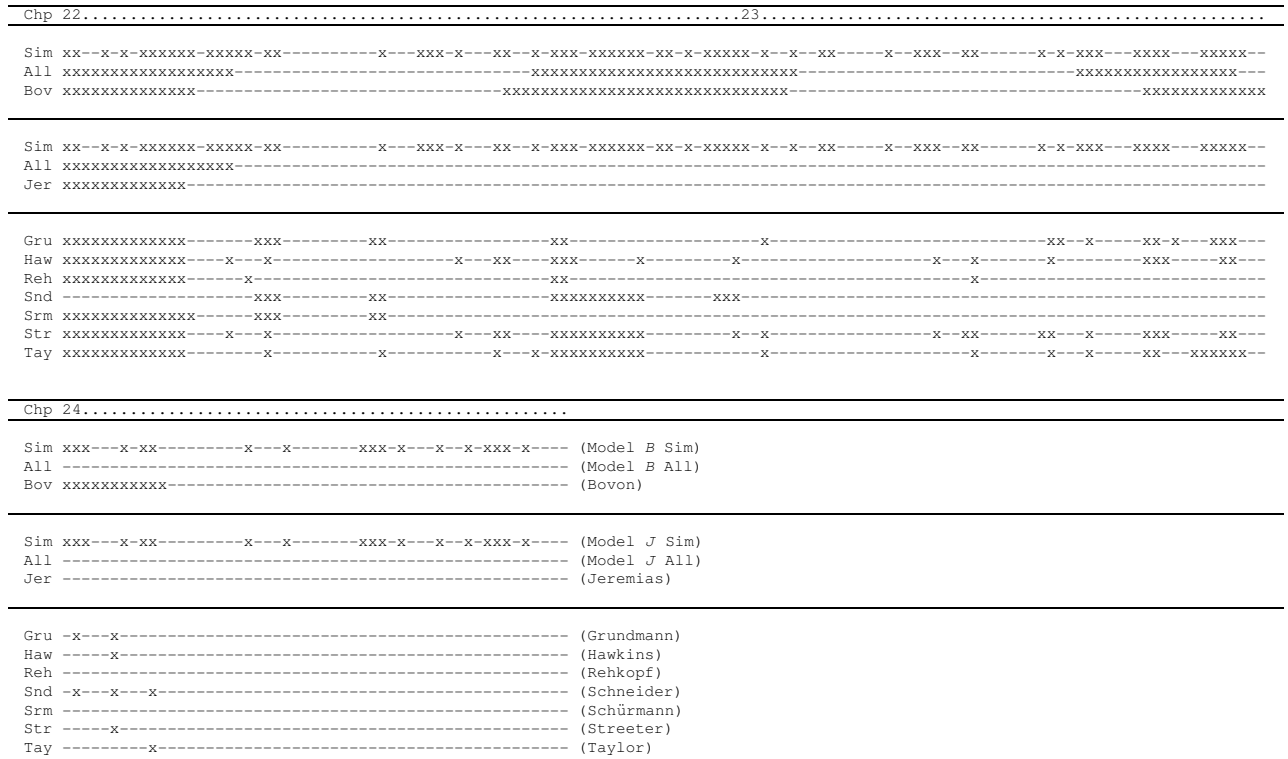

Table 4: Output of models *B* and *J*, and scholarly hypotheses on the test text, L_{test}. The symbol 'x' indicates that the verse is derived from Mark, and '–' indicates that it is not. The hypothesis from (Bovon, 2003), labelled 'Bov', is compared with the Sim (baseline) output and the All output of model *B*, as detailed in Table 5. The hypothesis from (Jeremias, 1966), 'Jer', is similarly compared with outputs of model *J*. Seven other scholarly hypotheses are also listed.

Elsewhere, *B* is more conservative than Bovon in proposing Markan derivation. For instance, the pericope Luke 24:1-11 is deemed non-derived, an opinion (partially) shared by some of the other seven researchers.

Comparison with Other Hypotheses

Another way of evaluating the output of *B* and *J* is to compare them with the hypotheses of other researchers. As shown in Table 6, $\hat{L}_{test.B}$ is more similar to $L_{test.B}$ than to the hypothesis of other researchers[9]. In other words, when the model is trained on Bovon's text-reuse hypothesis on the train text, its prediction on the test text matches most closely with that of the same researcher, Bovon.

Hypothesis	*B* ($\hat{L}_{test.B}$)	*J* ($\hat{L}_{test.J}$)
Bovon ($L_{test.B}$)	**0.838**	0.676
Jeremias ($L_{test.J}$)	0.721	**0.972**
Grundmann	0.726	0.866
Hawkins	0.737	0.877
Rehkopf	0.721	0.950
Schneider	0.676	0.782
Schürmann	0.698	0.950
Streeter	0.771	0.821
Taylor	0.793	0.821

Table 6: Comparison of the output of the models *B* and *J* with hypotheses by prominent researchers listed in (Neirynck, 1973). The metric is the percentage of verses deemed by both hypotheses to be "derived", or "non-derived".

[9]This is the list of researchers whose opinions on L_{test} are considered representative by (Neirynck, 1973). We have simplified their hypotheses, considering those "partially assimilated" and "reflect the influence of Mark" to be non-derived from Mark.

The differences between Bovon and the next two most similar hypotheses, Taylor and Streeter, are not statistically significant according to McNemar's test ($p = 0.27$ and $p = 0.10$ respectively), possibly a reflection of the small size of L_{test}; the differences are significant, however, with all other hypotheses ($p < 0.05$). Similar results are observed for Jeremias and $\hat{L}_{test.J}$.

6 Conclusion & Future Work

We have proposed a text-reuse model for ancient literary texts, with novel features that account for source alternation patterns. These features were validated on the Lukan Passion Narrative, an instance of text reuse in the Greek New Testament.

The model's predictions on this passage are compared to nine scholarly hypotheses. When tuned on the text-reuse hypothesis of a certain researcher on the train text, it favors the hypothesis of the same person on the test text. This demonstrates the model's ability to capture the researcher's particular understanding of text reuse.

While a computational model alone is unlikely to provide definitive answers, it can serve as a supplement to linguistic and literary-critical approaches to text-reuse analysis, and can be especially helpful when dealing with a large amount of candidate source texts.

Acknowledgements

This work grew out of a term project in the course "Gospel of Luke", taught by Professor François Bovon at Harvard Divinity School. It has also benefited much from discussions with Dr. Steven Lulich.

Finding document topics for improving topic segmentation

Olivier Ferret

Abstract

Topic segmentation and identification are often tackled as separate problems whereas they are both part of topic analysis. In this article, we study how topic identification can help to improve a topic segmenter based on word reiteration. We first present an unsupervised method for discovering the topics of a text. Then, we detail how these topics are used by segmentation for finding topical similarities between text segments. Finally, we show through the results of an evaluation done both for French and English the interest of the method we propose.

1 Introduction

In this article, we address the problem of linear topic segmentation, which consists in segmenting documents into topically homogeneous segments that does not overlap each other. This part of the Discourse Analysis field has received a constant interest since the initial work in this domain such as (Hearst, 1994). One criterion for classifying topic segmentation systems is the kind of knowledge they depend on. Most of them only rely on surface features of documents: word reiteration in (Hearst, 1994; Choi, 2000; Utiyama and Isahara, 2001; Galley et al., 2003) or discourse cues in (Passonneau and Litman, 1997; Galley et al., 2003). As such systems do not require external knowledge, they are not sensitive to domains but they are limited by the type of documents they can be applied to: lexical reiteration is reliable only if concepts are not too frequently expressed by several means (synonyms, etc.) and discourse cues are often rare and corpus-specific.

To overcome these difficulties, some systems make use of domain-independent knowledge about lexical cohesion: a lexical network built from a dictionary in (Kozima, 1993); a thesaurus in (Morris and Hirst, 1991); a large set of lexical co-occurrences collected from a corpus in (Choi et al., 2001). To a certain extent, these lexical networks enable topic segmenters to exploit a sort of concept reiteration. However, their lack of any explicit topical structure makes this kind of knowledge difficult to use when lexical ambiguity is high.

The most simple solution to this problem is to exploit knowledge about the topics that may occur in documents. Such topic models are generally built from a large set of example documents as in (Yamron et al., 1998), (Blei and Moreno, 2001) or in one component of (Beeferman et al., 1999). These statistical topic models enable segmenters to improve their precision but they also restrict their scope.

Hybrid systems that combine the approaches we have presented were also developed and illustrated the interest of such a combination: (Jobbins and Evett, 1998) combined word recurrence, co-occurrences and a thesaurus; (Beeferman et al., 1999) relied on both lexical modeling and discourse cues; (Galley et al., 2003) made use of word reiteration through lexical chains and discourse cues.

The work we report in this article takes place in the first category we have presented. It does not rely on any *a priori* knowledge and exploits word usage rather than discourse cues. More precisely, we present a new method for enhancing the results

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 480–487,
Prague, Czech Republic, June 2007.

of segmentation systems based on word reiteration without relying on any external knowledge.

2 Principles

In most of the algorithms in the text segmentation field, documents are represented as sequences of basic discourse units. When they are written texts, these units are generally sentences, which is also the case in our work. Each unit is turned into a vector of words, following the principles of the *Vector Space* model. Then, the similarity between the basic units of a text is evaluated by computing a similarity measure between the vectors that represent them. Such a similarity is considered as representative of the topical closeness of the corresponding units. This principle is also applied to groups of basic units, such as text segments, because of the properties of the *Vector Space* model. Segments are finally delimited by locating the areas where the similarity between units or groups of units is weak.

This quick overview highlights the important role of the evaluation of the similarity between discourse units in the segmentation process. When no external knowledge is used, this similarity is only based on the strict reiteration of words. But it can be enhanced by taking into account semantic relations between words. This was done for instance in (Jobbins and Evett, 1998) by taking semantic relations from Roget's Thesaurus. This resource was also used in (Morris and Hirst, 1991) where the similarity between discourse units was more indirectly evaluated through the lexical chains they share. The same approach was adopted in (Stokes et al., 2002) but with WordNet as the reference semantic resource.

In this article, we propose to improve the detection of topical similarity between text segments but without relying on any external knowledge. For each text to segment, we first identify its topics by performing an unsupervised clustering of its words according to their co-occurrents in the text. Thus, each of its topics is represented by a subset of its vocabulary. When the similarity between two segments is evaluated during segmentation, the words they share are first considered but the presence of words of the same topic is also taken into account. This makes it possible to find similar two segments that refer to the same topic although they do not share a lot of words. It is also a way to exploit long-range relations between words at a local level. More globally, it helps to reduce the false detection of topic shifts.

3 Unsupervised Topic Identification

The approach we propose first requires to discover the topics of texts. For performing such a task without using *a priori* knowledge, we assume that the most representative words of each of the topics of a text occur in similar contexts. Hence, for each word of the text with a minimal frequency, we collect its co-occurrents, we evaluate the pairwise similarity of these selected text words by relying on their co-occurrents and finally, we build topics by applying an unsupervised clustering method to them.

3.1 Building the similarity matrix of text words

The first step for discovering the topics of a text is a linguistic pre-processing of it. This pre-processing splits the text into sentences and represents each of them as the sequence of its lemmatized plain words, that is, nouns (proper and common nouns), verbs and adjectives. After filtering the low frequency words of the text (frequency < 3), the co-occurrents of the remaining words are classically collected by recording the co-occurrences in a fixed-size window (15 plain words) moved over the pre-processed text. As a result, each text word is represented by a vector that contains its co-occurrents and their co-occurrence frequency. The pairwise similarity between all the selected text words is then evaluated for building their similarity matrix. We classically apply the *Cosine* measure between the vectors that represent them for this evaluation.

3.2 From a similarity matrix to text topics

The final step for discovering the topics of a text is the unsupervised clustering of its words from their similarity matrix. We rely for this task on an adaptation of the Shared Nearest Neighbor (SNN) algorithm described in (Ertöz et al., 2001). This algorithm particularly fits our needs as it automatically determines the number of clusters – in our case the number of topics of a text – and does not take into account the elements that are not representative of the clusters it builds. This last point is important for our application as all the plain words of a text are not representative of its topics. The SNN algorithm

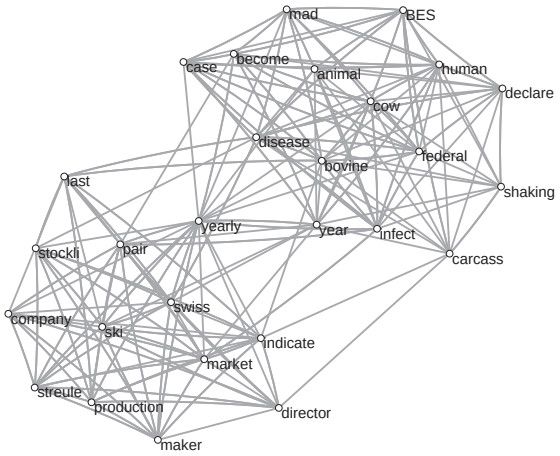

Figure 1: Similarity graph after its sparsification

(see Algorithm 1) performs clustering by detecting high-density areas in a similarity graph. In our case, the similarity graph is directly built from the similarity matrix: each vertex represents a text word and an edge links two words whose similarity is not null. The SNN algorithm splits up into two main stages: the first one finds the elements that are the most representative of their neighborhood. These elements are the seeds of the final clusters that are built in the second stage by aggregating the remaining elements to those selected by the first stage. This first stage

Algorithm 1 SNN algorithm

1. sparsification of the similarity graph
2. building of the SNN graph
3. computation of the distribution of strong links
4. search for topic seeds and filtering of noise
5. building of text topics
6. removal of insignificant topics
7. extension of text topics

starts by sparsifying the similarity graph, which is done by keeping only the links towards the k (k=10) most similar neighbors of each text word (step 1). Figure 1 shows the resulting graph for a two-topic document of our evaluation framework (see Section 5.1). Then, the similarity graph is transposed into a shared nearest neighbor (SNN) graph (step 2). In this graph, the similarity between two words is given by the number of direct neighbors they share in the similarity graph. This transposition makes the similarity values more reliable, especially for high-dimensional data like textual data. Strong links in the SNN graph are finally detected by applying a fixed threshold to the distribution of shared neighbor numbers (step 3). A word with a high number of strong links is taken as the seed of a topic as it is representative of the set of words that are linked to it. On the contrary, a word with few strong links is supposed to be outlier (step 4).

The second stage of the SNN algorithm first builds text topics by associating to topic seeds the remaining words that are the most similar to them provided that their number of shared neighbors is high enough (step 5). Moreover, the seeds that are judged as too close to each other are also grouped during this step in accordance with the same criteria. The last two steps bring small improvements to the results of this clustering. First, when the number of words of a topic is too small (size < 3), this topic is judged as insignificant and it is discarded (step 6). Its words are added to the set of words without topic after step 5. We added this step to the SNN algorithm to balance the fact that without any external knowledge, all the semantic relations between text words cannot be found by relying only on co-occurrence. Finally, the remaining text topics are extended by associating to them the words that are neither noise nor already part of a topic (step 7). As topics are defined at this point more precisely than at step 4, the integration of words that are not strongly linked to a topic seed can be safely performed by relying on the average strength of their links in the SNN graph with the words of the topic. After the SNN algorithm is applied, a set of topics is associated to the text to segment, each of them being defined as a subset of its vocabulary.

4 Using Text Topics for Segmentation

4.1 Topic segmentation using word reiteration

As *TextTiling*, the topic segmentation method of Hearst (Hearst, 1994), the topic segmenter we propose, called F06, first evaluates the lexical cohesion of texts and then finds their topic shifts by identifying breaks in this cohesion. The first step of this process is the linguistic pre-processing of texts, which is identical for topic segmentation to the pre-

processing described in Section 3.1 for the discovering of text topics. The evaluation of the lexical cohesion of a text relies as for *TextTiling* on a fixed-size focus window that is moved over the text to segment and stops at each sentence break. The cohesion in the part of text delimited by this window is evaluated by measuring the word reiteration between its two sides. This is done in our case by applying the *Dice coefficient* between the two sides of the focus window, following (Jobbins and Evett, 1998). This cohesion value is associated to the sentence break at the transition between the two sides of the window. More precisely, if W_l refers to the vocabulary of the left side of the focus window and W_r refers to the vocabulary of its right side, the cohesion in the window at position x is given by:

$$LC_{rec}(x) = \frac{2 \cdot card(W_l \cap W_r)}{card(W_l) + card(W_r)} \quad (1)$$

This measure was adopted instead of the *Cosine* measure used in *TextTiling* because its definition in terms of sets makes it easier to extend for taking into account other types of relations, as in (Jobbins and Evett, 1998). A cohesion value is computed for each sentence break of the text to segment and the final result is a cohesion graph of the text.

The last part of our algorithm is mainly taken from the *LCseg* system (Galley et al., 2003) and is divided into three steps:

- computation of a score evaluating the probability of each minimum of the cohesion graph to be a topic shift;
- removal of segments with a too small size;
- selection of topic shifts.

The computation of the score of a minimum m begins by finding the pair of maxima l and r around it. This score is then given by:

$$score(m) = \frac{LC(l) + LC(r) - 2 \cdot LC(m)}{2} \quad (2)$$

This score, whose values are between 0 and 1, is a measure of how high is the difference between the minimum and the maxima around it. Hence, it favors as possible topic shifts minima that correspond to sharp falls of lexical cohesion.

The next step is done by removing as a possible topic shift each minimum that is not farther than 2 sentences from its preceding neighbor. Finally, the selection of topic shifts is performed by applying a threshold computed from the distribution of minimum scores. Thus, a minimum m is kept as a topic shift if $score(m) > \mu - \alpha \cdot \sigma$, where μ is the average of minimum scores, σ their standard deviation and α is a modulator ($\alpha = 0.6$ in our experiments).

4.2 Using text topics to enhance segmentation

The heart of the algorithm we have presented above is the evaluation of lexical cohesion in the focus window, as given by Equation 1. This evaluation is also a weak point as $card(W_l \cap W_r)$ only relies on word reiteration. As a consequence, two different words that respectively belongs to W_l and W_r but also belong to the same text topic cannot contribute to the identification of a possible topical similarity between the two sides of the focus window.

The algorithm F06T is based on the same principles as F06 but it extends the evaluation of lexical cohesion by taking into account the topical proximity of words. The reference topics for judging this proximity are of course the text topics discovered by the method of Section 3. In this extended version, the evaluation of the cohesion in the focus window is made of three steps:

- computation of the word reiteration cohesion;
- determination of the topic(s) of the window;
- computation of the cohesion based on text topics and fusion of the two kinds of cohesion.

The first step is identical to the computation of the cohesion in F06. The second one aims at restricting the set of topics that are used in the last step to the topics that are actually representative of the content of the focus window, *i.e.* representative of the current context of discourse. This point is especially important in the areas where the current topic is changing because amplifying the influence of the surrounding topics can lead to the topic shift being missed. Hence, a topic is considered as representative of the content of the focus window only if it matches each side of this window. In practice, this matching is evaluated by applying the *Cosine* measure between the vector that represents one side of

the window and the vector that represents the topic[1] and by testing if the resulting value is higher than a fixed threshold (equal to 0.1 in the experiments of Section 5). It must be noted that several topics may be associated to the focus window. As the discovering of text topics is done in an unsupervised way and without any external knowledge, a theme of a text may be scattered over several identified topics and then, its presence can be characterized by several of them.

The last step of the cohesion evaluation first consists in determining for each side of the focus window the number of its words that belong to one of the topics associated to the window. The cohesion of the window is then given by Equation 3, that estimates the significance of the presence of the text topics in the window:

$$LC_{top}(x) = \frac{card(TW_l) + card(TW_r)}{card(W_l) + card(W_r)} \qquad (3)$$

where $TW_{i \in \{l,r\}} = (W_i \cap T_w) - (W_l \cap W_r)$ and T_w is the union of all the representations of the topics associated to the window. TW_i corresponds to the words of the i side of the window that belong to the topics of the window ($W_i \cap T_w$) but are not part of the vocabulary from which the lexical cohesion based on word reiteration is computed ($W_l \cap W_r$).

Finally, the global cohesion in the focus window is computed as the sum of the two kinds of cohesion, the one computed from word reiteration (see Equation 1) and the one computed from text topics (see Equation 3).

5 Evaluation

5.1 Evaluation framework

The main objective of our evaluation was to verify that taking into account text topics discovered without relying on external knowledge can actually improve a topic segmentation algorithm that is initially based on word reiteration. Since the work of Choi (Choi, 2000), the evaluation framework he proposed has become a kind of standard for the evaluation of topic segmentation algorithms. This framework is based on the building of artificial texts made of segments extracted from different documents. It has at least two advantages: the reference corpus is easy to build as it does not require human annotations; parameters such as the size of the documents or the segments can be precisely controlled. But it has also an obvious drawback: its texts are artificial. This is a problem in our case as our algorithm for discovering text topics exploits the fact that the words of a topic tend to co-occur at the document scale. This hypothesis is no longer valid for documents built according to the procedure of Choi. It is why we adapted his framework for having more realistic documents without losing its advantages. This adaptation concerns the way the document segments are selected. Instead of taking each segment from a different document, we only use two source documents. Each of them is split into a set of segments whose size is between 3 and 11 sentences, as for Choi, and an evaluation document is built by concatenating these segments in an alternate way from the beginning of the source documents, *i.e.* one segment from a source document and the following from the other one, until 10 segments are extracted. Moreover, in order to be sure that the boundary between two adjacent segments of an evaluation document actually corresponds to a topic shift, the source documents are selected in such a way that they refer to different topics. This point was controlled in our case by taking documents from the corpus of the CLEF 2003 evaluation for crosslingual information retrieval: each evaluation document was built from two source documents that had been judged as relevant for two different CLEF 2003 topics. Two evaluation corpora made of 100 documents each, one in French and one in English, were built following this procedure. Table 1 shows their main characteristics.

	French	**English**
# source doc.	128	87
# source topics	11	3
segments/doc.	10 (84%) 8 (16%)	10 (97%) 8 (3%)
sentences/doc.	65	68
plain words/doc.	797	604

Table 1: Data about our evaluation corpora

[1] Each word of the topic vector has a weight equal to 1. In the window vector, this weight is equal to the frequency of the word in the corresponding side of the window.

5.2 Topic identification

As F06T exploits document topics, we also evaluated our method for topic identification. This evaluation is based on the corpus of the previous section. For each of its documents, a reference topic is built from each group of segments that come from the same source document by gathering the words that only appear in these segments. A reference topic is associated to the discovered topic that shares with it the largest number of words. Three complementary measures were computed to evaluate the quality of discovered topics. The main one is purity, which is classically used for unsupervised clustering:

$$Purity = \sum_{i=1}^{k} \frac{v_i}{V} P(Td_i) \quad (4)$$

where $P(Td_i)$, the purity of the discovered topic Td_i, is equal to the fraction of the vocabulary of Td_i that is part of the vocabulary of the reference topic Td_i is assigned to, V is the vocabulary of all the discovered topics and v_i is the vocabulary of Td_i. The second measure evaluates to what extent the reference topics are represented among the discovered topics and is equal to the ratio between the number of discovered topics that are assigned to a reference topic (*assigned discovered topics*) and the number of reference topics. The last measure estimates how strongly the vocabulary of reference topics is present among the discovered topics and is equal to the ratio between the size of the vocabulary of the assigned discovered topics and the size of the vocabulary of reference topics. Table 2 gives the mean

	purity	**reference topics (%)**	**ref. topic vocab. (%)**
French	0.771 (0.117)	89.5 (23.9)	29.9 (7.8)
English	0.766 (0.082)	99.0 (10.0)	31.6 (5.3)

Table 2: Evaluation of topic identification

of each measure, followed by its standard deviation. Results are globally similar for French and English. They show that our method for topic identification builds topics that are rather pure, *i.e.* each of them is strongly tied to a reference topic, but their content is rather sparse in comparison with the content of their associated reference topics.

5.3 Topic segmentation

For validating the hypothesis that underlies our work, we applied F06 and F06T to find the topic bounds in the documents of our two evaluation corpora. Moreover, we also tested four well known segmenters on our corpora to compare the results of F06 and F06T with state-of-the-art algorithms. We classically used the error metric P_k proposed in (Beeferman et al., 1999) to measure segmentation accuracy. P_k evaluates the probability that a randomly chosen pair of sentences, separated by k sentences, is wrongly classified, *i.e.* they are found in the same segment while they are actually in different ones (miss) or they are found in different segments while they are actually in the same one (false alarm). We also give the value of *WindowDiff* (WD), a variant of P_k proposed in (Pevzner and Hearst, 2002) that corrects some of its insufficiencies. Tables 3 and 4 show

systems	$\mathbf{P_k}$	$\mathbf{p_{val}}$**(F06)**	$\mathbf{p_{val}}$**(F06T)**	**WD**
U00	25.91	**0.003**	**1.3e-07**	27.42
C99	27.57	**4.2e-05**	**3.6e-10**	35.42
TextTiling*	21.08	0.699	**0.037**	27.43
LCseg	20.55	0.439	0.111	28.31
F06	21.58	⁄	**0.013**	27.83
F06T	*18.46*	**0.013**	⁄	*24.05*

Table 3: Evaluation of topic segmentation for the French corpus (P_k and WD as percentages)

the results of our evaluations for topic segmentation (smallest values are best results). U00 is the system described in (Utiyama and Isahara, 2001), C99 the one proposed in (Choi, 2000) and *LCseg* is presented in (Galley et al., 2003). *TextTiling** is a variant of *TextTiling* in which the final identification of topic shifts is taken from (Galley et al., 2003). All these systems were used as F06 and F06T without fixing the number of topic shifts to find. Moreover, their parameters were tuned for our evaluation corpus to obtain their best results. For each result, we also give the significance level p_{val} of its difference for P_k with F06 and F06T, evaluated by a one-side t-test with a null hypothesis of equal means. Levels lower than 0.05 are considered as statistically significant (bold-faced values). The first important point to notice about these tables is the fact that

systems	P_k	p_{val}(F06)	p_{val}(F06T)	WD
U00	19.42	**0.048**	**4.3e-05**	21.22
C99	21.63	**1.2e-04**	**1.8e-09**	30.64
TextTiling*	15.81	0.308	0.111	19.80
LCseg	14.78	**0.043**	0.496	19.73
F06	16.90	/	**0.010**	20.93
F06T	*14.06*	**0.010**	/	*18.31*

Table 4: Evaluation of topic segmentation for the English corpus (P_k and WD as percentages)

F06T has significantly better results than F06, both for French and English. Hence, it confirms our hypothesis about the interest of taking into account the topics of a text for its segmentation, even if these topics were discovered in an unsupervised way and without using external knowledge. Moreover, F06T have the best results among all the tested algorithms, with a significant difference in most of the cases.

Another notable point about these results is their stability across our two corpora, even if these corpora are quite similar. Whereas F06 and F06T were initially developed on a corpus in French, their results on the English corpus are comparable to their results on the French test corpus, both for the difference between them and the difference with the four other algorithms. The comparison with these algorithms also illustrates the relationships between them: *TextTiling**, *LCseg*, F06 and F06T share a large number of principles and their overall results are significantly higher than the results of U00 and C99. This trend is different from the one observed from the Choi corpus for which algorithms such C99 or U00 have good results (P_k for C99, U00, F06 and F06T is respectively equal to 12%, 10%, 14% and 14%). This means probably that algorithms with good results on a corpus built as the Choi corpus will not necessarily have good results on "true" texts, which agrees with (Georgescul et al., 2006). Finally, we can observe that all these algorithms have better results on the English corpus than on the French one. As the two corpora are quite similar, this difference seems to come from their difference of language, perhaps because repetitions are more discouraged in French than in English from a stylistic viewpoint. This tends to be confirmed by the ratio between the size of the lemmatized vocabulary of each corpus and their number of tokens, equal to 8% for the French corpus and to 5.6% for the English corpus.

6 Related Work

One of the main problems addressed by our work is the detection of the topical similarity of two text units. We have tackled this problem following an endogenous approach, which is new in the topic segmentation field to our knowledge. The main advantage of this option is that it does not require external knowledge. Moreover, it can integrate relations between words, such as proper nouns for instance, that are unlikely to be found in an external resource.

Other solutions have been already proposed to solve the problem we consider. Most of them consist of two steps: first, they automatically build a semantic representation of words from the co-occurrences collected from a large corpus; then, they use this representation for enhancing the representation of each text unit to compare. This overall principle is implemented with different forms by several topic segmenters. In CWM (Choi et al., 2001), a variant of C99, each word of a sentence is replaced by its representation in a *Latent Semantic Analysis* (LSA) space. In the work of Ponte and Croft (Ponte and Croft, 1997), the representations of sentences are expanded by adding to them words selected from an external corpus by the means of the *Local Context Analysis* (LCA) method. Finally in (Caillet et al., 2004), a set of concepts are learnt from a corpus in an unsupervised way by using the X-means clustering algorithm and the paragraphs of documents are represented in the space defined by these concepts. In fact, the way we use relations between words is closer to (Jobbins and Evett, 1998), even if the relations in this work come from a network of co-occurrences or a thesaurus rather than from text topics. In both cases the similarity of two text units is determined by the proportion of their words that are part of a relation across the two units.

More globally, our work exploits the topics of a text for its segmentation. This kind of approach was also explored in (Blei and Moreno, 2001) where probabilistic topic models were built in an unsupervised way. More recently, (Purver et al., 2006) has also proposed a method for unsupervised topic modeling to address both topic segmentation and identi-

fication. (Purver et al., 2006) is closer to our work than (Blei and Moreno, 2001) because it does not require to build topic models from a corpus but as in our case, its results do not outperform *LCseg* (Galley et al., 2003) while its model is far more complex.

7 Conclusion and Future Work

In this article, we have first proposed an unsupervised method for discovering the topics of a text without relying on external knowledge. Then, we have shown how these topics can be used for improving a topic segmentation method based on word reiteration. Moreover, we have proposed an adaptation of the evaluation framework of Choi that aims at building more realistic evaluation documents. Finally, we have demonstrated the interest of the method we present through its evaluation both on a French and an English corpus.

However, the solution we have proposed for improving the identification of topical similarities between text excerpts cannot completely make up for not using any external knowledge. Hence, we plan to use a network of lexical co-occurrences, which is a source of knowledge that is easy to build automatically from a large corpus. More precisely, we intend to extend our method for discovering text topics by combining the co-occurrence graph of a document with such a network. This network could also be used more directly for topic segmentation as in (Jobbins and Evett, 1998).

Abstract

We investigate different feature sets for performing automatic sentence-level discourse segmentation within a general machine learning approach, including features derived from either finite-state or context-free annotations. We achieve the best reported performance on this task, and demonstrate that our SPADE-inspired context-free features are critical to achieving this level of accuracy. This counters recent results suggesting that purely finite-state approaches can perform competitively.

1 Introduction

Discourse structure annotations have been demonstrated to be of high utility for a number of NLP applications, including automatic text summarization (Marcu, 1998; Marcu, 1999; Cristea et al., 2005), sentence compression (Sporleder and Lapata, 2005), natural language generation (Prasad et al., 2005) and question answering (Verberne et al., 2006). These annotations include sentence segmentation into discourse units along with the linking of discourse units, both within and across sentence boundaries, into a labeled hierarchical structure. For example, the tree in Figure 1 shows a sentence-level discourse tree for the string "Prices have dropped but remain quite high, according to CEO Smith," which has three discourse segments, each labeled with either "Nucleus" or "Satellite" depending on how central the segment is to the coherence of the text.

There are a number of corpora annotated with discourse structure, including the well-known RST Treebank (Carlson et al., 2002); the Discourse GraphBank (Wolf and Gibson, 2005); and the Penn Discourse Treebank (Miltsakaki et al., 2004). While the annotation approaches differ across these corpora, the requirement of sentence segmentation into sub-sentential discourse units is shared across all approaches. These resources have facilitated research into stochastic models and algorithms for automatic discourse structure annotation in recent years.

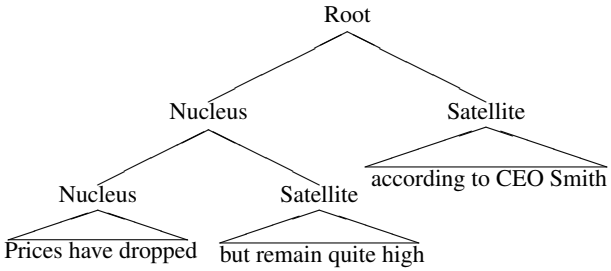

Figure 1: Example Nucleus/Satellite labeled sentence-level discourse tree.

Using the RST Treebank as training and evaluation data, Soricut and Marcu (2003) demonstrated that their automatic sentence-level discourse parsing system could achieve near-human levels of accuracy, if it was provided with manual segmentations and manual parse trees. Manual segmentation was primarily responsible for this performance boost over their fully automatic system, thus making the case that automatic discourse segmentation is the primary impediment to high accuracy automatic sentence-level discourse structure annotation. Their models and algorithm – subsequently packaged together into the publicly available SPADE discourse parser[1] – make use of the output of the Charniak (2000) parser to derive syntactic indicator features for segmentation and discourse parsing.

Sporleder and Lapata (2005) also used the RST Treebank as training data for data-driven discourse parsing algorithms, though their focus, in contrast to Soricut and Marcu (2003), was to avoid context-free parsing and rely exclusively on features in their model that could be derived via finite-state chunkers and taggers. The annotations that they derive are dis-

[1] http://www.isi.edu/publications/licensed-sw/spade/

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 488–495,
Prague, Czech Republic, June 2007.

course "chunks", i.e., sentence-level segmentation and non-hierarchical nucleus/span labeling of segments. They demonstrate that their models achieve comparable results to SPADE without the use of any context-free features. Once again, segmentation is the part of the process where the automatic algorithms most seriously underperform.

In this paper we take up the question posed by the results of Sporleder and Lapata (2005): how much, if any, accuracy reduction should we expect if we choose to use only finite-state derived features, rather than those derived from full context-free parses? If little accuracy is lost, as their results suggest, then it would make sense to avoid relatively expensive context-free parsing, particularly if the amount of text to be processed is large or if there are real-time processing constraints on the system. If, however, the accuracy loss is substantial, one might choose to avoid context-free parsing only in the most time-constrained scenarios.

While Sporleder and Lapata (2005) demonstrated that their finite-state system could perform as well as the SPADE system, which uses context-free parse trees, this does not directly answer the question of the utility of context-free derived features for this task. SPADE makes use of a particular kind of feature from the parse trees, and does not train a general classifier making use of other features beyond the parse-derived indicator features. As we shall show, its performance is not the highest that can be achieved via context-free parser derived features.

In this paper, we train a classifier using a general machine learning approach and a range of finite-state and context-free derived features. We investigate the impact on discourse segmentation performance when one feature set is used versus another, in such a way establishing the utility of features derived from context-free parses. In the course of so doing, we achieve the best reported performance on this task, an absolute F-score improvement of 5.0% over SPADE, which represents a more than 34% relative error rate reduction.

By focusing on segmentation, we provide an approach that is generally applicable to all of the various annotation approaches, given the similarities between the various sentence-level segmentation guidelines. Given that segmentation has been shown to be a primary impediment to high accuracy sentence-level discourse structure annotation, this represents a large step forward in our ability to automatically parse the discourse structure of text, whatever annotation approach we choose.

2 Methods

2.1 Data

For our experiments we use the Rhetorical Structure Theory Discourse Treebank (Carlson et al., 2002), which we will denote RST-DT, a corpus annotated with discourse segmentation and relations according to Rhetorical Structure Theory (Mann and Thompson, 1988). The RST-DT consists of 385 documents from the Wall Street Journal, about 176,000 words, which overlaps with the Penn Wall St. Journal (WSJ) Treebank (Marcus et al., 1993).

The segmentation of sentences in the RST-DT is into clause-like units, known as elementary discourse units, or *edus*. We will use the two terms '*edu*' and 'segment' interchangeably throughout the rest of the paper. Human agreement for this segmentation task is quite high, with agreement between two annotators at an F-score of 98.3 for unlabeled segmentation (Soricut and Marcu, 2003).

The RST-DT corpus annotates *edu* breaks, which typically include sentence boundaries, but sentence boundaries are not explicitly annotated in the corpus. To perform sentence-level processing and evaluation, we aligned the RST-DT documents to the same documents in the Penn WSJ Treebank, and used the sentence boundaries from that corpus.[2] An additional benefit of this alignment is that the Penn WSJ Treebank tokenization is then available for parsing purposes. Simple minimum edit distance alignment effectively allowed for differences in punctuation representation (e.g., double quotes) and tokenization when deriving the optimal alignment.

The RST-DT corpus is partitioned into a training set of 347 documents and a test set of 38 documents. This test set consists of 991 sentences with 2,346 segments. For training purposes, we created a held-out development set by selecting every tenth sentence of the training set. This development set was used for feature development and for selecting the number of iterations used when training models.

2.2 Evaluation

Previous research into RST-DT segmentation and parsing has focused on subsets of the 991 sentence test set during evaluation. Soricut and Marcu (2003)

[2] A small number of document final parentheticals are in the RST-DT and not in the Penn WSJ Treebank, which our alignment approach takes into account.

omitted sentences that were not exactly spanned by a subtree of the treebank, so that they could focus on sentence-level discourse parsing. By our count, this eliminates 40 of the 991 sentences in the test set from consideration. Sporleder and Lapata (2005) went further and established a smaller subset of 608 sentences, which omitted sentences with only one segment, i.e., sentences which themselves are atomic *edus*.

Since the primary focus of this paper is on segmentation, there is no strong reason to omit any sentences from the test set, hence our results will evaluate on all 991 test sentences, with two exceptions. First, in Section 2.3, we compare SPADE results under our configuration with results from Sporleder and Lapata (2005) in order to establish comparability, and this is done on their 608 sentence subset. Second, in Section 3.2, we investigate feeding our segmentation into the SPADE system, in order to evaluate the impact of segmentation improvements on their sentence-level discourse parsing performance. For those trials, the 951 sentence subset from Soricut and Marcu (2003) is used. All other trials use the full 991 sentence test set.

Segmentation evaluation is done with precision, recall and F1-score of segmentation boundaries. Given a word string $w_1 \ldots w_k$, we can index word boundaries from 0 to k, so that each word w_i falls between boundaries $i-1$ and i. For sentence-based segmentation, indices 0 and k, representing the beginning and end of the string, are known to be segment boundaries. Hence Soricut and Marcu (2003) evaluate with respect to sentence internal segmentation boundaries, i.e., with indices j such that $0<j<k$ for a sentence of length k. Let g be the number of sentence-internal segmentation boundaries in the gold standard, t the number of sentence-internal segmentation boundaries in the system output, and m the number of correct sentence-internal segmentation boundaries in the system output. Then

$$P = \frac{m}{t} \quad R = \frac{m}{g} \quad \text{and} \quad F1 = \frac{2PR}{P+R} = \frac{2m}{g+t}$$

In Sporleder and Lapata (2005), they were primarily interested in labeled segmentation, where the segment initial boundary was labeled with the segment type. In such a scenario, the boundary at index 0 is no longer known, hence their evaluation included those boundaries, even when reporting unlabeled results. Thus, in section 2.3, for comparison with reported results in Sporleder and Lapata (2005), our F1-score is defined accordingly, i.e., segmentation boundaries j such that $0 \leq j < k$.

Segmentation system	F1
Sporleder and Lapata best (reported)	88.40
SPADE	
Sporleder and Lapata configuration (reported):	87.06
current configuration:	91.04

Table 1: Segmentation results on the Sporleder and Lapata (2005) data set, with accuracy defined to include sentence initial segmentation boundaries.

In addition, we will report unlabeled bracketing precision, recall and F1-score, as defined in the PARSEVAL metrics (Black et al., 1991) and evaluated via the widely used *evalb* package. We also use *evalb* when reporting labeled and unlabeled discourse parsing results in Section 3.2.

2.3 Baseline SPADE setup

The publicly available SPADE package, which encodes the approach in Soricut and Marcu (2003), is taken as the baseline for this paper. We made several modifications to the script from the default, which account for better baseline performance than is achieved with the default configuration. First, we modified the script to take given parse trees as input, rather than running the Charniak parser itself. This allowed us to make two modifications that improved performance: turning off tokenization in the Charniak parser, and reranking. The default script that comes with SPADE does not turn off tokenization inside of the parser, which leads to degraded performance when the input has already been tokenized in the Penn Treebank style. Secondly, Charniak and Johnson (2005) showed how reranking of the 50-best output of the Charniak (2000) parser gives substantial improvements in parsing accuracy. These two modifications to the Charniak parsing output used by the SPADE system lead to improvements in its performance compared to previously reported results.

Table 1 compares segmentation results of three systems on the Sporleder and Lapata (2005) 608 sentence subset of the evaluation data: (1) their best reported system; (2) the SPADE system results reported in that paper; and (3) the SPADE system results with our current configuration. The evaluation uses the unlabeled F1 measure as defined in that paper, which counts sentence initial boundaries in the scoring, as discussed in the previous section. As can be seen from these results, our improved configuration of SPADE gives us large improvements over the previously reported SPADE performance on this subset. As a result, we feel that we can use SPADE

as a very strong baseline for evaluation on the entire test set.

Additionally, we modified the SPADE script to allow us to provide our segmentations to the full discourse parsing that it performs, in order to evaluate the improvements to discourse parsing yielded by any improvements to segmentation.

2.4 Segmentation classifier

For this paper, we trained a binary classifier, which was applied independently at each word w_i in the string $w_1 \dots w_k$, to decide whether that word is the last in a segment. Note that w_k is the last word in the string, and is hence ignored. We used a log-linear model with no Markov dependency between adjacent tags,[3] and trained the parameters of the model with the perceptron algorithm, with averaging to control for over-training (Collins, 2002).

Let $C=\{E, I\}$ be the set of classes: segmentation boundary (E) or non-boundary (I). Let $f(c, i, w_1 \dots w_k)$ be a function that takes as input a class value c, a word index i and the word string $w_1 \dots w_k$ and returns a d-dimensional vector of feature values for that word index in that string with that class. For example, one feature might be $(c = E, w_i = \text{the})$, which returns the value 1 when $c = E$ and the current word is 'the', and returns 0 otherwise. Given a d-dimensional parameter vector ϕ, the output of the classifier is that class which maximizes the dot product between the feature and parameter vectors:

$$\hat{c}(i, w_1 \dots w_k) = \underset{c \in C}{\operatorname{argmax}} \ \phi \cdot f(c, i, w_1 \dots w_k) \quad (1)$$

In training, the weights in ϕ are initialized to 0. For m epochs (passes over the training data), for each word in the training data (except sentence final words), the model is updated. Let i be the current word position in string $w_1 \dots w_k$ and suppose that there have been $j-1$ previous updates to the model parameters. Let $\bar{c}_i$ be the true class label, and let $\hat{c}_i$ be shorthand for $\hat{c}(i, w_1 \dots w_k)$ in equation 1. Then the parameter vector ϕ_j at step j is updated as follows:

$$\phi_j = \phi_{j-1} - f(\hat{c}, i, w_1 \dots w_k) + f(\bar{c}, i, w_1 \dots w_k) \quad (2)$$

As stated in Section 2.1, we reserved every tenth sentence as held-out data. After each pass over the training data, we evaluated the system performance on this held-out data, and chose the model that optimized accuracy on that set. The averaged perceptron was used on held-out and evaluation sets. See Collins (2002) for more details on this approach.

2.5 Features

To tease apart the utility of finite-state derived features and context-free derived features, we consider three feature sets: (1) basic finite-state features; (2) context-free features; and (3) finite-state approximation to context-free features. Note that every feature must include exactly one class label c in order to discriminate between classes in equation 1. Hence when presenting features, it can be assumed that the class label is part of the feature, even if it is not explicitly mentioned.

The three feature sets are not completely disjoint. We include simple position-based features in every system, defined as follows. Because *edus* are typically multi-word strings, it is less likely for a word near the beginning or end of a sentence to be at an *edu* boundary. Thus it is reasonable to expect the position within a sentence of a token to be a helpful feature. We created 101 indicator features, representing percentages from 0 to 100. For a string of length k, at position i, we round i/k to two decimal places and provide a value of 1 for the corresponding quantized position feature and 0 for the other position features.

2.5.1 Basic finite-state features

Our baseline finite-state feature set includes simple tagger derived features, as well as features based on position in the string and n-grams[4]. We annotate tag sequences onto the word sequence via a competitive discriminatively trained tagger (Hollingshead et al., 2005), trained for each of two kinds of tag sequences: part-of-speech (POS) tags and shallow parse tags. The shallow parse tags define non-hierarchical base constituents ("chunks"), as defined for the CoNLL-2000 shared task (Tjong Kim Sang and Buchholz, 2000). These can either be used as tag or chunk sequences. For example, the tree in Figure 2 represents a shallow (non-hierarchical) parse tree, with four base constituents. Each base constituent X begins with a word labeled with B_X, which signifies that this word begins the constituent. All other words within a constituent X are labeled

[3] Because of the sparsity of boundary tags, Markov dependencies between tags buy no additional system accuracy.

[4] We tried using a list of 311 cue phrases from Knott (1996) to define features, but did not derive any system improvement through this list, presumably because our simple n-gram features already capture many such lexical cues.

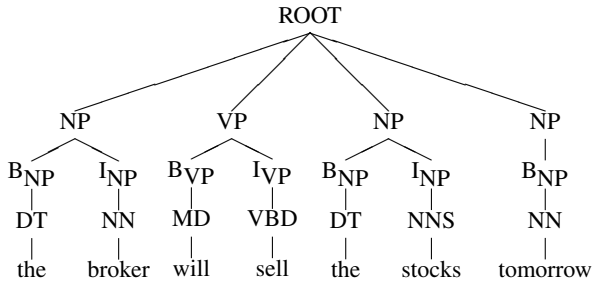

Figure 2: Tree representation of shallow parses, with B(egin) and I(nside) tags

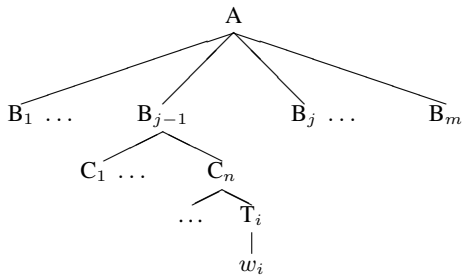

Figure 3: Parse tree schematic for describing context-free segmentation features

I_X, and words outside of any base constituent are labeled O. In such a way, each word is labeled with both a POS-tag and a B/I/O tag.

For our three sequences (lexical, POS-tag and shallow tag), we define n-gram features surrounding the potential discourse boundary. If the current word is w_i, the hypothesized boundary will occur between w_i and w_{i+1}. For this boundary position, the 6-gram including the three words before and the three words after the boundary is included as a feature; additionally, all n-grams for $n < 6$ such that either w_i or w_{i+1} (or both) is in the n-gram are included as features. In other words, all n-grams in a six word window of boundary position i are included as features, except those that include neither w_i nor w_{i+1} in the n-gram. The identical feature templates are used with POS-tag and shallow tag sequences as well, to define tag n-gram features.

This feature set is very close to that used in Sporleder and Lapata (2005), but not identical. Their n-gram feature definitions were different (though similar), and they made use of cue phrases from Knott (1996). In addition, they used a rule-based clauser that we did not. Despite such differences, this feature set is quite close to what is described in that paper.

2.5.2 Context-free features

To describe our context-free features, we first present how SPADE made use of context-free parse trees within their segmentation algorithm, since this forms the basis of our features. The SPADE features are based on productions extracted from full syntactic parses of the given sentence. The primary feature for a discourse boundary after word w_i is based on the lowest constituent in the tree that spans words $w_m \dots w_n$ such that $m \leq i < n$. For example, in the parse tree schematic in Figure 3, the constituent labeled with A is the lowest constituent in the tree whose span crosses the potential discourse boundary after w_i. The primary feature is the production that expands this constituent in the tree, with the proposed segmentation boundary marked, which in this case is: $A \rightarrow B_1 \dots B_{j-1} || B_j \dots B_m$, where $||$ denotes the segmentation boundary. In SPADE, the production is lexicalized by the head words of each constituent, which are determined using standard head-percolation techniques. This feature is used to predict a boundary as follows: if the relative frequency estimate of a boundary given the production feature in the corpus is greater than 0.5, then a boundary is predicted; otherwise not. If the production has not been observed frequently enough, the lexicalization is removed and the relative frequency of a boundary given the unlexicalized production is used for prediction. If the observations of the unlexicalized production are also too sparse, then only the children adjacent to the boundary are maintained in the feature, e.g., $A \rightarrow *B_{j-1} || B_j *$ where $*$ represents zero or more categories. Further smoothing is used when even this is unobserved.

We use these features as the starting point for our context-free feature set: the lexicalized production $A \rightarrow B_1 \dots B_{j-1} || B_j \dots B_m$, as defined above for SPADE, is a feature in our model, as is the unlexicalized version of the production. As with the other features that we have described, this feature is used as an indicator feature in the classifier applied at the word w_i preceding the hypothesized boundary. In addition to these full production features, we use the production with only children adjacent to the boundary, denoted by $A \rightarrow *B_{j-1} || B_j *$. This production is used in four ways: fully lexicalized; unlexicalized; only category B_{j-1} lexicalized; and only category B_j lexicalized. We also use $A \rightarrow *B_{j-2} B_{j-1} || *$ and $A \rightarrow * || B_j B_{j+1} *$ features, both unlexicalized and with the boundary-adjacent category lexicalized. If there is no category B_{j-2} or B_{j+1}, they are replaced with "N/A".

In addition to these features, we fire the same features for all productions on the path from A down

Segmentation system	Segment Boundary accuracy			Bracketing accuracy		
	Recall	Precision	F1	Recall	Precision	F1
SPADE	85.4	85.5	85.5	77.7	77.9	77.8
Classifier: Basic finite-state	81.5	83.3	82.4	73.6	74.5	74.0
Classifier: Full finite-state	84.1	87.9	86.0	78.0	80.0	79.0
Classifier: Context-free	84.7	91.1	87.8	80.3	83.7	82.0
Classifier: All features	89.7	91.3	90.5	84.9	85.8	85.3

Table 2: Segmentation results on all 991 sentences in the RST-DT test set. Segment boundary accuracy is for sentence internal boundaries only, following Soricut and Marcu (2003). Bracketing accuracy is for unlabeled flat bracketing of the same segments. While boundary accuracy correctly depicts segmentation results, the harsher flat bracketing metric better predicts discourse parsing performance.

to the word w_i. For these productions, the segmentation boundary || will occur after all children in the production, e.g., $B_{j-1} \rightarrow C_1 \ldots C_n||$, which is then used in both lexicalized and unlexicalized forms. For the feature with only categories adjacent to the boundary, we again use "N/A" to denote the fact that no category occurs to the right of the boundary: $B_{j-1} \rightarrow *C_n||$N/A. Once again, these are lexicalized as described above.

2.5.3 Finite-state approximation features

An approximation to our context-free features can be made by using the shallow parse tree, as shown in Figure 2, in lieu of the full hierarchical parse tree. For example, if the current word was "sell" in the tree in Figure 2, the primary feature would be ROOT $\rightarrow$ NP VP||NP NP, and it would have an unlexicalized version and three lexicalized versions: the category immediately prior to the boundary lexicalized; the category immediately after the boundary lexicalized; and both lexicalized. For lexicalization, we choose the final word in the constituent as the lexical head for the constituent. This is a reasonable first approximation, because such typically left-headed categories as PP and VP lose their arguments in the shallow parse.

As a practical matter, we limit the number of categories in the flat production to 8 to the left and 8 to the right of the boundary. In a manner similar to the n-gram features that we defined in Section 2.5.1, we allow all combinations with less than 8 contiguous categories on each side, provided that at least one of the adjacent categories is included in the feature. Each feature has an unlexicalized and three lexicalized versions, as described above.

3 Experiments

We performed a number of experiments to determine the relative utility of features derived from full context-free syntactic parses and those derived solely from shallow finite-state tagging. Our primary concern is with intra-sentential discourse segmentation, but we are also interested in how much the improved segmentation helps discourse parsing.

The syntactic parser we use for all context-free syntactic parses used in either SPADE or our classifier is the Charniak parser with reranking, as described in Charniak and Johnson (2005). The Charniak parser and reranker were trained on the sections of the Penn Treebank not included in the RST-DT test set.

All statistical significance testing is done via the stratified shuffling test (Yeh, 2000).

3.1 Segmentation

Table 2 presents segmentation results for SPADE and four versions of our classifier. The "Basic finite-state" system uses only finite-state sequence features as defined in Section 2.5.1, while the "Full finite-state" also includes the finite-state approximation features from Section 2.5.3. The "Context-free" system uses the SPADE-inspired features detailed in Section 2.5.2, but none of the features from Sections 2.5.1 or 2.5.3. Finally, the "All features" section includes features from all three sections.[5]

Note that the full finite-state system is considerably better than the basic finite-state system, demonstrating the utility of these approximations of the SPADE-like context-free features. The performance of the resulting "Full" finite-state system is not statistically significantly different from that of SPADE (p=0.193), despite no reliance on features derived from context-free parses.

The context-free features, however, even without any of the finite-state sequence features (even lexical n-grams) outperforms the best finite-state system by almost two percent absolute, and the system with all features improves on the best finite-state system by over four percent absolute. The system

[5] In the "All features" condition, the finite-state approximation features defined in Section 2.5.3 only include a maximum of 3 children to the left and right of the boundary, versus a maximum of 8 for the "Full finite-state" system. This was found to be optimal on the development set.

Segmentation	Unlabeled	Nuc/Sat
SPADE	76.9	70.2
Classifier: Full finite state	78.1	71.1
Classifier: All features	83.5	76.1

Table 3: Discourse parsing results on the 951 sentence Soricut and Marcu (2003) evaluation set, using SPADE for parsing, and various methods for segmentation. Scores are unlabeled and labeled (Nucleus/Satellite) bracketing accuracy (F1). The first line shows SPADE performing both segmentation and discourse parsing. The other two lines show SPADE performing discourse parsing with segmentations produced by our classifier using different combinations of features.

with all features is statistically significantly better than both SPADE and the "Full finite-state" classifier system, at $p < 0.001$. This large improvement demonstrates that the context-free features can provide a very large system improvement.

3.2 Discourse parsing

It has been shown that accurate discourse segmentation within a sentence greatly improves the overall parsing accuracy to near human levels (Soricut and Marcu, 2003). Given our improved segmentation results presented in the previous section, improvements would be expected in full sentence-level discourse parsing. To achieve this, we modified the SPADE script to accept our segmentations when building the fully hierarchical discourse tree. The results for three systems are presented in Table 3: SPADE, our "Full finite-state" system, and our system with all features. Results for unlabeled bracketing are presented, along with results for labeled bracketing, where the label is either Nucleus or Satellite, depending upon whether or not the node is more central (Nucleus) to the coherence of the text than its sibling(s) (Satellite). This label set has been shown to be of particular utility for indicating which segments are more important to include in an automatically created summary or compressed sentence (Sporleder and Lapata, 2005; Marcu, 1998; Marcu, 1999; Cristea et al., 2005).

Once again, the finite-state system does not perform statistically significantly different from SPADE on either labeled or unlabeled discourse parsing. Using all features, however, results in greater than 5% absolute accuracy improvement over both of these systems, which is significant, in all cases, at $p < 0.001$.

4 Discussion and future directions

Our results show that context-free parse derived features are critical for achieving the highest level of accuracy in sentence-level discourse segmentation. Given that *edus* are by definition clause-like units, it is not surprising that accurate full syntactic parse trees provide highly relevant information unavailable from finite-state approaches. Adding context-free features to our best finite-state feature model reduces error in segmentation by 32.1%, an increase in absolute F-score of 4.5%. These increases are against a finite-state segmentation model that is powerful enough to be statistically indistinguishable from SPADE.

Our experiments also confirm that increased segmentation accuracy yields significantly better discourse parsing accuracy, as previously shown to be the case when providing reference segmentations to a parser (Soricut and Marcu, 2003). The segmentation reduction in error of 34.5% propagates to a 28.6% reduction in error for unlabeled discourse parse trees, and a 19.8% reduction in error for trees labeled with Nucleus and Satellite.

We have several key directions in which to continue this work. First, given that a general machine learning approach allowed us to improve upon SPADE's segmentation performance, we also believe that it will prove useful for improving full discourse parsing, both at the sentence level and beyond. For efficient inter-sentential discourse parsing, we see the need for an additional level of segmentation at the paragraph level. Whereas most sentences correspond to a well-formed subtree, Sporleder and Lascarides (2004) report that over 20% of the paragraph boundaries in the RST-DT do not correspond to a well-formed subtree in the human annotated discourse parse for that document. Therefore, to perform accurate and efficient parsing of the RST-DT at the paragraph level, the text should be segmented into paragraph-like segments that conform to the human-annotated subtree boundaries, just as sentences are segmented into *edus*.

We also intend to begin work on the other discourse annotated corpora. While most work on textual discourse parsing has made use of the RST-DT corpus, the Discourse GraphBank corpus provides a competing annotation that is not constrained to tree structures (Wolf and Gibson, 2005). Once accurate levels of segmentation and parsing for both corpora are attained, it will be possible to perform extrinsic evaluations to determine their relative utility for different NLP tasks. Recent work has shown promising preliminary results for recognizing and labeling relations of GraphBank structures (Wellner et al., 2006), in the case that the algorithm is provided with

manually segmented sentences. Sentence-level segmentation in the GraphBank is very similar to that in the RST-DT, so our segmentation approach should work well for Discourse GraphBank style parsing.

The Penn Discourse Treebank (Miltsakaki et al., 2004), or PDTB, uses a relatively flat annotation of discourse structure, in contrast to the hierarchical structures found in the other two corpora. It contains annotations for discourse connectives and their arguments, where an argument can be as small as a nominalization or as large as several sentences. This approach obviates the need to create a set of discourse relations, but sentence internal segmentation is still a necessary step. Though segmentation in the PDTB tends to larger units than *edus*, our approach to segmentation should be straightforwardly applicable to their segmentation style.

Acknowledgments

Thanks to Caroline Sporleder and Mirella Lapata for their test data and helpful comments. Thanks also to Radu Soricut for helpful input. This research was supported in part by NSF Grant #IIS-0447214. Abstract

Over the last fifty years, the "Big Five" model of personality traits has become a standard in psychology, and research has systematically documented correlations between a wide range of linguistic variables and the Big Five traits. A distinct line of research has explored methods for automatically generating language that varies along personality dimensions. We present PERSONAGE (PERSONAlity GEnerator), the first highly parametrizable language generator for extraversion, an important aspect of personality. We evaluate two personality generation methods: (1) direct generation with particular parameter settings suggested by the psychology literature; and (2) overgeneration and selection using statistical models trained from judge's ratings. Results show that both methods reliably generate utterances that vary along the extraversion dimension, according to human judges.

1 Introduction

Over the last fifty years, the "Big Five" model of personality traits has become a standard in psychology (extraversion, neuroticism, agreeableness, conscientiousness, and openness to experience), and research has systematically documented correlations between a wide range of linguistic variables and the Big Five traits (Mehl et al., 2006; Norman, 1963; Oberlander and Gill, 2006; Pennebaker and King, 1999). A distinct line of research has explored methods for automatically generating language that varies along personality dimensions, targeting applications such as computer gaming and educational virtual worlds (André et al., 2000; Isard et al., 2006; Loyall and Bates, 1997; Piwek, 2003; Walker et al., 1997) *inter alia*. Other work suggests a clear utility for generating language manifesting personality (Reeves and Nass, 1996). However, to date, (1) research in generation has not systematically exploited the psycholinguistic findings; and (2) there has been little evaluation showing that automatic generators can produce language with recognizable personality variation.

Alt	Realization	Extra
5	Err... it seems to me that Le Marais isn't as bad as the others.	1.83
4	Right, I mean, Le Marais is the only restaurant that is any good.	2.83
8	Ok, I mean, Le Marais is a quite french, kosher and steak house place, you know and the atmosphere isn't nasty, it has nice atmosphere. It has friendly service. It seems to me that the service is nice. It isn't as bad as the others, is it?	5.17
9	Well, it seems to me that I am sure you would like Le Marais. It has good food, the food is sort of rather tasty, the ambience is nice, the atmosphere isn't sort of nasty, it features rather friendly servers and its price is around 44 dollars.	5.83
3	I am sure you would like Le Marais, you know. The atmosphere is acceptable, the servers are nice and it's a french, kosher and steak house place. Actually, the food is good, even if its price is 44 dollars.	6.00
10	It seems to me that Le Marais isn't as bad as the others. It's a french, kosher and steak house place. It has friendly servers, you know but it's somewhat expensive, you know!	6.17
2	Basically, actually, I am sure you would like Le Marais. It features friendly service and acceptable atmosphere and it's a french, kosher and steak house place. Even if its price is 44 dollars, it just has really good food, nice food.	6.17

Table 1: Recommendations along the extraversion dimension, with the average extraversion rating from human judges on a scale from 1 to 7. Alt-2 and 3 are from the extravert set, Alt-4 and 5 are from the introvert set, and others were randomly generated.

Our aim is to produce a highly parameterizable generator whose outputs vary along personality dimensions. We hypothesize that such language can

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 496–503,
Prague, Czech Republic, June 2007.

be generated by varying parameters suggested by psycholinguistic research. So, we must first map the psychological findings to parameters of a natural language generator (NLG). However, this presents several challenges: (1) The findings result from studies of genres of language, such as stream-of-consciousness essays (Pennebaker and King, 1999), and informal conversations (Mehl et al., 2006), and thus may not apply to fixed content domains used in NLG; (2) Most findings are based on self-reports of personality, but we want to affect observer's perceptions; (3) The findings consist of weak but significant correlations, so that individual parameters may not have a strong enough effect to produce recognizable variation within a single utterance; (4) There are many possible mappings of the findings to generation parameters; and (5) It is unclear whether only specific speech-act types manifest personality or whether all utterances do.

Thus this paper makes several contributions. First, Section 2 summarizes the linguistic reflexes of extraversion, organized by the modules in a standard NLG system, and propose a mapping from these findings to NLG parameters. To our knowledge this is the first attempt to put forward a systematic framework for generating language manifesting personality. We start with the extraversion dimension because it is an important personality factor, with many associated linguistic variables. We believe that our framework will generalize to the other dimensions in the Big Five model. Second, Sections 3 and 4 describe the PERSONAGE (PERSONAlity GEnerator) generator and its 29 parameters. Table 1 shows examples generated by PERSONAGE for recommendations in the restaurant domain, along with human extraversion judgments. Third, Sections 5 and 6 describe experiments evaluating two generation methods. We first show that (1) the parameters generate utterances that vary significantly on the extraversion dimension, according to human judgments; and (2) we can train a statistical model that matches human performance in assigning extraversion ratings to generation outputs produced with random parameter settings. Section 7 sums up and discusses future work.

2 Psycholinguistic Findings and PERSONAGE Parameters

We hypothesize that personality can be made manifest in evaluative speech acts in any dialogue domain, i.e. utterances responding to requests to RECOMMEND or COMPARE domain entities, such as restaurants or movies (Isard et al., 2006; Stent et al., 2004). Thus, we start with the SPaRKy generator[1], which produces evaluative recommendations and comparisons in the restaurant domain, for a database of restaurants in New York City. There are eight attributes for each restaurant: the name and address, scalar attributes for *price*, *food quality*, *atmosphere*, and *service* and categorical attributes for *neighborhood* and *type of cuisine*. SPaRKy is based on the standard NLG architecture (Reiter and Dale, 2000), and consists of the following modules:

1. Content Planning: refine communicative goals, select and structure content;
2. Sentence planning; choose linguistic resources (lexicon, syntax) to achieve goals;
3. Realization: use grammar (syntax, morphology) to generate surface utterances.

Given the NLG architecture, speech-act types, and domain, the first step then is to summarise psychological findings on extraversion and map them to this architecture. The column **NLG modules** of Table 2 gives the proposed mapping. The first row specifies findings for the content planning module and the other rows are aspects of sentence planning. Realization is achieved with the RealPro surface realizer (Lavoie and Rambow, 1997). An examination of the introvert and extravert findings in Table 2 highlights the challenges above, i.e. exploiting these findings in a systematic way within a parameterizable NLG system.

The column **Parameter** in Table 2 proposes parameters (explained in Sections 3 and 4) that are manipulated within each module to realize the findings in the other columns. Each parameter varies continuously from 0 to 1, where end points are meant to produce extreme but plausible output. Given the challenges above, it is important to note that these parameters represent *hypotheses* about how a finding can be mapped into *any* NLG system. The **Intro** and **Extra** columns at the right hand side of the **Parameter** column indicate a range of settings for this parameter, suggested by the psychological findings, to produce introverted vs. extraverted language.

SPaRKy produces content plans for restaurant recommendations and comparisons that are modified by the parameters. The sample content plan for a recommendation in Figure 1 corresponds to the outputs in Table 1. While Table 1 shows that PERSONAGE's parameters have various pragmatic effects, they preserve the meaning at the Gricean intention level (dialogue goal). Each content plan contains a claim (nucleus) about the overall quality of

Table 2: Summary of language cues for extraversion, based on Dewaele and Furnham (1999); Furnham (1990); Mehl et al. (2006); Oberlander and Gill (2006); Pennebaker and King (1999), as well as PERSONAGE's corresponding generation parameters. Asterisks indicate hypotheses, rather than results. For details on aggregation parameters, see Section 4.2.

Relations:	JUSTIFY (nuc:1, sat:2); JUSTIFY (nuc:1, sat:3); JUSTIFY (nuc:1, sat:4); JUSTIFY (nuc:1, sat:5); JUSTIFY (nuc:1, sat:6)
Content:	1. assert(best (*Le Marais*)) 2. assert(is (*Le Marais*, cuisine (*French*))) 3. assert(has (*Le Marais*, food-quality (*good*))) 4. assert(has (*Le Marais*, service (*good*))) 5. assert(has (*Le Marais*, decor (*decent*))) 6. assert(is (*Le Marais*, price (*44 dollars*)))

Figure 1: A content plan for a recommendation.

the selected restaurant(s), supported by a set of satellite content items describing their attributes. See Table 1. Claims can be expressed in different ways, such as *RESTAURANT_NAME is the best*, while the attribute satellites follow the pattern *RESTAURANT_NAME has MODIFIER ATTRIBUTE_NAME*, as in *Le Marais has good food*. Recommendations are characterized by a JUSTIFY rhetorical relation associating the claim with all other content items, which are linked together through an INFER relation. In comparisons, the attributes of multiple restaurants are compared using a CONTRAST relation. An optional claim about the quality of all restaurants can also be expressed as the nucleus of an ELABORATE relation, with the rest of the content plan tree as a satellite.

3 Content Planning

Content planning selects and structures the content to be communicated. Table 2 specifies 10 parameters hypothesized to affect this process which are explained below.

Content size: Extraverts are more talkative than introverts (Furnham, 1990; Pennebaker and King, 1999), although it is not clear whether they actually produce more content, or are just redundant and wordy. Thus various parameters relate to the amount and type of content produced. The VERBOSITY parameter controls the number of content items selected from the content plan. For example, Alt-5 in Table 1 is terse, while Alt-2 expresses all the items in the content plan. The REPETITION parameter adds an exact repetition: the content item is duplicated and linked to the original content by a RESTATE

rhetorical relation. In a similar way, the RESTATEMENT parameter adds paraphrases of content items to the plan, that are obtained from the initial handcrafted generation dictionary (see Section 4.1) and by automatically substituting content words with the most frequent WordNet synonym (see Section 4.4). Alt-9 in Table 1 contains restatements for the food quality and the atmosphere attributes.

Polarity: Extraverts tend to be more positive; introverts are characterized as engaging in more 'problem talk' and expressions of dissatisfaction (Thorne, 1987). To control for polarity, content items are defined as positive or negative based on the scalar value of the corresponding attribute. The *type of cuisine* and *neighborhood* attributes have neutral polarity. There are multiple parameters associated with polarity. The CONTENT POLARITY parameter controls whether the content is mostly negative (e.g. *X has mediocre food*), neutral (e.g. *X is a Thai restaurant*), or positive. From the filtered set of content items, the POLARISATION parameter determines whether the final content includes items with extreme scalar values (e.g. *X has fantastic staff*).

In addition, polarity can also be implied more subtly through rhetorical structure. The CONCESSIONS parameter controls how negative and positive information is presented, i.e. whether two content items with different polarity are presented objectively, or if one is foregrounded and the other backgrounded. If two opposed content items are selected for a concession, a CONCESS rhetorical relation is inserted between them. While the CONCESSIONS parameter captures the tendency to put information into perspective, the CONCESSION POLARITY parameter controls whether the positive or the negative content is concessed, i.e. marked as the satellite of the CONCESS relation. The last sentence of Alt-3 in Table 1 illustrates a positive concession, in which the good food quality is put before the high price.

Content ordering: Although extraverts use more positive language (Pennebaker and King, 1999; Thorne, 1987), it is unclear how they position the positive content within their utterances. Additionally, the position of the claim affects the persuasiveness of an argument (Carenini and Moore, 2000): starting with the claim facilitates the hearer's understanding, while finishing with the claim is more effective if the hearer disagrees. The POSITIVE CONTENT FIRST parameter therefore controls whether positive content items – including the claim – appear first or last, and the order in which the content items are aggregated. However, some operations can still impose a specific ordering (e.g. BECAUSE cue word to realize the JUSTIFY relation, see Section 4.2).

4 Sentence Planning

Sentence planning chooses the linguistic resources from the lexicon and the syntactic and discourse structures to achieve the communicative goals specified in the input content plan. Table 2 specifies four sets of findings and parameters for different aspects of sentence planning discussed below.

4.1 Syntactic template selection

PERSONAGE's input generation dictionary is made of 27 Deep Syntactic Structures (DSyntS): 9 for the recommendation claim, 12 for the comparison claim, and one per attribute. Selecting a DSyntS requires assigning it automatically to a point in a three dimensional space described below. All parameter values are normalized over all the DSyntS, so the DSyntS closest to the target value can be computed.

Syntactic complexity: Furnham (1990) suggests that introverts produce more complex constructions: the CLAIM COMPLEXITY parameter controls the depth of the syntactic structure chosen to represent the claim, e.g. the claim *X is the best* is rated as less complex than *X is one of my favorite restaurants*.

Self-references: Extraverts make more self-references than introverts (Pennebaker and King, 1999). The SELF-REFERENCE parameter controls whether the claim is made in the first person, based on the speaker's own experience, or whether the claim is reported as objective or information obtained elsewhere. The self-reference value is obtained from the syntactic structure by counting the number of first person pronouns. For example, the claim of Alt-2 in Table 1, i.e. *I am sure you would like Le Marais*, will be rated higher than *Le Marais isn't as bad as the others* in Alt-5.

Polarity: While polarity can be expressed by content selection and structure, it can also be directly associated with the DSyntS. The CLAIM POLARITY parameter determines the DSyntS selected to realize the claim. DSyntS are manually annotated for polarity. For example, Alt-4's claim in Table 1, i.e. *Le Marais is the only restaurant that is any good*, has a lower polarity than Alt-2.

4.2 Aggregation operations

SPaRKy aggregation operations are used (See Stent et al. (2004)), with additional operations for concessions and restatements. See Table 2. The probability of the operations biases the production of complex clauses, periods and formal cue words for introverts, to express their preference for complex syn-

tactic constructions, long pauses and rich vocabulary (Furnham, 1990). Thus, the introvert parameters favor operations such as RELATIVE CLAUSE for the INFER relation, PERIOD HOWEVER CUE WORD for CONTRAST, and ALTHOUGH ADVERBIAL CLAUSE for CONCESS, that we hypothesize to result in more formal language. Extravert aggregation produces longer sentences with simpler constructions and informal cue words. Thus extravert utterances tend to use operations such as a CONJUNCTION to realize the INFER and RESTATE relations, and the EVEN IF ADVERBIAL CLAUSE for CONCESS relations.

4.3 Pragmatic transformations

This section describes the insertion of markers in the DSyntS to produce various pragmatic effects.

Hedges: Hedges correlate with introversion (Pennebaker and King, 1999) and affect politeness (Brown and Levinson, 1987). Thus there are parameters for inserting a wide range of hedges, both affective and epistemic, such as *kind of, sort of, quite, rather, somewhat, like, around, err, I think that, it seems that, it seems to me that,* and *I mean*. Alt-5 in Table 1 shows hedges *err* and *it seems to me that*.

To model extraverts use of more social language, agreement and backchannel behavior (Dewaele and Furnham, 1999; Pennebaker and King, 1999), we use informal acknowledgments such as *yeah, right, ok*. Acknowledgments that may affect introversion are *I see*, expressing self-reference and cognitive load, and the *well* cue word implying reservation from the speaker (see Alt-9).

To model social connection and emotion we added mechanisms for inserting emphasizers such as *you know, basically, actually, just have, just is,* and exclamations. Alt-3 in Table 1 shows the insertion of *you know* and *actually*.

Although similar hedges can be grouped together, each hedge has a unique pragmatic effect. For example, *you know* implies positive-face redressment, while *actually* doesn't. A parameter for each hedge controls the likelihood of its selection.

To control the general level of hedging, a HEDGE VARIATION parameter defines how many different hedges are selected (maximum of 5), while the frequency of an individual hedge is controlled by a HEDGE REPETITION parameter, up to a maximum of 2 identical hedges per utterance.

The syntactic structure of hedges are defined as well as constraints on their insertion point in the utterance's syntactic structure. Each time a hedge is selected, it is randomly inserted at one of the insertion points respecting the constraints, until the specified frequency is reached. For example, a constraint on the hedge *kind of* is that it modifies adjectives.

Tag questions: Tag questions are also politeness markers (Brown and Levinson, 1987). They redress the hearer's positive face by claiming common ground. A TAG QUESTION INSERTION parameter leads to negating the auxiliary of the verb and pronominalizing the subject, e.g. *X has great food* results in the insertion of *doesn't it?*, as in Alt-8.

Negations: Introverts use significantly more negations (Pennebaker and King, 1999). Although the content parameters select more negative polarity content items for introvert utterances, we also manipulate negations, while keeping the content constant, by converting adjectives to the negative of their antonyms, e.g. *the atmosphere is nice* was transformed to *not nasty* in Alt-9 in Table 1.

Subject implicitness: Heylighen and Dewaele (2002) found that extraverts use more implicit language than introverts. To control the level of implicitness, the SUBJECT IMPLICITNESS parameter determines whether predicates describing restaurant attributes are expressed with the restaurant in the subject, or with the attribute itself (e.g., *it has good food* vs. *the food is tasty* in Alt-9).

4.4 Lexical choice

Introverts use a richer vocabulary (Dewaele and Furnham, 1999), so the LEXICON FREQUENCY parameter selects lexical items by their normalized frequency in the British National Corpus. WordNet synonyms are used to obtain a pool of synonyms, as well as adjectives extracted from a corpus of restaurant reviews for all levels of polarity (e.g. the adjective *tasty* in Alt-9 is a high polarity modifier of the food attribute). Synonyms are manually checked to make sure they are interchangeable. For example, the content item expressed originally as *it has decent service* is transformed to *it features friendly service* in Alt-2, and to *the servers are nice* in Alt-3.

5 Experimental Method and Hypotheses

Our primary hypothesis is that language generated by varying parameters suggested by psycholinguistic research can be recognized as extravert or introvert. To test this hypothesis, three expert judges evaluated a set of generated utterances as if they had been uttered by a friend responding in a dialogue to a request to recommend restaurants. These utterances had been generated to systematically manipulate extraversion/introversion parameters.

The judges rated each utterance for perceived extraversion, by answering the two questions measur-

ing that trait from the Ten-Item Personality Inventory, as this instrument was shown to be psychometrically superior to a 'single item per trait' questionnaire (Gosling et al., 2003). The answers are averaged to produce an extraversion rating ranging from 1 (highly introvert) to 7 (highly extravert). Because it was unclear whether the generation parameters in Table 2 would produce natural sounding utterances, the judges also evaluated the naturalness of each utterance on the same scale. The judges rated 240 utterances, grouped into 20 sets of 12 utterances generated from the same content plan. They rated one randomly ordered set at a time, but viewed all 12 utterances in that set before rating them. The utterances were generated to meet two experimental goals. First, to test the direct control of the perception of extraversion. 2 introvert utterances and 2 extravert utterances were generated for each content plan (80 in total) using the parameter values in Table 2. Multiple outputs were generated with both parameter settings normally distributed with a 15% standard deviation. Second, 8 utterances for each content plan (160 in total) were generated with random parameter values. These random utterances make it possible to: (1) improve PERSONAGE's direct output by calibrating its parameters more precisely; and (2) build a statistical model that selects utterances matching input personality values after an overgeneration phase (see Section 6.2). The inter-rater agreement for extraversion between the judges over all 240 utterances (average Pearson's correlation of 0.57) shows that the magnitude of the differences of perception between judges is almost constant ($\sigma = .037$). A low agreement can yield a high correlation (e.g. if all values differ by a constant factor), so we also compute the intraclass correlation coefficient r based on a two-way random effect model. We obtain a r of 0.79, which is significant at the $p < .001$ level (reliability of average measures, identical to Cronbach's alpha). This is comparable to the agreement of judgments of personality in Mehl et al. (2006) (mean $r = 0.84$).

6 Experimental Results

6.1 Hypothesized parameter settings

Table 1 provides examples of PERSONAGE's output and extraversion ratings. To assess whether PERSONAGE generates language that can be recognized as introvert and extravert, we did a independent sample t-test between the average ratings of the 40 introvert and 40 extravert utterances (parameters with 15% standard deviation as in Table 2). Table 3 shows that introvert utterances have an average rating of 2.96 out of 7 while extravert utterances have an average rating of 5.98. These ratings are significantly different at the $p < .001$ level (two-tailed). In addition, if we divide the data into two equal-width bins around the neutral extravert rating (4 out of 7), then PERSONAGE's utterance ratings fall in the bin predicted by the parameter set 89.2% of the time. Extravert utterance are also slightly more natural than the introvert ones ($p < .001$).

Rating	Introvert	Extravert	Random
Extraversion	2.96	5.98	5.02
Naturalness	4.93	5.78	4.51

Table 3: Average extraversion and naturalness ratings for the utterances generated with introvert, extravert, and random parameters.

Table 3 also shows that the 160 random parameter utterances produce an average extraversion rating of 5.02, both significantly higher than the introvert set and lower than the extravert set ($p < .001$). Interestingly, the random utterances, which may combine linguistic variables associated with both introverts and extraverts, are less natural than the introvert ($p = .059$) and extravert sets ($p < .001$).

6.2 Statistical models evaluation

We also investigate a second approach: overgeneration with random parameter settings, followed by ranking via a statistical model trained on the judges' feedback. This approach supports generating utterances for any input extraversion value, as well as determining which parameters affect the judges' perception.

We model perceived personality ratings ($1 \ldots 7$) with regression models from the Weka toolbox (Witten and Frank, 2005). We used the full dataset of 160 averaged ratings for the random parameter utterances. Each utterance was associated with a feature vector with the generation decisions for each parameter in Section 2. To reduce data sparsity, we select features that correlate significantly with the ratings ($p < .10$) with a coefficient higher than 0.1.

Regression models are evaluated using the mean absolute error and the correlation between the predicted score and the actual average rating. Table 4 shows the mean absolute error on a scale from 1 to 7 over ten 10-fold cross-validations for the 4 best regression models: Linear Regression (LR), M5' model tree (M5), and Support Vector Machines (i.e. SMOreg) with linear kernels (SMO_1) and radial-

basis function kernels (SMO_r). All models significantly outperform the baseline (0.83 mean absolute error, $p < .05$), but surprisingly the linear model performs the best with a mean absolute error of 0.65. The best model produces a correlation coefficient of 0.59 with the judges' ratings, which is higher than the correlations between pairs of judges, suggesting that the model performs as well as a human judge.

Metric	**LR**	**M5**	**SMO_1**	**SMO_r**
Absolute error	**0.65**	0.66	0.72	0.70
Correlation	**0.59**	0.56	0.54	0.57

Table 4: Mean absolute regression errors (scale from 1 to 7) and correlation coefficients over ten 10-fold cross-validations, for 4 models: Linear Regression (LR), M5' model tree (M5), Support Vector Machines with linear kernels (SMO_1) and radial-basis function kernels (SMO_r). All models significantly outperform the mean baseline (0.83 error, $p < .05$).

The M5' regression tree in Figure 2 assigns a rating given the features. Verbosity plays the most important role: utterances with 4 or more content items are modeled as more extravert. Given a low verbosity, lexical frequency and restatements determine the extraversion level, e.g. utterances with less than 4 content items and infrequent words are perceived as very introverted (rating of 2.69 out of 7). For verbose utterances, the *you know* hedge indicates extraversion, as well as concessions, restatements, self-references, and positive content. Although relatively simple, these models are useful for identifying new personality markers, as well as calibrating parameters in the direct generation model.

7 Discussion and Conclusions

We present and evaluate PERSONAGE, a parameterizable generator that produces outputs that vary along the extraversion personality dimension. This paper makes four contributions:

1. We present a systematic review of psycholinguistic findings, organized by the NLG reference architecture;
2. We propose a mapping from these findings to generation parameters for each NLG module and a real-time implementation of a generator using these parameters[2]. To our knowledge this is the first attempt to put forward a systematic framework for generating language that manifests personality;
3. We present an evaluation experiment showing that we can control the parameters to produce recognizable linguistic variation along the extraversion personality dimension. Thus, we show that the weak correlations reported in other genres of language, and for self-reports rather than observers, carry over to the production of single evaluative utterances with recognizable personality in a restricted domain;
4. We present the results of a training experiment showing that given an output, we can train a model that matches human performance in assigning an extraversion rating to that output.

Some of the challenges discussed in the introduction remain. We have shown that evaluative utterances in the restaurant domain can manifest personality, but more research is needed on which speech acts recognisably manifest personality in a restricted domain. We also showed that the mapping we hypothesised of findings to generation parameters was effective, but there may be additional parameters that the psycholinguistic findings could be mapped to.

Our work was partially inspired by the ICONOCLAST and PAULINE parameterizable generators (Bouayad-Agha et al., 2000; Hovy, 1988), which vary the style, rather than the personality, of the generated texts. Walker et al. (1997) describe a generator intended to affect perceptions of personality, based on Brown and Levinson's theory of politeness (Brown and Levinson, 1987), that uses some of the linguistic constructions implemented here, such as tag questions and hedges, but it was never evaluated. Research by André et al. (2000); Piwek (2003) uses personality variables to affect the linguistic behaviour of conversational agents, but they did not systematically manipulate parameters, and their generators were not evaluated. Reeves and Nass (1996) demonstrate that manipulations of personality affect many aspects of user's perceptions, but their experiments use handcrafted utterances, rather than generated utterances. Cassell and Bickmore (2003) show that extraverts prefer systems utilizing discourse plans that include small talk. Paiva and Evans' trainable generator (2005) produces outputs that correspond to a set of linguistic variables measured in a corpus of target texts. Their method is similar to our statistical method using regression trees, but provides direct control. The method reported in Mairesse and Walker (2005) for training individualized sentence planners ranks the outputs produced by an overgeneration phase, rather than directly predicting a scalar value, as we do here. The closest work to ours is probably Isard et al.'s CRAG-2 system (2006), which overgenerates and ranks using ngram language models trained on a corpus labelled for all Big Five personality dimensions. However, CRAG-2 has no explicit parameter control, and it has yet to be evaluated.

[2] An online demo is available at `www.dcs.shef.ac.uk/cogsys/personage.html`

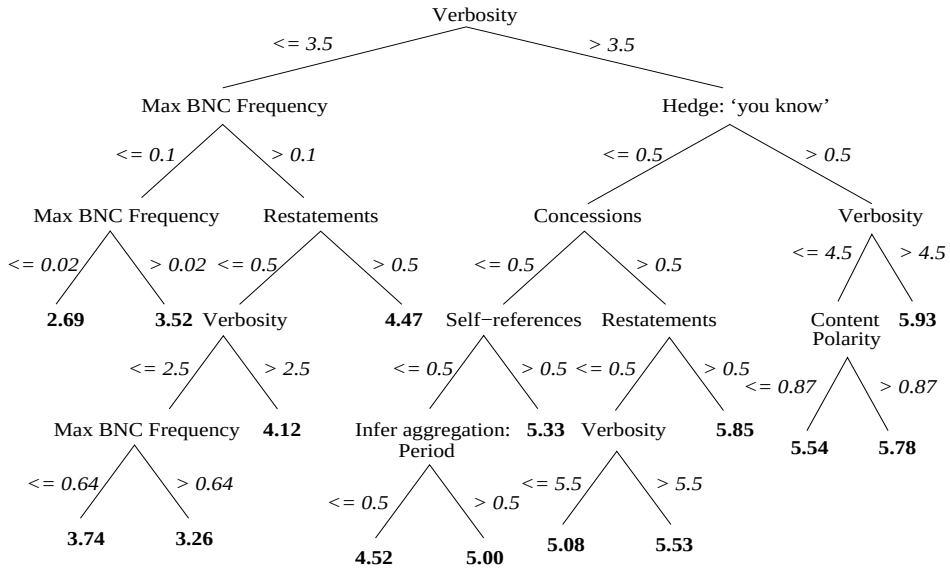

Figure 2: M5' regression tree. The output ranges from 1 to 7, where 7 means strongly extravert.

In future work, we hope to directly compare the direct generation method of Section 6.1 with the overgenerate and rank method of Section 6.2, and to use these results to refine PERSONAGE's parameter settings. We also hope to extend PERSONAGE's generation capabilities to other Big Five traits, identify additional features to improve the model's performance, and evaluate the effect of personality variation on user satisfaction in various applications.

Making Sense of Sound: Unsupervised Topic Segmentation over Acoustic Input

Igor Malioutov, Alex Park, Regina Barzilay, and **James Glass**
Massachusetts Institute of Technology
{igorm,malex,regina,glass}@csail.mit.edu

Abstract

We address the task of unsupervised topic segmentation of speech data operating over raw acoustic information. In contrast to existing algorithms for topic segmentation of speech, our approach does not require input transcripts. Our method predicts topic changes by analyzing the distribution of reoccurring acoustic patterns in the speech signal corresponding to a single speaker. The algorithm robustly handles noise inherent in acoustic matching by intelligently aggregating information about the similarity profile from multiple local comparisons. Our experiments show that audio-based segmentation compares favorably with transcript-based segmentation computed over noisy transcripts. These results demonstrate the desirability of our method for applications where a speech recognizer is not available, or its output has a high word error rate.

1 Introduction

An important practical application of topic segmentation is the analysis of spoken data. Paragraph breaks, section markers and other structural cues common in written documents are entirely missing in spoken data. Insertion of these structural markers can benefit multiple speech processing applications, including audio browsing, retrieval, and summarization.

Not surprisingly, a variety of methods for topic segmentation have been developed in the past (Beeferman et al., 1999; Galley et al., 2003; Dielmann and Renals, 2005). These methods typically assume that a segmentation algorithm has access not only to acoustic input, but also to its transcript. This assumption is natural for applications where the transcript has to be computed as part of the system output, or it is readily available from other system components. However, for some domains and languages, the transcripts may not be available, or the recognition performance may not be adequate to achieve reliable segmentation. In order to process such data, we need a method for topic segmentation that does not require transcribed input.

In this paper, we explore a method for topic segmentation that operates directly on a raw acoustic speech signal, without using any input transcripts. This method predicts topic changes by analyzing the distribution of reoccurring acoustic patterns in the speech signal corresponding to a single speaker. In the same way that unsupervised segmentation algorithms predict boundaries based on changes in lexical distribution, our algorithm is driven by changes in the distribution of acoustic patterns. The central hypothesis here is that similar sounding acoustic sequences produced by the same speaker correspond to similar lexicographic sequences. Thus, by analyzing the distribution of acoustic patterns we could approximate a traditional content analysis based on the lexical distribution of words in a transcript.

Analyzing high-level content structure based on low-level acoustic features poses interesting computational and linguistic challenges. For instance, we need to handle the noise inherent in matching based on acoustic similarity, because of possible varia-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 504–511,
Prague, Czech Republic, June 2007.

tions in speaking rate or pronunciation. Moreover, in the absence of higher-level knowledge, information about word boundaries is not always discernible from the raw acoustic input. This causes problems because we have no obvious unit of comparison. Finally, noise inherent in the acoustic matching procedure complicates the detection of distributional changes in the comparison matrix.

The algorithm presented in this paper demonstrates the feasibility of topic segmentation over raw acoustic input corresponding to a single speaker. We first apply a variant of the dynamic time warping algorithm to find similar fragments in the speech input through alignment. Next, we construct a comparison matrix that aggregates the output of the alignment stage. Since aligned utterances are separated by gaps and differ in duration, this representation gives rise to sparse and irregular input. To obtain robust similarity change detection, we invoke a series of transformations to smooth and refine the comparison matrix. Finally, we apply the minimum-cut segmentation algorithm to the transformed comparison matrix to detect topic boundaries.

We compare the performance of our method against traditional transcript-based segmentation algorithms. As expected, the performance of the latter depends on the accuracy of the input transcript. When a manual transcription is available, the gap between audio-based segmentation and transcript-based segmentation is substantial. However, in a more realistic scenario when the transcripts are fraught with recognition errors, the two approaches exhibit similar performance. These results demonstrate that audio-based algorithms are an effective and efficient solution for applications where transcripts are unavailable or highly errorful.

2 Related Work

Speech-based Topic Segmentation A variety of supervised and unsupervised methods have been employed to segment speech input. Some of these algorithms have been originally developed for processing written text (Beeferman et al., 1999). Others are specifically adapted for processing speech input by adding relevant acoustic features such as pause length and speaker change (Galley et al., 2003; Dielmann and Renals, 2005). In parallel, researchers extensively study the relationship between discourse structure and intonational variation (Hirschberg and Nakatani, 1996; Shriberg et al., 2000). However, all of the existing segmentation methods require as input a speech transcript of reasonable quality. In contrast, the method presented in this paper does not assume the availability of transcripts, which prevents us from using segmentation algorithms developed for written text.

At the same time, our work is closely related to unsupervised approaches for text segmentation. The central assumption here is that sharp changes in lexical distribution signal the presence of topic boundaries (Hearst, 1994; Choi et al., 2001). These approaches determine segment boundaries by identifying homogeneous regions within a similarity matrix that encodes pairwise similarity between textual units, such as sentences. Our segmentation algorithm operates over a distortion matrix, but the unit of comparison is the speech signal over a time interval. This change in representation gives rise to multiple challenges related to the inherent noise of acoustic matching, and requires the development of new methods for signal discretization, interval comparison and matrix analysis.

Pattern Induction in Acoustic Data Our work is related to research on unsupervised lexical acquisition from continuous speech. These methods aim to infer vocabulary from unsegmented audio streams by analyzing regularities in pattern distribution (de Marcken, 1996; Brent, 1999; Venkataraman, 2001). Traditionally, the speech signal is first converted into a string-like representation such as phonemes and syllables using a phonetic recognizer.

Park and Glass (2006) have recently shown the feasibility of an audio-based approach for word discovery. They induce the vocabulary from the audio stream directly, avoiding the need for phonetic transcription. Their method can accurately discover words which appear with high frequency in the audio stream. While the results obtained by Park and Glass inspire our approach, we cannot directly use their output as proxies for words in topic segmentation. Many of the content words occurring only a few times in the text are pruned away by this method. Our results show that this data that is too sparse and noisy for robustly discerning changes in

lexical distribution.

3 Algorithm

The audio-based segmentation algorithm identifies topic boundaries by analyzing changes in the distribution of acoustic patterns. The analysis is performed in three steps. First, we identify recurring patterns in the audio stream and compute distortion between them (Section 3.1). These acoustic patterns correspond to high-frequency words and phrases, but they only cover a fraction of the words that appear in the input. As a result, the distributional profile obtained during this process is too sparse to deliver robust topic analysis. Second, we generate an acoustic comparison matrix that aggregates information from multiple pattern matches (Section 3.2). Additional matrix transformations during this step reduce the noise and irregularities inherent in acoustic matching. Third, we partition the matrix to identify segments with a homogeneous distribution of acoustic patterns (Section 3.3).

3.1 Comparing Acoustic Patterns

Given a raw acoustic waveform, we extract a set of acoustic patterns that occur frequently in the speech document. Continuous speech includes many word sequences that lack clear low-level acoustic cues to denote word boundaries. Therefore, we cannot perform this task through simple counting of speech segments separated by silence. Instead, we use a local alignment algorithm to search for similar speech segments and quantify the amount of distortion between them. In what follows, we first present a vector representation used in this computation, and then specify the alignment algorithm that finds similar segments.

MFCC Representation We start by transforming the acoustic signal into a vector representation that facilitates the comparison of acoustic sequences. First, we perform silence detection on the original waveform by registering a pause if the energy falls below a certain threshold for a duration of 2s. This enables us to break up the acoustic stream into continuous spoken utterances.

This step is necessary as it eliminates spurious alignments between silent regions of the acoustic waveform. Note that silence detection is not equivalent to word boundary detection, as segmentation by silence detection alone only accounts for 20% of word boundaries in our corpus.

Next, we convert each utterance into a time series of vectors consisting of Mel-scale cepstral coefficients (MFCCs). This compact low-dimensional representation is commonly used in speech processing applications because it approximates human auditory models.

The process of extracting MFCCs from the speech signal can be summarized as follows. First, the 16 kHz digitized audio waveform is normalized by removing the mean and scaling the peak amplitude. Next, the short-time Fourier transform is taken at a frame interval of 10 ms using a 25.6 ms Hamming window. The spectral energy from the Fourier transform is then weighted by Mel-frequency filters (Huang et al., 2001). Finally, the discrete cosine transform of the log of these Mel-frequency spectral coefficients is computed, yielding a series of 14-dimensional MFCC vectors. We take the additional step of whitening the feature vectors, which normalizes the variance and decorrelates the dimensions of the feature vectors (Bishop, 1995). This whitened spectral representation enables us to use the standard unweighted Euclidean distance metric. After this transformation, the distances in each dimension will be uncorrelated and have equal variance.

Alignment Now, our goal is to identify acoustic patterns that occur multiple times in the audio waveform. The patterns may not be repeated exactly, but will most likely reoccur in varied forms. We capture this information by extracting pairs of patterns with an associated distortion score. The computation is performed using a sequence alignment algorithm.

Table 1 shows examples of alignments automatically computed by our algorithm. The corresponding phonetic transcriptions[1] demonstrate that the matching procedure can robustly handle variations in pronunciations. For example, two instances of the word *"direction"* are matched to one another despite different pronunciations, ("d ay" vs. "d ax" in the first syllable). At the same time, some aligned pairs form erroneous matches, such as *"my prediction"* matching *"y direction"* due to their high acoustic

similarity.

The alignment algorithm operates on the audio waveform represented by a list of silence-free utterances $(u_1, u_2, \ldots, u_n)$. Each utterance u' is a time series of MFCC vectors $(\vec{x'_1}, \vec{x'_2}, \ldots, \vec{x'_m})$. Given two input utterances u' and u'', the algorithm outputs a set of alignments between the corresponding MFCC vectors. The alignment distortion score is computed by summing the Euclidean distances of matching vectors.

To compute the optimal alignment we use a variant of the dynamic time warping algorithm (Huang et al., 2001). For every possible starting alignment point, we optimize the following dynamic programming objective:

$$D(i_k, j_k) = d(i_k, j_k) + \min \begin{cases} D(i_k - 1, j_k) \\ D(i_k, j_k - 1) \\ D(i_k - 1, j_k - 1) \end{cases}$$

In the equation above, i_k and j_k are alignment endpoints in the k-th subproblem of dynamic programming.

This objective corresponds to a descent through a dynamic programming trellis by choosing right, down, or diagonal steps at each stage.

During the search process, we consider not only the alignment distortion score, but also the shape of the alignment path. To limit the amount of temporal warping, we enforce the following constraint:

$$\left|(i_k - i_1) - (j_k - j_1)\right| \leq R, \forall k, \qquad (1)$$

$$i_k \leq N_x \quad \text{and} \quad j_k \leq N_y,$$

where N_x and N_y are the number of MFCC samples in each utterance. The value $2R + 1$ is the width of the diagonal band that controls the extent of temporal warping. The parameter R is tuned on a development set.

This alignment procedure may produce paths with high distortion subpaths. Therefore, we trim each path to retain the subpath with lowest average distortion and length at least L. More formally, given an alignment of length N, we seek to find m and n such that:

$$\underset{1 \leq m \leq n \leq N}{\arg\min} \frac{1}{n - m + 1} \sum_{k=m}^{n} d(i_k, j_k) \qquad n - m \geq L$$

We accomplish this by computing the length constrained minimum average distortion subsequence of the path sequence using an $O(N \log(L))$ algorithm proposed by Lin et al (2002). The length parameter, L, allows us to avoid overtrimming and control the length of alignments that are found. After trimming, the distortion of each alignment path is normalized by the path length.

Alignments with a distortion exceeding a prespecified threshold are pruned away to ensure that the aligned phrasal units are close acoustic matches. This parameter is tuned on a development set.

In the next section, we describe how to aggregate information from multiple noisy matches into a representation that facilitates boundary detection.

3.2 Construction of Acoustic Comparison Matrix

The goal of this step is to construct an acoustic comparison matrix that will guide topic segmentation. This matrix encodes variations in the distribution of acoustic patterns for a given speech document. We construct this matrix by first discretizing the acoustic signal into constant-length blocks and then computing the distortion between pairs of blocks.

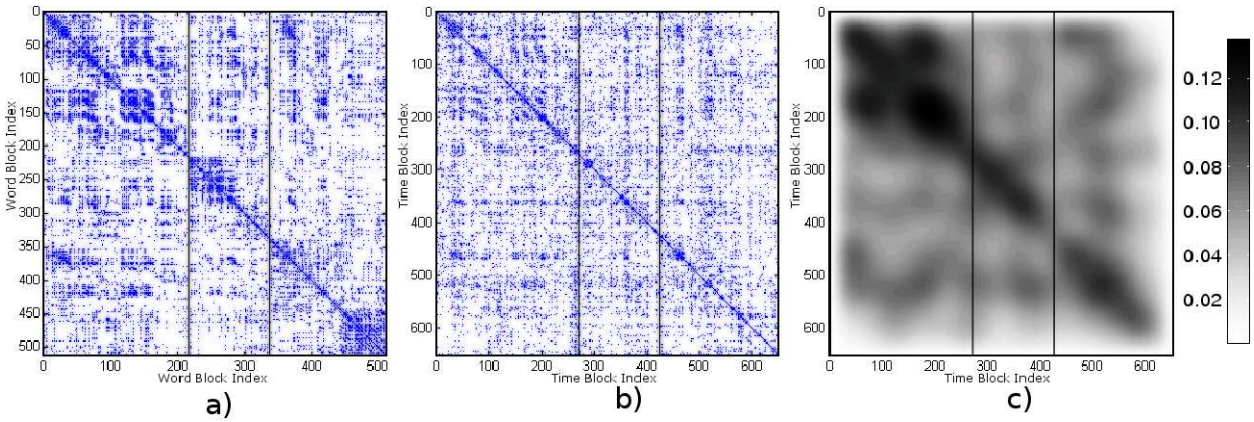

Figure 1: a) Similarity matrix for a Physics lecture constructed using a manual transcript. b) Similarity matrix for the same lecture constructed from acoustic data. The intensity of a pixel indicates the degree of block similarity. c) Acoustic comparison matrix after 2000 iterations of anisotropic diffusion. Vertical lines correspond to the reference segmentation.

Unfortunately, the paths and distortions generated during the alignment step (Section 3.1) cannot be mapped directly to an acoustic comparison matrix. Since we compare only commonly repeated acoustic patterns, some portions of the signal correspond to gaps between alignment paths. In fact, in our corpus only 67% of the data is covered by alignment paths found during the alignment stage. Moreover, many of these paths are not disjoint. For instance, our experiments show that 74% of them overlap with at least one additional alignment path. Finally, these alignments vary significantly in duration, ranging from 0.350 ms to 2.7 ms in our corpus.

Discretization and Distortion Computation To compensate for the irregular distribution of alignment paths, we quantize the data by splitting the input signal into uniform contiguous time blocks. A time block does not necessarily correspond to any one discovered alignment path. It may contain several complete paths and also portions of other paths. We compute the aggregate distortion score $D(x, y)$ of two blocks x and y by summing the distortions of all alignment paths that fall within x and y.

Matrix Smoothing Equipped with a block distortion measure, we can now construct an acoustic comparison matrix. In principle, this matrix can be processed employing standard methods developed for text segmentation. However, as Figure 1 illustrates, the structure of the acoustic matrix is quite different from the one obtained from text. In a transcript similarity matrix shown in Figure 1 a), reference boundaries delimit homogeneous regions with high internal similarity. On the other hand, looking at the acoustic similarity matrix[2] shown in Figure 1 b), it is difficult to observe any block structure corresponding to the reference segmentation.

This deficiency can be attributed to the sparsity of acoustic alignments. Consider, for example, the case when a segment is interspersed with blocks that contain very few or no complete paths. Even though the rest of the blocks in the segment could be closely related, these path-free blocks dilute segment homogeneity. This is problematic because it is not always possible to tell whether a sudden shift in scores signifies a transition or if it is just an artifact of irregularities in acoustic matching. Without additional matrix processing, these irregularities will lead the system astray.

We further refine the acoustic comparison matrix using *anisotropic diffusion*. This technique has been developed for enhancing edge detection accuracy in image processing (Perona and Malik, 1990), and has been shown to be an effective smoothing method in text segmentation (Ji and Zha, 2003). When applied to a comparison matrix, anisotropic diffusion reduces score variability within homogeneous re-

[2]We converted the original comparison distortion matrix to the similarity matrix by subtracting the component distortions from the maximum alignment distortion score.

gions of the matrix and makes edges between these regions more pronounced. Consequently, this transformation facilitates boundary detection, potentially increasing segmentation accuracy. In Figure 1 c), we can observe that the boundary structure in the diffused comparison matrix becomes more salient and corresponds more closely to the reference segmentation.

3.3 Matrix Partitioning

Given a target number of segments k, the goal of the partitioning step is to divide a matrix into k square submatrices along the diagonal. This process is guided by an optimization function that maximizes the homogeneity within a segment or minimizes the homogeneity across segments. This optimization problem can be solved using one of many unsupervised segmentation approaches (Choi et al., 2001; Ji and Zha, 2003; Malioutov and Barzilay, 2006).

In our implementation, we employ the minimum-cut segmentation algorithm (Shi and Malik, 2000; Malioutov and Barzilay, 2006). In this graph-theoretic framework, segmentation is cast as a problem of partitioning a weighted undirected graph that minimizes the *normalized-cut criterion*. The minimum-cut method achieves robust analysis by jointly considering all possible partitionings of a document, moving beyond localized decisions. This allows us to aggregate comparisons from multiple locations, thereby compensating for the noise of individual matches.

4 Evaluation Set-Up

Data We use a publicly available[3] corpus of introductory Physics lectures described in our previous work (Malioutov and Barzilay, 2006). This material is a particularly appealing application area for an audio-based segmentation algorithm — many academic subjects lack transcribed data for training, while a high ratio of in-domain technical terms limits the use of out-of-domain transcripts. This corpus is also challenging from the segmentation perspective because the lectures are long and transitions between topics are subtle.

[3]See `http://www.csail.mit.edu/~igorm/acl06.html`

The corpus consists of 33 lectures, with an average length of 8500 words and an average duration of 50 minutes. On average, a lecture was annotated with six segments, and a typical segment corresponds to two pages of a transcript. Three lectures from this set were used for development, and 30 lectures were used for testing. The lectures were delivered by the same speaker.

To evaluate the performance of traditional transcript-based segmentation algorithms on this corpus, we also use several types of transcripts at different levels of recognition accuracy. In addition to manual transcripts, our corpus contains two types of automatic transcripts, one obtained using speaker-dependent (SD) models and the other obtained using speaker-independent (SI) models. The speaker-independent model was trained on 85 hours of out-of-domain general lecture material and contained no speech from the speaker in the test set. The speaker-dependent model was trained by using 38 hours of audio data from other lectures given by the speaker. Both recognizers incorporated word statistics from the accompanying class textbook into the language model. The word error rates for the speaker-independent and speaker-dependent models are 44.9% and 19.4%, respectively.

Evaluation Metrics We use the P_k and WindowDiff measures to evaluate our system (Beeferman et al., 1999; Pevzner and Hearst, 2002). The P_k measure estimates the probability that a randomly chosen pair of words within a window of length k words is inconsistently classified. The WindowDiff metric is a variant of the P_k measure, which penalizes false positives and near misses equally. For both of these metrics, lower scores indicate better segmentation accuracy.

Baseline We use the state-of-the-art mincut segmentation system by Malioutov and Barzilay (2006) as our point of comparison. This model is an appropriate baseline, because it has been shown to compare favorably with other top-performing segmentation systems (Choi et al., 2001; Utiyama and Isahara, 2001). We use the publicly available implementation of the system.

As additional points of comparison, we test the uniform and random baselines. These correspond to segmentations obtained by uniformly placing

	P_k	WindowDiff
MAN	0.298	0.311
SD	0.340	0.351
AUDIO	**0.358**	**0.370**
SI	0.378	0.390
RAND	0.472	0.497
UNI	0.476	0.484

Table 2: Segmentation accuracy for audio-based segmentor (AUDIO), random (RAND), uniform (UNI) and three transcript-based segmentation algorithms that use manual (MAN), speaker-dependent (SD) and speaker-independent (SI) transcripts. For all of the algorithms, the target number of segments is set to the reference number of segments.

boundaries along the span of the lecture and selecting random boundaries, respectively.

To control for segmentation granularity, we specify the number of segments in the reference segmentation for both our system and the baselines.

Parameter Tuning We tuned the number of quantized blocks, the edge cutoff parameter of the minimum cut algorithm, and the anisotropic diffusion parameters on a heldout set of three development lectures. We used the same development set for the baseline segmentation systems.

5 Results

The goal of our evaluation experiments is two-fold. First, we are interested in understanding the conditions in which an audio-based segmentation is advantageous over a transcript-based one. Second, we aim to analyze the impact of various design decisions on the performance of our algorithm.

Comparison with Transcript-Based Segmentation Table 2 shows the segmentation accuracy of the audio-based segmentation algorithm and three transcript-based segmentors on the set of 30 Physics lectures. Our algorithm yields an average P_k measure of 0.358 and an average WindowDiff measure of 0.370. This result is markedly better than the scores attained by uniform and random segmentations. As expected, the best segmentation results are obtained using manual transcripts. However, the gap between audio-based segmentation and transcript-based segmentation narrows when the recognition accuracy decreases. In fact, performance of the audio-based segmentation beats the transcript-based segmentation baseline obtained using speaker-independent (SI) models (0.358 for AUDIO versus P_k measurements of 0.378 for SI).

Analysis of Audio-based Segmentation A central challenge in audio-based segmentation is how to overcome the noise inherent in acoustic matching. We addressed this issue by using anisotropic diffusion to refine the comparison matrix. We can quantify the effects of this smoothing technique by generating segmentations directly from the similarity matrix. We obtain similarities from the distortions in the comparison matrix by subtracting the distortion scores from the maximum distortion:

$$S(x, y) = \max_{s_i, s_j} [D(s_i, s_j)] - D(x, y)$$

Using this matrix with the min-cut algorithm, segmentation accuracy drops to a P_k measure of 0.418 (0.450 WindowDiff). This difference in performance shows that anisotropic diffusion compensates for noise introduced during acoustic matching.

An alternative solution to the problem of irregularities in audio-based matching is to compute clusters of acoustically similar utterances. Each of the derived clusters can be thought of as a unique word type.[4] We compute these clusters, employing a method for unsupervised vocabulary induction developed by Park and Glass (2006). Using the output of their algorithm, the continuous audio stream is transformed into a sequence of word-like units, which in turn can be segmented using any standard transcript-based segmentation algorithm, such as the minimum-cut segmentor. On our corpus, this method achieves disappointing results — a P_k measure of 0.423 (0.424 WindowDiff). The result can be attributed to the sparsity of clusters[5] generated by this method, which focuses primarily on discovering the frequently occurring content words.

6 Conclusion and Future Work

We presented an unsupervised algorithm for audio-based topic segmentation. In contrast to existing

[4] In practice, a cluster can correspond to a phrase, word, or word fragment (See Table 1 for examples).

[5] We tuned the number of clusters on the development set.

algorithms for speech segmentation, our approach does not require an input transcript. Thus, it can be used in domains where a speech recognizer is not available or its output is too noisy. Our approach approximates the distribution of cohesion ties by considering the distribution of acoustic patterns. Our experimental results demonstrate the utility of this approach: audio-based segmentation compares favorably with transcript-based segmentation computed over noisy transcripts.

The segmentation algorithm presented in this paper focuses on one source of linguistic information for discourse analysis — lexical cohesion. Multiple studies of discourse structure, however, have shown that prosodic cues are highly predictive of changes in topic structure (Hirschberg and Nakatani, 1996; Shriberg et al., 2000). In a supervised framework, we can further enhance audio-based segmentation by combining features derived from pattern analysis with prosodic information. We can also explore an unsupervised fusion of these two sources of information; for instance, we can induce informative prosodic cues by using distributional evidence.

Another interesting direction for future research lies in combining the results of noisy recognition with information obtained from distribution of acoustic patterns. We hypothesize that these two sources provide complementary information about the audio stream, and therefore can compensate for each other's mistakes. This combination can be particularly fruitful when processing speech documents with multiple speakers or background noise.

Abstract

A Bloom filter (BF) is a randomised data structure for set membership queries. Its space requirements are significantly below lossless information-theoretic lower bounds but it produces false positives with some quantifiable probability. Here we explore the use of BFs for language modelling in statistical machine translation.

We show how a BF containing n-grams can enable us to use much larger corpora and higher-order models complementing a conventional n-gram LM within an SMT system. We also consider (i) how to include approximate frequency information efficiently within a BF and (ii) how to reduce the error rate of these models by first checking for lower-order sub-sequences in candidate n-grams. Our solutions in both cases retain the one-sided error guarantees of the BF while taking advantage of the Zipf-like distribution of word frequencies to reduce the space requirements.

1 Introduction

Language modelling (LM) is a crucial component in statistical machine translation (SMT). Standard n-gram language models assign probabilities to translation hypotheses in the target language, typically as smoothed trigram models, e.g. (Chiang, 2005). Although it is well-known that higher-order LMs and models trained on additional monolingual corpora can yield better translation performance, the challenges in deploying large LMs are not trivial. Increasing the order of an n-gram model can result in an exponential increase in the number of parameters; for corpora such as the English Gigaword corpus, for instance, there are 300 million distinct trigrams and over 1.2 billion 5-grams. Since a LM may be queried millions of times per sentence, it should ideally reside locally in memory to avoid time-consuming remote or disk-based look-ups.

Against this background, we consider a radically different approach to language modelling: instead of explicitly storing all distinct n-grams, we store a randomised representation. In particular, we show that the *Bloom filter* (Bloom (1970); BF), a simple space-efficient randomised data structure for representing sets, may be used to represent statistics from larger corpora and for higher-order n-grams to complement a conventional smoothed trigram model within an SMT decoder. [1]

The space requirements of a Bloom filter are quite spectacular, falling significantly below information-theoretic error-free lower bounds while query times are constant. This efficiency, however, comes at the price of *false positives*: the filter may erroneously report that an item not in the set is a member. False negatives, on the other hand, will never occur: the error is said to be *one-sided*.

In this paper, we show that a Bloom filter can be used effectively for language modelling within an SMT decoder and present the *log-frequency Bloom filter*, an extension of the standard Boolean BF that

[1] For extensions of the framework presented here to stand-alone smoothed Bloom filter language models, we refer the reader to a companion paper (Talbot and Osborne, 2007).

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 512–519,
Prague, Czech Republic, June 2007.

takes advantage of the Zipf-like distribution of corpus statistics to allow frequency information to be associated with n-grams in the filter in a space-efficient manner. We then propose a mechanism, *sub-sequence filtering*, for reducing the error rates of these models by using the fact that an n-gram's frequency is bound from above by the frequency of its least frequent sub-sequence.

We present machine translation experiments using these models to represent information regarding higher-order n-grams and additional larger monolingual corpora in combination with conventional smoothed trigram models. We also run experiments with these models in isolation to highlight the impact of different order n-grams on the translation process. Finally we provide some empirical analysis of the effectiveness of both the log frequency Bloom filter and sub-sequence filtering.

2 The Bloom filter

In this section, we give a brief overview of the Bloom filter (BF); refer to Broder and Mitzenmacher (2005) for a more in detailed presentation. A BF represents a set $\mathcal{S} = \{x_1, x_2, ..., x_n\}$ with n elements drawn from a universe $\mathcal{U}$ of size N. The structure is attractive when $N \gg n$. The only significant storage used by a BF consists of a bit array of size m. This is initially set to hold zeroes. To train the filter we hash each item in the set k times using distinct hash functions $h_1, h_2, ..., h_k$. Each function is assumed to be independent from each other and to map items in the universe to the range 1 to m uniformly at random. The k bits indexed by the hash values for each item are set to 1; the item is then discarded. Once a bit has been set to 1 it remains set for the lifetime of the filter. Distinct items may not be hashed to k distinct locations in the filter; we ignore collisons. Bits in the filter can, therefore, be *shared* by distinct items allowing significant space savings but introducing a non-zero probability of false positives at test time. There is no way of directly retrieving or ennumerating the items stored in a BF.

At test time we wish to discover whether a given item was a member of the original set. The filter is queried by hashing the test item using the same k hash functions. If all bits referenced by the k hash values are 1 then we *assume* that the item was a member; if any of them are 0 then we *know* it was not. True members are always correctly identified, but a false positive will occur if all k corresponding bits were set by other items during training and the item was not a member of the training set. This is known as a *one-sided error*.

The probability of a false postive, f, is clearly the probability that none of k randomly selected bits in the filter are still 0 after training. Letting p be the proportion of bits that are still zero after these n elements have been inserted, this gives,

$$f = (1-p)^k.$$

As n items have been entered in the filter by hashing each k times, the probability that a bit is still zero is,

$$p^{'} = \left(1 - \frac{1}{m}\right)^{kn} \approx e^{-\frac{kn}{m}}$$

which is the expected value of p. Hence the false positive rate can be approximated as,

$$f = (1-p)^k \approx (1-p^{'})^k \approx \left(1 - e^{-\frac{kn}{m}}\right)^k.$$

By taking the derivative we find that the number of functions k^* that minimizes f is,

$$k^* = \ln 2 \cdot \frac{m}{n}.$$

which leads to the intuitive result that exactly half the bits in the filter will be set to 1 when the optimal number of hash functions is chosen.

The fundmental difference between a Bloom filter's space requirements and that of any lossless representation of a set is that the former does not depend on the size of the (exponential) universe N from which the set is drawn. A lossless representation scheme (for example, a hash map, trie etc.) must depend on N since it assigns a distinct representation to each possible set drawn from the universe.

3 Language modelling with Bloom filters

In our experiments we make use of both standard (i.e. Boolean) BFs containing n-gram types drawn from a training corpus and a novel BF scheme, the *log-frequency Bloom filter*, that allows frequency information to be associated efficiently with items stored in the filter.

Algorithm 1 Training frequency BF

Input: $\mathcal{S}_{train}$, $\{h_1, ...h_k\}$ and $\mathcal{BF} = \emptyset$
Output: $\mathcal{BF}$
for all $x \in \mathcal{S}_{train}$ **do**
  $c(x) \leftarrow$ frequency of n-gram x in $\mathcal{S}_{train}$
  $qc(x) \leftarrow$ quantisation of $c(x)$ (Eq. 1)
  for $j = 1$ to $qc(x)$ **do**
    for $i = 1$ to k **do**
      $h_i(x) \leftarrow$ hash of event $\{x, j\}$ under h_i
      $\mathcal{BF}[h_i(x)] \leftarrow 1$
    end for
  end for
end for
return $\mathcal{BF}$

Algorithm 2 Test frequency BF

Input: x, $MAXQCOUNT$, $\{h_1, ...h_k\}$ and $\mathcal{BF}$
Output: Upper bound on $qc(x) \in \mathcal{S}_{train}$
for $j = 1$ to $MAXQCOUNT$ **do**
  for $i = 1$ to k **do**
    $h_i(x) \leftarrow$ hash of event $\{x, j\}$ under h_i
    if $\mathcal{BF}[h_i(x)] = 0$ **then**
      return $j - 1$
    end if
  end for
end for

3.1 Log-frequency Bloom filter

The efficiency of our scheme for storing n-gram statistics within a BF relies on the Zipf-like distribution of n-gram frequencies in natural language corpora: most events occur an extremely small number of times, while a small number are very frequent.

We quantise raw frequencies, $c(x)$, using a logarithmic codebook as follows,

$$qc(x) = 1 + \lfloor \log_b c(x) \rfloor. \quad (1)$$

The precision of this codebook decays exponentially with the raw counts and the scale is determined by the base of the logarithm b; we examine the effect of this parameter in experiments below.

Given the quantised count $qc(x)$ for an n-gram x, the filter is trained by entering composite events consisting of the n-gram appended by an integer counter j that is incremented from 1 to $qc(x)$ into the filter. To retrieve the quantised count for an n-gram, it is first appended with a count of 1 and hashed under the k functions; if this tests positive, the count is incremented and the process repeated. The procedure terminates as soon as any of the k hash functions hits a 0 and the previous count is reported. The one-sided error of the BF and the training scheme ensure that the actual quantised count cannot be larger than this value. As the counts are quantised logarithmically, the counter will be incremented only a small number of times. The training and testing routines are given here as Algorithms 1 and 2 respectively.

Errors for the log-frequency BF scheme are one-sided: frequencies will never be underestimated. The probability of overestimating an item's frequency decays exponentially with the size of the overestimation error d (i.e. as f^d for $d > 0$) since each erroneous increment corresponds to a single false positive and d such independent events must occur together.

3.2 Sub-sequence filtering

The error analysis in Section 2 focused on the false positive rate of a BF; if we deploy a BF within an SMT decoder, however, the actual error rate will also depend on the *a priori* membership probability of items presented to it. The error rate Err is,

$$Err = Pr(x \notin S_{train}|Decoder)f.$$

This implies that, unlike a conventional lossless data structure, the model's accuracy depends on other components in system and how it is queried.

We take advantage of the monotonicity of the n-gram event space to place upper bounds on the frequency of an n-gram prior to testing for it in the filter and potentially truncate the outer loop in Algorithm 2 when we know that the test could only return postive in error.

Specifically, if we have stored lower-order n-grams in the filter, we can infer that an n-gram cannot present, if any of its sub-sequences test negative. Since our scheme for storing frequencies can never *underestimate* an item's frequency, this relation will generalise to frequencies: an n-gram's frequency cannot be greater than the frequency of its least frequent sub-sequence as reported by the filter,

$$c(w_1, ..., w_n) \leq \min\{c(w_1, ..., w_{n-1}), c(w_2, ..., w_n)\}.$$

We use this to reduce the effective error rate of BF-LMs that we use in the experiments below.

3.3 Bloom filter language model tests

A standard BF can implement a Boolean 'language model' test: have we seen some fragment of language before? This does not use any frequency information. The *Boolean BF-LM* is a standard BF containing all n-grams of a certain length in the training corpus, $\mathcal{S}_{train}$. It implements the following binary feature function in a log-linear decoder,

$$\phi_{\mathbf{bool}}(x) \geq \delta(x \in \mathcal{S}_{train})$$

Separate Boolean BF-LMs can be included for different order n and assigned distinct log-linear weights that are learned as part of a minimum error rate training procedure (see Section 4).

The *log-frequency BF-LM* implements a multinomial feature function in the decoder that returns the value associated with an n-gram by Algorithm 2.

$$\phi_{\mathbf{logfreq}}(x) \geq qc(x) \in \mathcal{S}_{train}$$

Sub-sequence filtering can be performed by using the minimum value returned by lower-order models as an upper-bound on the higher-order models.

By boosting the score of hypotheses containing n-grams observed in the training corpus while remaining agnostic for unseen n-grams (with the exception of errors), these feature functions have more in common with maximum entropy models than conventionally smoothed n-gram models.

4 Experiments

We conducted a range of experiments to explore the effectiveness and the error-space trade-off of Bloom filters for language modelling in SMT. The space-efficiency of these models also allows us to investigate the impact of using much larger corpora and higher-order n-grams on translation quality. While our main experiments use the Bloom filter models *in conjunction* with a conventional smoothed trigram model, we also present experiments with these models in isolation to highlight the impact of different order n-grams on the translation process. Finally, we present some empirical analysis of both the log-frequency Bloom filter and the sub-sequence filtering technique which may be of independent interest.

Model	EP-KN-3	EP-KN-4	AFP-KN-3
Memory	64M	99M	1.3G
gzip size	21M	31M	481M
1-gms	62K	62K	871K
2-gms	1.3M	1.3M	16M
3-gms	1.1M	1.0M	31M
4-gms	N/A	1.1M	N/A

Table 1: Baseline and Comparison Models

4.1 Experimental set-up

All of our experiments use publically available resources. We use the French-English section of the *Europarl* (EP) corpus for parallel data and language modelling (Koehn, 2003) and the *English Gigaword Corpus* (LDC2003T05; GW) for additional language modelling.

Decoding is carried-out using the Moses decoder (Koehn and Hoang, 2007). We hold out 500 test sentences and 250 development sentences from the parallel text for evaluation purposes. The feature functions in our models are optimised using minimum error rate training and evaluation is performed using the BLEU score.

4.2 Baseline and comparison models

Our baseline LM and other comparison models are conventional n-gram models smoothed using modified Kneser-Ney and built using the SRILM Toolkit (Stolcke, 2002); as is standard practice these models drop entries for n-grams of size 3 and above when the corresponding discounted count is less than 1. The baseline language model, EP-KN-3, is a trigram model trained on the English portion of the parallel corpus. For additional comparisons we also trained a smoothed 4-gram model on this Europarl data (EP-KN-4) and a trigram model on the Agence France Press section of the Gigaword Corpus (AFP-KN-3).

Table 1 shows the amount of memory these models take up on disk and compressed using the *gzip* utility in parentheses as well as the number of distinct n-grams of each order. We give the gzip compressed size as an optimistic lower bound on the size of any lossless representation of each model.[2]

[2]Note, in particular, that gzip compressed files do *not* support direct random access as required by our application.

Corpus	Europarl	Gigaword
1-gms	61K	281K
2-gms	1.3M	5.4M
3-gms	4.7M	275M
4-gms	9.0M	599M
5-gms	10.3M	842M
6-gms	10.7M	957M

Table 2: Number of distinct n-grams

4.3 Bloom filter-based models

To create Bloom filter LMs we gathered n-gram counts from both the Europarl (EP) and the whole of the Gigaword Corpus (GW). Table 2 shows the numbers of distinct n-grams in these corpora. Note that we use no pruning for these models and that the numbers of distinct n-grams is of the same order as that of the recently released Google Ngrams dataset (LDC2006T13). In our experiments we create a range of models referred to by the corpus used (EP or GW), the order of the n-gram(s) entered into the filter (1 to 10), whether the model is Boolean (Bool-BF) or provides frequency information (Freq-BF), whether or not sub-sequence filtering was used (FTR) and whether it was used in conjunction with the baseline trigram (+EP-KN-3).

4.4 Machine translation experiments

Our first set of experiments examines the relationship between memory allocated to the BF and BLEU score. We present results using the Boolean BF-LM in isolation and then both the Boolean and log-frequency BF-LMS to add 4-grams to our baseline 3-gram model.Our second set of experiments adds 3-grams and 5-grams from the Gigaword Corpus to our baseline. Here we constrast the Boolean BF-LM with the log-frequency BF-LM with different quantisation bases (2 = fine-grained and 5 = coarse-grained). We then evaluate the sub-sequence filtering approach to reducing the actual error rate of these models by adding both 3 and 4-grams from the Gigaword Corpus to the baseline. Since the BF-LMs easily allow us to deploy very high-order n-gram models, we use them to evaluate the impact of different order n-grams on the translation process presenting results using the Boolean and log-frequency BF-LM *in isolation* for n-grams of order 1 to 10.

Model	EP-KN-3	EP-KN-4	AFP-KN-3
BLEU	28.51	29.24	29.17
Memory	64M	99M	1.3G
gzip size	21M	31M	481M

Table 3: Baseline and Comparison Models

4.5 Analysis of BF extensions

We analyse our log-frequency BF scheme in terms of the additional memory it requires and the error rate compared to a non-redundant scheme. The non-redundant scheme involves entering *just* the exact quantised count for each n-gram and then searching over the range of possible counts at test time starting with the count with maximum *a priori* probability (i.e. 1) and incrementing until a count is found or the whole codebook has been searched (here the size is 16).

We also analyse the sub-sequence filtering scheme directly by creating a BF with only 3-grams and a BF containing both 2-grams and 3-grams and comparing their *actual* error rates when presented with 3-grams that are all known to be negatives.

5 Results

5.1 Machine translation experiments

Table 3 shows the results of the baseline (EP-KN-3) and other conventional n-gram models trained on larger corpora (AFP-KN-3) and using higher-order dependencies (EP-KN-4). The larger models improve somewhat on the baseline performance.

Figure 1 shows the relationship between space allocated to the BF models and BLEU score (left) and false positive rate (right) respectively. These experiments do *not* include the baseline model. We can see a clear correlation between memory / false positive rate and translation performance.

Adding 4-grams in the form of a Boolean BF or a log-frequency BF (see Figure 2) improves on the 3-gram baseline with little additional memory (around 4MBs) while performing on a par with or above the Europarl 4-gram model with around 10MBs; this suggests that a lossy representation of the unpruned set of 4-grams contains more useful information than a lossless representation of the pruned set.[3]

[3] An unpruned modified Kneser-Ney 4-gram model on the Eurpoparl data scores slightly higher - 29.69 - while taking up 489MB (132MB gzipped).

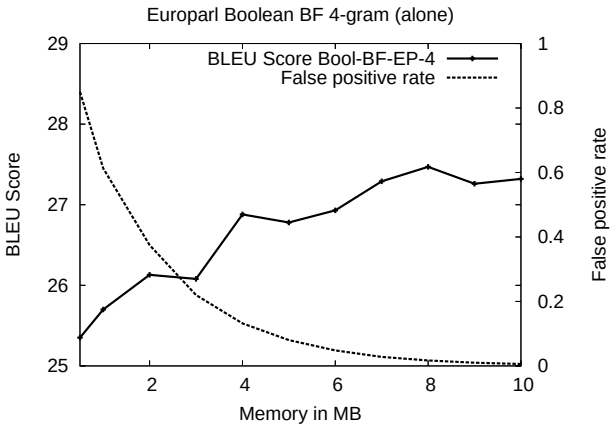

Figure 1: Space/Error vs. BLEU Score.

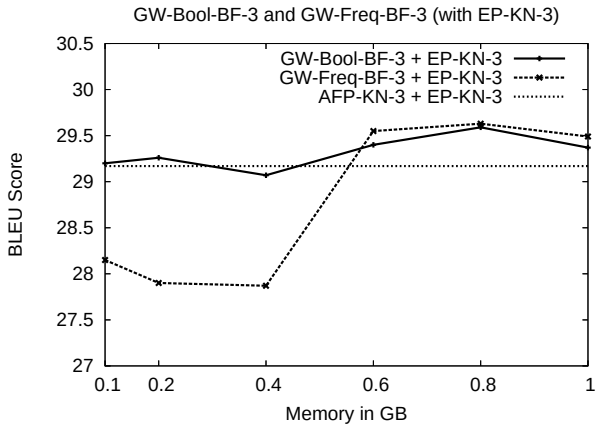

Figure 3: Adding GW 3-grams with Bloom filters.

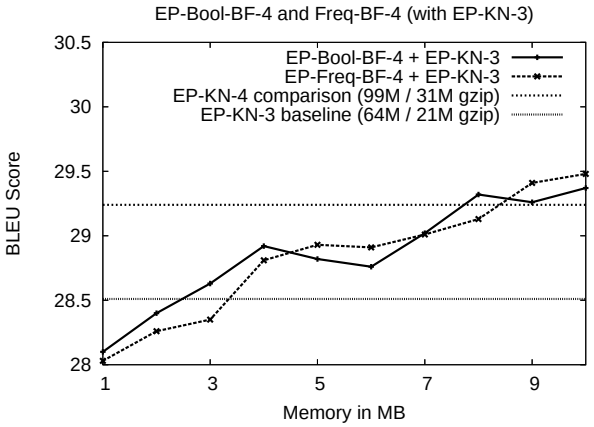

Figure 2: Adding 4-grams with Bloom filters.

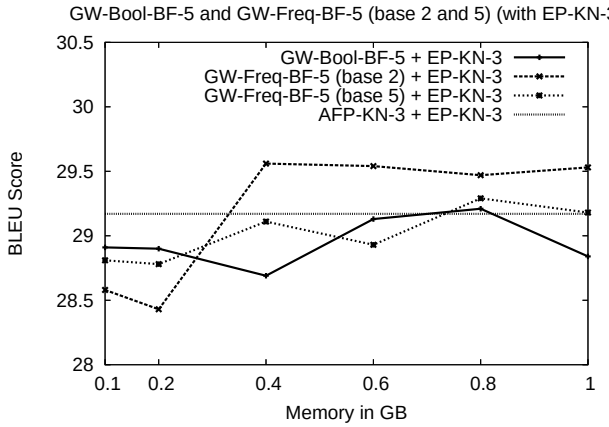

Figure 4: Comparison of different quantisation rates.

As the false positive rate exceeds 0.20 the performance is severly degraded. Adding 3-grams drawn from the whole of the Gigaword corpus rather than simply the Agence France Press section results in slightly improved performance with signficantly less memory than the AFP-KN-3 model (see Figure 3).

Figure 4 shows the results of adding 5-grams drawn from the Gigaword corpus to the baseline. It also contrasts the Boolean BF and the log-frequency BF suggesting in this case that the log-frequency BF can provide useful information when the quantisation base is relatively fine-grained (base 2). The Boolean BF and the base 5 (coarse-grained quantisation) log-frequency BF perform approximately the same. The base 2 quantisation performs worse for smaller amounts of memory, possibly due to the larger set of events it is required to store.

Figure 5 shows sub-sequence filtering resulting in a small increase in performance when false positive rates are high (i.e. less memory is allocated). We believe this to be the result of an increased *a priori* membership probability for n-grams presented to the filter under the sub-sequence filtering scheme.

Figure 6 shows that for this task the most useful n-gram sizes are between 3 and 6.

5.2 Analysis of BF extensions

Figure 8 compares the memory requirements of the log-frequencey BF (base 2) and the Boolean

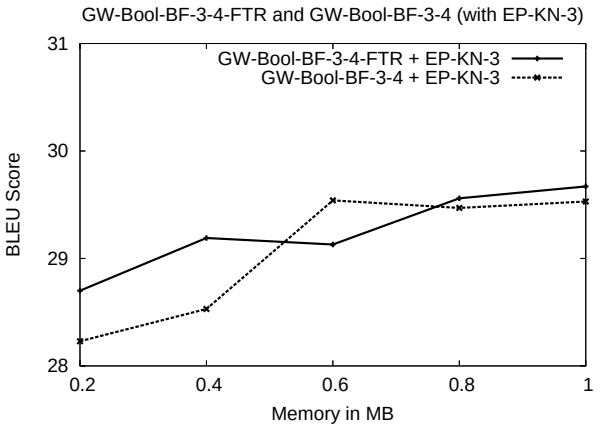

Figure 5: Effect of sub-sequence filtering.

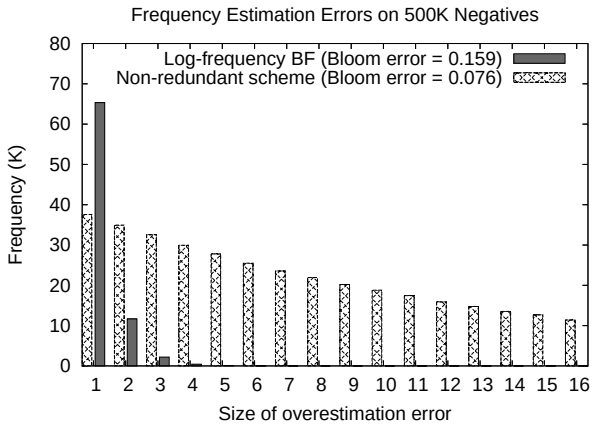

Figure 7: Frequency estimation errors.

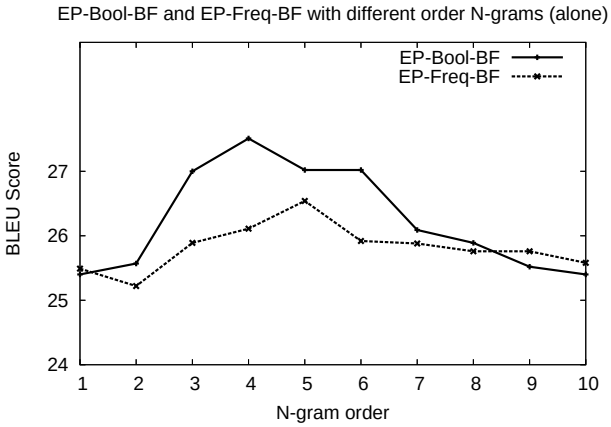

Figure 6: Impact of n-grams of different sizes.

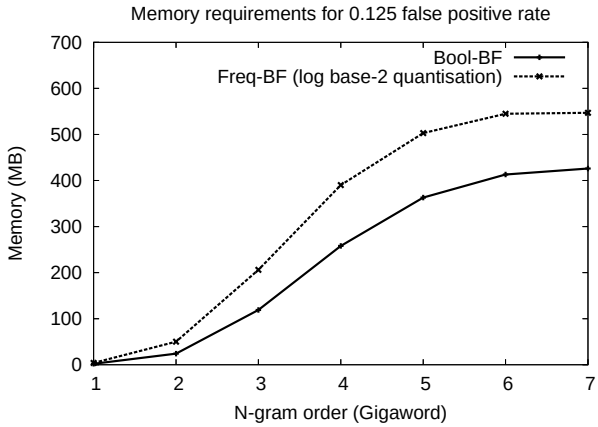

Figure 8: Comparison of memory requirements.

BF for various order n-gram sets from the Gigaword Corpus with the same underlying false positive rate (0.125). The additional space required by our scheme for storing frequency information is less than a factor of 2 compared to the standard BF.

Figure 7 shows the number and size of frequency estimation errors made by our log-frequency BF scheme and a non-redundant scheme that stores only the exact quantised count. We presented 500K negatives to the filter and recorded the frequency of overestimation errors of each size. As shown in Section 3.1, the probability of overestimating an item's frequency under the log-frequency BF scheme decays exponentially in the size of this overestimation error. Although the non-redundant scheme requires fewer items be stored in the filter and, therefore, has a lower underlying false positive rate (0.076 versus 0.159), in practice it incurs a *much* higher error rate (0.717) with many large errors.

Figure 9 shows the impact of sub-sequence filtering on the actual error rate. Although, the false positive rate for the BF containing 2-grams, in addition, to 3-grams (filtered) is higher than the false positive rate of the unfiltered BF containing only 3-grams, the actual error rate of the former is lower for models with less memory. By testing for 2-grams prior to querying for the 3-grams, we can avoid performing some queries that may otherwise have incurred errors using the fact that a 3-gram cannot be present if one of its constituent 2-grams is absent.

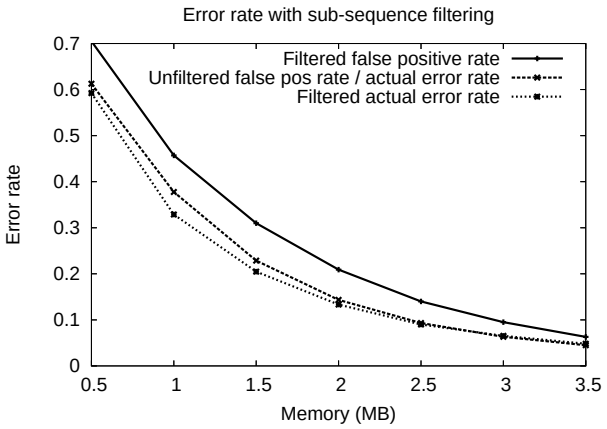

Figure 9: Error rate with sub-sequence filtering.

6 Related Work

We are not the first people to consider building very large scale LMs: Kumar et al. used a four-gram LM for re-ranking (Kumar et al., 2005) and in unpublished work, Google used substantially larger n-grams in their SMT system. Deploying such LMs requires either a cluster of machines (and the overheads of remote procedure calls), per-sentence filtering (which again, is slow) and/or the use of some other lossy compression (Goodman and Gao, 2000). Our approach can complement all these techniques.

Bloom filters have been widely used in database applications for reducing communications overheads and were recently applied to encode word frequencies in information retrieval (Linari and Weikum, 2006) using a method that resembles the non-redundant scheme described above. Extensions of the BF to associate frequencies with items in the set have been proposed e.g., (Cormode and Muthukrishn, 2005); while these schemes are more general than ours, they incur greater space overheads for the distributions that we consider here.

7 Conclusions

We have shown that Bloom Filters can form the basis for space-efficient language modelling in SMT. Extending the standard BF structure to encode corpus frequency information and developing a strategy for reducing the error rates of these models by sub-sequence filtering, our models enable higher-order n-grams and larger monolingual corpora to be used more easily for language modelling in SMT. In a companion paper (Talbot and Osborne, 2007) we have proposed a framework for deriving conventional smoothed n-gram models from the log-frequency BF scheme allowing us to do away entirely with the standard n-gram model in an SMT system. We hope the present work will help establish the Bloom filter as a practical alternative to conventional associative data structures used in computational linguistics. The framework presented here shows that with some consideration for its workings, the randomised nature of the Bloom filter need not be a significant impediment to is use in applications.

Abstract

We propose a novel approach to crosslingual language model (LM) adaptation based on bilingual Latent Semantic Analysis (bLSA). A bLSA model is introduced which enables latent topic distributions to be efficiently transferred across languages by enforcing a one-to-one topic correspondence during training. Using the proposed bLSA framework crosslingual LM adaptation can be performed by, first, inferring the topic posterior distribution of the source text and then applying the inferred distribution to the target language N-gram LM via marginal adaptation. The proposed framework also enables rapid bootstrapping of LSA models for new languages based on a source LSA model from another language. On Chinese to English speech and text translation the proposed bLSA framework successfully reduced word perplexity of the English LM by over 27% for a unigram LM and up to 13.6% for a 4-gram LM. Furthermore, the proposed approach consistently improved machine translation quality on both speech and text based adaptation.

1 Introduction

Language model adaptation is crucial to numerous speech and translation tasks as it enables higher-level contextual information to be effectively incorporated into a background LM improving recognition or translation performance. One approach is to employ Latent Semantic Analysis (LSA) to capture in-domain word unigram distributions which are then integrated into the background N-gram LM. This approach has been successfully applied in automatic speech recognition (ASR) (Tam and Schultz, 2006) using the Latent Dirichlet Allocation (LDA) (Blei et al., 2003). The LDA model can be viewed as a Bayesian topic mixture model with the topic mixture weights drawn from a Dirichlet distribution. For LM adaptation, the topic mixture weights are estimated based on in-domain adaptation text (e.g. ASR hypotheses). The adapted mixture weights are then used to interpolate a topic-dependent unigram LM, which is finally integrated into the background N-gram LM using marginal adaptation (Kneser et al., 1997)

In this paper, we propose a framework to perform LM adaptation across languages, enabling the adaptation of a LM from one language based on the adaptation text of another language. In statistical machine translation (SMT), one approach is to apply LM adaptation on the target language based on an initial translation of input references (Kim and Khudanpur, 2003; Paulik et al., 2005). This scheme is limited by the coverage of the translation model, and overall by the quality of translation. Since this approach only allows to apply LM adaptation *after* translation, available knowledge cannot be applied to extend the coverage. We propose a bilingual LSA model (bLSA) for crosslingual LM adaptation that can be applied *before* translation. The bLSA model consists of two LSA models: one for each side of the language trained on parallel document corpora. The key property of the bLSA model is that

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 520–527,
Prague, Czech Republic, June 2007.

the latent topic of the source and target LSA models can be assumed to be a one-to-one correspondence and thus share a common latent topic space since the training corpora consist of bilingual parallel data. For instance, say topic 10 of the Chinese LSA model is about politics. Then topic 10 of the English LSA model is set to also correspond to politics and so forth. During LM adaptation, we first infer the topic mixture weights from the source text using the source LSA model. Then we transfer the inferred mixture weights to the target LSA model and thus obtain the target LSA marginals. The challenge is to enforce the one-to-one topic correspondence. Our proposal is to share common variational Dirichlet posteriors over the topic mixture weights of a document pair in the LDA-style model. The beauty of the bLSA framework is that the model searches for a common latent topic space in an unsupervised fashion, rather than to require manual interaction. Since the topic space is language independent, our approach supports topic transfer in multiple language pairs in O(N) where N is the number of languages.

Related work includes the Bilingual Topic Admixture Model (BiTAM) for word alignment proposed by (Zhao and Xing, 2006). Basically, the BiTAM model consists of topic-dependent translation lexicons modeling $Pr(c|e,k)$ where c, e and k denotes the source Chinese word, target English word and the topic index respectively. On the other hand, the bLSA framework models $Pr(c|k)$ and $Pr(e|k)$ which is different from the BiTAM model. By their different modeling nature, the bLSA model usually supports more topics than the BiTAM model. Another work by (Kim and Khudanpur, 2004) employed crosslingual LSA using singular value decomposition which concatenates bilingual documents into a single input supervector before projection.

We organize the paper as follows: In Section 2, we introduce the bLSA framework including Latent Dirichlet-Tree Allocation (LDTA) (Tam and Schultz, 2007) as a correlated LSA model, bLSA training and crosslingual LM adaptation. In Section 3, we present the effect of LM adaptation on word perplexity, followed by SMT experiments reported in BLEU on both speech and text input in Section 3.3. Section 4 describes conclusions and future works.

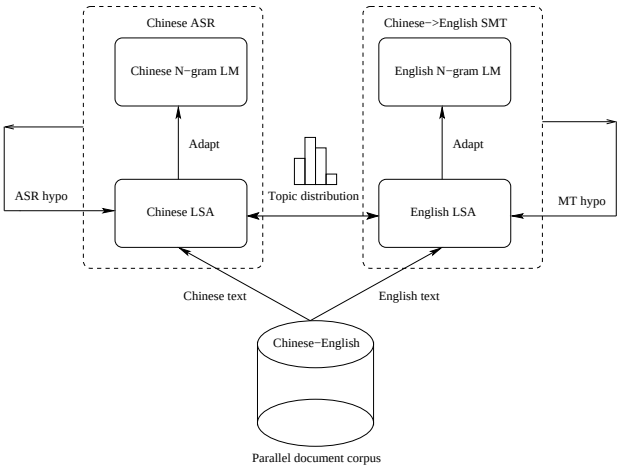

Figure 1: Topic transfer in bilingual LSA model.

2 Bilingual Latent Semantic Analysis

The goal of a bLSA model is to enforce a one-to-one topic correspondence between monolingual LSA models, each of which can be modeled using an LDA-style model. The role of the bLSA model is to transfer the inferred latent topic distribution from the source language to the target language assuming that the topic distributions on both sides are identical. The assumption is reasonable for parallel document pairs which are faithful translations. Figure 1 illustrates the idea of topic transfer between monolingual LSA models followed by LM adaptation. One observation is that the topic transfer can be bi-directional meaning that the "flow" of topic can be from ASR to SMT or vice versa. In this paper, we only focus on ASR-to-SMT direction. Our target is to minimize the word perplexity on the target language through LM adaptation. Before we introduce the heuristic of enforcing a one-to-one topic correspondence, we describe the Latent Dirichlet-Tree Allocation (LDTA) for LSA.

2.1 Latent Dirichlet-Tree Allocation

The LDTA model extends the LDA model in which correlation among latent topics are captured using a Dirichlet-Tree prior. Figure 2 illustrates a depth-two Dirichlet-Tree. A tree of depth one simply falls back to the LDA model. The LDTA model is a generative model with the following generative process:

1. Sample a vector of branch probabilities $b_j \sim$

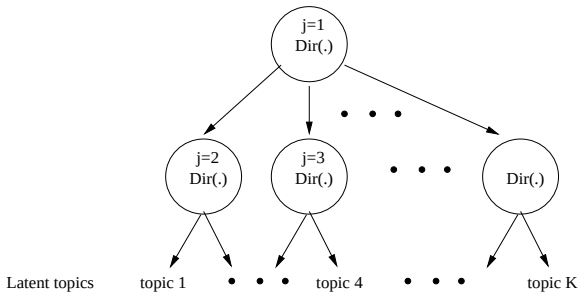

Figure 2: Dirichlet-Tree prior of depth two.

$Dir(\alpha_j)$ for each node $j = 1...J$ where α_j denotes the parameter (aka the pseudo-counts of its outgoing branches) of the Dirichlet distribution at node j.

2. Compute the topic proportions as:

$$\theta_k = \prod_{jc} b_{jc}^{\delta_{jc}(k)} \quad (1)$$

where $\delta_{jc}(k)$ is an indicator function which sets to unity when the c-th branch of the j-th node leads to the leaf node of topic k and zero otherwise. The k-th topic proportion θ_k is computed as the product of branch probabilities from the root node to the leaf node of topic k.

3. Generate a document using the topic multinomial for each word w_i:

$$z_i \sim Mult(\theta)$$
$$w_i \sim Mult(\beta_{.z_i})$$

where $\beta_{.z_i}$ denotes the topic-dependent unigram LM indexed by z_i.

The joint distribution of the latent variables (topic sequence z_1^n and the Dirichlet nodes over child branches b_j) and an observed document w_1^n can be written as follows:

$$p(w_1^n, z_1^n, b_1^J) = p(b_1^J|\{\alpha_j\}) \prod_i^n \beta_{w_i z_i} \cdot \theta_{z_i}$$

$$\text{where} \quad p(b_1^J|\{\alpha_j\}) = \prod_j^J Dir(b_j; \alpha_j) \propto \prod_{jc} b_{jc}^{\alpha_{jc}-1}$$

Similar to LDA training, we apply the variational Bayes approach by optimizing the lower bound of the marginalized document likelihood:

$$L(w_1^n; \Lambda, \Gamma) = E_q[\log \frac{p(w_1^n, z_1^n, b_1^J; \Lambda)}{q(z_1^n, b_1^J; \Gamma)}]$$
$$= E_q[\log p(w_1^n|z_1^n)] + E_q[\log \frac{p(z_1^n|b_1^J)}{q(z_1^n)}]$$
$$+ E_q[\log \frac{p(b_1^J; \{\alpha_j\})}{q(b_1^J; \{\gamma_j\})}]$$

where $q(z_1^n, b_1^J; \Gamma) = \prod_i^n q(z_i) \cdot \prod_j^J q(b_j)$ is a factorizable variational posterior distribution over the latent variables parameterized by Γ which are determined in the E-step. Λ is the model parameters for a Dirichlet-Tree $\{\alpha_j\}$ and the topic-dependent unigram LM $\{\beta_{wk}\}$. The LDTA model has an E-step similar to the LDA model:

E-Step:

$$\gamma_{jc} = \alpha_{jc} + \sum_i^n \sum_k^K q_{ik} \cdot \delta_{jc}(k) \quad (2)$$

$$q_{ik} \propto \beta_{w_i k} \cdot e^{E_q[\log \theta_k]} \quad (3)$$

where

$$E_q[\log \theta_k] = \sum_{jc} \delta_{jc}(k) E_q[\log b_{jc}]$$
$$= \sum_{jc} \delta_{jc}(k) \left(\Psi(\gamma_{jc}) - \Psi(\sum_c \gamma_{jc}) \right)$$

where q_{ik} denotes $q(z_i = k)$ meaning the variational topic posterior of word w_i. Eqn 2 and Eqn 3 are executed iteratively until convergence is reached.

M-Step:

$$\beta_{wk} \propto \sum_i^n q_{ik} \cdot \delta(w_i, w) \quad (4)$$

where $\delta(w_i, w)$ is a Kronecker Delta function. The alpha parameters can be estimated with iterative methods such as Newton-Raphson or simple gradient ascent procedure.

2.2 Bilingual LSA training

For the following explanations, we assume that our source and target languages are Chinese and English respectively. The bLSA model training is a

two-stage procedure. At the first stage, we train a Chinese LSA model using the Chinese documents in parallel corpora. We applied the variational EM algorithm (Eqn 2–4) to train a Chinese LSA model. Then we used the model to compute the term $e^{E_q[\log \theta_k]}$ needed in Eqn 3 for each Chinese document in parallel corpora. At the second stage, we apply the same $e^{E_q[\log \theta_k]}$ to *bootstrap* an English LSA model, which is the key to enforce a one-to-one topic correspondence. Now the hyper-parameters of the variational Dirichlet posteriors of each node in the Dirichlet-Tree are shared among the Chinese and English model. Precisely, we apply only Eqn 3 with fixed $e^{E_q[\log \theta_k]}$ in the E-step and Eqn 4 in the M-step on $\{\beta_{wk}\}$ to bootstrap an English LSA model. Notice that the E-step is non-iterative resulting in rapid LSA training. In short, given a monolingual LSA model, we can rapidly bootstrap LSA models of new languages using parallel document corpora. Notice that the English and Chinese vocabulary sizes do not need to be similar. In our setup, the Chinese vocabulary comes from the ASR system while the English vocabulary comes from the English part of the parallel corpora. Since the topic transfer can be bi-directional, we can perform the bLSA training in a reverse manner, i.e. training an English LSA model followed by bootstrapping a Chinese LSA model.

2.3 Crosslingual LM adaptation

Given a source text, we apply the E-step to estimate variational Dirichlet posterior of each node in the Dirichlet-Tree. We estimate the topic weights on the source language using the following equation:

$$\hat{\theta}_k^{(CH)} \propto \prod_{jc} \left(\frac{\gamma_{jc}}{\sum_{c'} \gamma_{jc'}} \right)^{\delta_{jc}(k)} \quad (5)$$

Then we apply the topic weights into the target LSA model to obtain an in-domain LSA marginals:

$$Pr_{EN}(w) = \sum_{k=1}^{K} \beta_{wk}^{(EN)} \cdot \hat{\theta}_k^{(CH)} \quad (6)$$

We integrate the LSA marginal into the target background LM using marginal adaptation (Kneser et al., 1997) which minimizes the Kullback-Leibler divergence between the adapted LM and the background LM:

$$Pr_a(w|h) \propto \left(\frac{Pr_{ldta}(w)}{Pr_{bg}(w)} \right)^{\beta} \cdot Pr_{bg}(w|h) \quad (7)$$

Likewise, LM adaptation can take place on the source language as well due to the bi-directional nature of the bLSA framework when target-side adaptation text is available. In this paper, we focus on LM adaptation on the target language for SMT.

3 Experimental Setup

We evaluated our bLSA model using the Chinese–English parallel document corpora consisting of the Xinhua news, Hong Kong news and Sina news. The combined corpora contains 67k parallel documents with 35M Chinese (CH) words and 43M English (EN) words. Our spoken language translation system translates from Chinese to English. The Chinese vocabulary comes from the ASR decoder while the English vocabulary is derived from the English portion of the parallel training corpora. The vocabulary sizes for Chinese and English are 108k and 69k respectively. Our background English LM is a 4-gram LM trained with the modified Kneser-Ney smoothing scheme using the SRILM toolkit on the same training text. We explore the bLSA training in both directions: EN→CH and CH→EN meaning that an English LSA model is trained first and a Chinese LSA model is bootstrapped or vice versa. Experiments explore which bootstrapping direction yield best results measured in terms of English word perplexity. The number of latent topics is set to 200 and a balanced binary Dirichlet-Tree prior is used.

With an increasing interest in the ASR-SMT coupling for spoken language translation, we also evaluated our approach with Chinese ASR hypotheses and compared with Chinese manual transcriptions. We are interested to see the impact due to recognition errors on the ASR hypotheses compared to the manual transcriptions. We employed the CMU-InterACT ASR system developed for the GALE 2006 evaluation. We trained acoustic models with over 500 hours of quickly transcribed speech data released by the GALE program and the LM with over 800M-word Chinese corpora. The character error rates on the CCTV, RFA and NTDTV shows in the RT04 test set are 7.4%, 25.5% and 13.1% respectively.

Topic index	Top words
"CH-40"	flying, submarine, aircraft, air, pilot, land, mission, brand-new
"EN-40"	air, sea, submarine, aircraft, flight, flying, ship, test
"CH-41"	satellite, han-tian, launch, space, china, technology, astronomy
"EN-41"	space, satellite, china, technology, satellites, science
"CH-42"	fire, airport, services, marine, accident, air
"EN-42"	fire, airport, services, department, marine, air, service

Table 1: Parallel topics extracted by the bLSA model. Top words on the Chinese side are translated into English for illustration purpose.

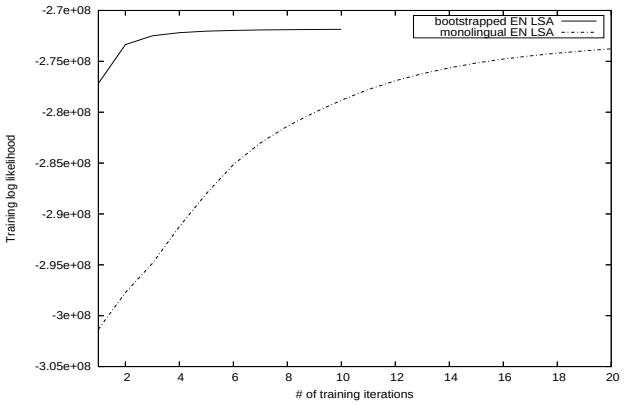

Figure 3: Comparison of training log likelihood of English LSA models bootstrapped from a Chinese LSA and from a flat monolingual English LSA.

3.1 Analysis of the bLSA model

By examining the top-words of the extracted parallel topics, we verify the validity of the heuristic described in Section 2.2 which enforces a one-to-one topic correspondence in the bLSA model. Table 1 shows the latent topics extracted by the CH→EN bLSA model. We can see that the Chinese-English topic words have strong correlations. Many of them are actually translation pairs with similar word rankings. From this viewpoint, we can interpret bLSA as a crosslingual word trigger model. The result indicates that our heuristic is effective to extract parallel latent topics. As a sanity check, we also examine the likelihood of the training data when an English LSA model is bootstrapped. We can see from Figure 3 that the likelihood increases monotonically with the number of training iterations. The figure also shows that by sharing the variational Dirichlet posteriors from the Chinese LSA model, we can bootstrap an English LSA model *rapidly* compared to monolingual English LSA training with both training procedures started from the same flat model.

LM (43M)	CCTV	RFA	NTDTV
BG EN unigram	1065	1220	1549
+CH→EN (CH ref)	755	880	1113
+EN→CH (CH ref)	762	896	1111
+CH→EN (CH hypo)	757	885	1126
+EN→CH (CH hypo)	766	896	1129
+CH→EN (EN ref)	731	838	1075
+EN→CH (EN ref)	747	848	1087

Table 2: English word perplexity (PPL) on the RT04 test set using a unigram LM.

3.2 LM adaptation results

We trained the bLSA models on both CH→EN and EN→CH directions and compared their LM adaptation performance using the Chinese ASR hypotheses (hypo) and the manual transcriptions (ref) as input. We adapted the English background LM using the LSA marginals described in Section 2.3 for each show on the test set.

We first evaluated the English word perplexity using the EN unigram LM generated by the bLSA model. Table 2 shows that the bLSA-based LM adaptation reduces the word perplexity by over 27% relative compared to an unadapted EN unigram LM. The results indicate that the bLSA model successfully leverages the text from the source language and improves the word perplexity on the target language. We observe that there is almost no performance difference when either the ASR hypotheses or the manual transcriptions are used for adaptation. The result is encouraging since the bLSA model may be insensitive to moderate recognition errors through the projection of the input adaptation text into the latent topic space. We also apply an English translation reference for adaptation to show an oracle performance. The results using the Chinese hypotheses are not too far off from the oracle performance. Another observation is that the CH→EN bLSA model seems to give better performance than the EN→CH bLSA model. However, their differences are not significant. The result may imply that the direction of the bLSA training is not important since the latent topic space captured by either language is similar when parallel training corpora are used. Table 3 shows the word perplexity when the background 4-gram English LM is adapted with the tuning parameter β set

LM (43M, $\beta = 0.7$)	CCTV	RFA	NTDTV
BG EN 4-gram	118	212	203
+CH→EN (CH ref)	102	191	179
+EN→CH (CH ref)	102	198	179
+CH→EN (CH hypo)	102	193	180
+EN→CH (CH hypo)	103	198	180
+CH→EN (EN ref)	100	186	176
+EN→CH (EN ref)	101	190	176

Table 3: English word perplexity (PPL) on the RT04 test set using a 4-gram LM.

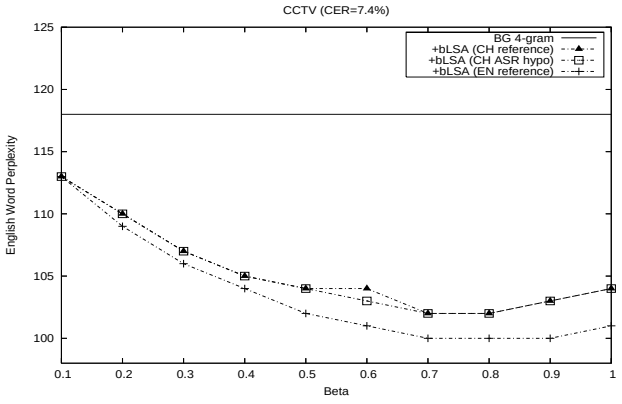

Figure 4: Word perplexity with different β using manual reference or ASR hypotheses on CCTV.

to 0.7. Figure 4 shows the change of perplexity with different β. We see that the adaptation performance using the ASR hypotheses or the manual transcriptions are almost identical on different β with an optimal value at around 0.7. The results show that the proposed approach successfully reduces the perplexity in the range of 9–13.6% relative compared to an unadapted baseline on different shows when ASR hypotheses are used. Moreover, we observe similar performance using ASR hypotheses or manual Chinese transcriptions which is consistent with the results on Table 2. On the other hand, it is interesting to see that the performance gap from the oracle adaptation is somewhat related to the degree of mismatch between the test show and the training condition. The gap looks wider on the RFA and NTDTV shows compared to the CCTV show.

3.3 Incorporating bLSA into Spoken Language Translation

To investigate the effectiveness of bLSA LM adaptation for spoken language translation, we incorporated the proposed approach into our state-of-the-art phrase-based SMT system. Translation performance was evaluated on the RT04 broadcast news evaluation set when applied to both the manual transcriptions and 1-best ASR hypotheses. During evaluation two performance metrics, BLEU (Papineni et al., 2002) and NIST, were computed. In both cases, a single English reference was used during scoring. In the transcription case the original English references were used. For the ASR case, as utterance segmentation was performed automatically, the number of sentences generated by ASR and SMT differed from the number of English references. In this case, Levenshtein alignment was used to align the translation output to the English references before scoring.

3.4 Baseline SMT Setup

The baseline SMT system consisted of a non adaptive system trained using the same Chinese-English parallel document corpora used in the previous experiments (Sections 3.1 and 3.2). For phrase extraction a cleaned subset of these corpora, consisting of 1M Chinese-English sentence pairs, was used. SMT decoding parameters were optimized using manual transcriptions and translations of 272 utterances from the RT04 development set (LDC2006E10).

SMT translation was performed in two stages using an approach similar to that in (Vogel, 2003). First, a translation lattice was constructed by matching all possible bilingual phrase-pairs, extracted from the training corpora, to the input sentence. Phrase extraction was performed using the "*PESA*" (Phrase Pair Extraction as Sentence Splitting) approach described in (Vogel, 2005). Next, a search was performed to find the best path through the lattice, i.e. that with maximum *translation-score*. During search reordering was allowed on the target language side. The final translation result was that hypothesis with maximum *translation-score*, which is a log-linear combination of 10 scores consisting of Target LM probability, Distortion Penalty, Word-Count Penalty, Phrase-Count and six Phrase-Alignment scores. Weights for each component score were optimized to maximize BLEU-score on the development set using MER optimization as described in (Venugopal et al., 2005).

SMT Target LM	Translation Quality - BLEU (NIST) CCTV	RFA	NTDTV	ALL
	Manual Transcription			
Baseline LM:	0.162 (5.212)	0.087 (3.854)	0.140 (4.859)	0.132 (5.146)
bLSA (bLSA-Adapted LM):	0.164 (5.212)	0.087 (3.897)	0.143 (4.864)	0.134 (5.162)
	1-best ASR Output			
CER (%)	7.4	25.5	13.1	14.9
Baseline LM:	0.129 (4.15)	0.051 (2.77)	0.086 (3.50)	0.095 (3.90)
bLSA (bLSA-Adapted LM):	0.132 (4.16)	0.050 (2.79)	0.089 (3.53)	0.096 (3.91)

Table 4: Translation performance of baseline and bLSA-Adapted Chinese-English SMT systems on manual transcriptions and 1-best ASR hypotheses

3.5 Performance of Baseline SMT System

First, the baseline system performance was evaluated by applying the system described above to the reference transcriptions and 1-best ASR hypotheses generated by our Mandarin speech recognition system. The translation accuracy in terms of BLEU and NIST for each individual show ("*CCTV*", "*RFA*", and "*NTDTV*"), and for the complete test-set, are shown in Table 4 (**Baseline LM**). When applied to the reference transcriptions an overall BLEU score of 0.132 was obtained. BLEU-scores ranged between 0.087 and 0.162 for the "*RFA*", "*NTDTV*" and "*CCTV*" shows, respectively. As the "*RFA*" show contained a large segment of conversational speech, translation quality was considerably lower for this show due to genre mismatch with the training corpora of newspaper text.

For the 1-best ASR hypotheses, an overall BLEU score of 0.095 was achieved. For the ASR case, the relative reduction in BLEU scores for the RFA and NTDTV shows is large, due to the significantly lower recognition accuracies for these shows. BLEU score is also degraded due to poor alignment of references during scoring.

3.6 Incorporation of bLSA Adaptation

Next, the effectiveness of bLSA based LM adaptation was evaluated. For each show the target English LM was adapted using bLSA-adaptation, as described in Section 2.3. SMT was then applied using an identical setup to that used in the baseline experiments.

The translation accuracy when bLSA adaptation was incorporated is shown in Table 4. When applied to the manual transcriptions, bLSA adaptation improved the overall BLEU-score by 1.7% relative (from 0.132 to 0.134). For all three shows bLSA adaptation gained higher BLEU and NIST metrics. A similar trend was also observed when the proposed approach was applied to the 1-best ASR output. On the evaluation set a relative improvement in BLEU score of 1.0% was gained.

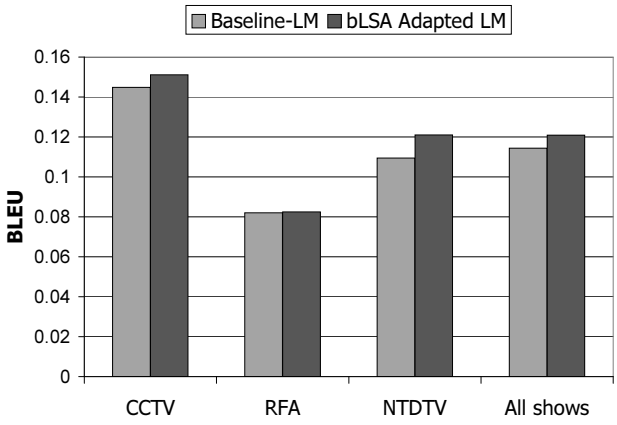

Figure 5: BLEU score for those 25% utterances which resulted in different translations after bLSA adaptation (manual transcriptions)

The semantic interpretation of the majority of utterances in broadcast news are not affected by topic context. In the experimental evaluation it was observed that only 25% of utterances produced different translation output when bLSA adaptation was performed compared to the topic-independent baseline. Although the improvement in translation quality (BLEU) was small when evaluated over the entire test set, the improvement in BLEU score for

these 25% utterances was significant. The translation quality for the baseline and bLSA-adaptive system when evaluated only on these utterances is shown in Figure 5 for the manual transcription case. On this subset of utterances an overall improvement in BLEU of 0.007 (5.7% relative) was gained, with a gain of 0.012 (10.6% relative) points for the "*NTDTV*" show. A similar trend was observed when applied to the 1-best ASR output. In this case a relative improvement in BLEU of 12.6% was gained for "*NTDTV*", and for "All shows" 0.007 (3.7%) was gained. Current evaluation metrics for translation, such as "BLEU", do not consider the relative importance of specific words or phrases during translation and thus are unable to highlight the true effectiveness of the proposed approach. In future work, we intend to investigate other evaluation metrics which consider the relative informational content of words.

4 Conclusions

We proposed a bilingual latent semantic model for crosslingual LM adaptation in spoken language translation. The bLSA model consists of a set of monolingual LSA models in which a one-to-one topic correspondence is enforced between the LSA models through the sharing of variational Dirichlet posteriors. Bootstrapping a LSA model for a new language can be performed rapidly with topic transfer from a well-trained LSA model of another language. We transfer the inferred topic distribution from the input source text to the target language effectively to obtain an in-domain target LSA marginals for LM adaptation. Results showed that our approach significantly reduces the word perplexity on the target language in both cases using ASR hypotheses and manual transcripts. Interestingly, the adaptation performance is not much affected when ASR hypotheses were used. We evaluated the adapted LM on SMT and found that the evaluation metrics are crucial to reflect the actual improvement in performance. Future directions include the exploration of story-dependent LM adaptation with automatic story segmentation instead of show-dependent adaptation due to the possibility of multiple stories within a show. We will investigate the incorporation of monolingual documents for potentially better bilingual LSA modeling.

Coreference Resolution Using Semantic Relatedness Information from Automatically Discovered Patterns

Xiaofeng Yang **Jian Su**

Abstract

Semantic relatedness is a very important factor for the coreference resolution task. To obtain this semantic information, corpus-based approaches commonly leverage patterns that can express a specific semantic relation. The patterns, however, are designed manually and thus are not necessarily the most effective ones in terms of accuracy and breadth. To deal with this problem, in this paper we propose an approach that can automatically find the effective patterns for coreference resolution. We explore how to automatically discover and evaluate patterns, and how to exploit the patterns to obtain the semantic relatedness information. The evaluation on ACE data set shows that the pattern based semantic information is helpful for coreference resolution.

1 Introduction

Semantic relatedness is a very important factor for coreference resolution, as noun phrases used to refer to the same entity should have a certain semantic relation. To obtain this semantic information, previous work on reference resolution usually leverages a semantic lexicon like WordNet (Vieira and Poesio, 2000; Harabagiu et al., 2001; Soon et al., 2001; Ng and Cardie, 2002). However, the drawback of WordNet is that many expressions (especially for proper names), word senses and semantic relations are not available from the database (Vieira and Poesio, 2000). In recent years, increasing interest has been seen in mining semantic relations from large text corpora. One common solution is to utilize a pattern that can represent a specific semantic relation (e.g., "*X such as Y*" for *is-a* relation, and "*X and other Y*" for *other*-relation). Instantiated with two given noun phrases, the pattern is searched in a large corpus and the occurrence number is used as a measure of their semantic relatedness (Markert et al., 2003; Modjeska et al., 2003; Poesio et al., 2004).

However, in the previous pattern based approaches, the selection of the patterns to represent a specific semantic relation is done in an ad hoc way, usually by linguistic intuition. The manually selected patterns, nevertheless, are not necessarily the most effective ones for coreference resolution from the following two concerns:

- *Accuracy*. Can the patterns (e.g., "*X such as Y*") find as many NP pairs of the specific semantic relation (e.g. *is-a*) as possible, with a high precision?
- *Breadth*. Can the patterns cover a wide variety of semantic relations, not just *is-a*, by which coreference relationship is realized? For example, in some annotation schemes like ACE, "Beijing:China" are coreferential as the capital and the country could be used to represent the government. The pattern for the common "is-a" relation will fail to identify the NP pairs of such a "capital-country" relation.

To deal with this problem, in this paper we propose an approach which can automatically discover effective patterns to represent the semantic relations

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 528–535,
Prague, Czech Republic, June 2007.

for coreference resolution. We explore two issues in our study:

(1) *How to automatically acquire and evaluate the patterns?* We utilize a set of coreferential NP pairs as seeds. For each seed pair, we search a large corpus for the texts where the two noun phrases co-occur, and collect the surrounding words as the surface patterns. We evaluate a pattern based on its commonality or association with the positive seed pairs.

(2) *How to mine the patterns to obtain the semantic relatedness information for coreference resolution?* We present two strategies to exploit the patterns: choosing the top best patterns as a set of pattern features, or computing the reliability of semantic relatedness as a single feature. In either strategy, the obtained features are applied to do coreference resolution in a supervised-learning way.

To our knowledge, our work is the first effort that systematically explores these issues in the coreference resolution task. We evaluate our approach on ACE data set. The experimental results show that the pattern based semantic relatedness information is helpful for the coreference resolution.

The remainder of the paper is organized as follows. Section 2 gives some related work. Section 3 introduces the framework for coreference resolution. Section 4 presents the model to obtain the pattern-based semantic relatedness information. Section 5 discusses the experimental results. Finally, Section 6 summarizes the conclusions.

2 Related Work

Earlier work on coreference resolution commonly relies on semantic lexicons for semantic relatedness knowledge. In the system by Vieira and Poesio (2000), for example, WordNet is consulted to obtain the synonymy, hypernymy and meronymy relations for resolving the definite anaphora. In (Harabagiu et al., 2001), the path patterns in WordNet are utilized to compute the semantic consistency between NPs. Recently, Ponzetto and Strube (2006) suggest to mine semantic relatedness from Wikipedia, which can deal with the data sparseness problem suffered by using WordNet.

Instead of leveraging existing lexicons, many researchers have investigated corpus-based approaches to mine semantic relations. Garera and Yarowsky (2006) propose an unsupervised model which extracts hypernym relation for resloving definite NPs. Their model assumes that a definite NP and its hypernym words usually co-occur in texts. Thus, for a definite-NP anaphor, a preceding NP that has a high co-occurrence statistics in a large corpus is preferred for the antecedent.

Bean and Riloff (2004) present a system called BABAR that uses contextual role knowledge to do coreference resolution. They apply an IE component to unannotated texts to generate a set of extraction caseframes. Each caseframe represents a linguistic expression and a syntactic position, e.g. "murder of <NP>", "killed <patient>". From the caseframes, they derive different types of contextual role knowledge for resolution, for example, whether an anaphor and an antecedent candidate can be filled into co-occurring caseframes, or whether they are substitutable for each other in their caseframes. Different from their system, our approach aims to find surface patterns that can directly indicate the coreference relation between two NPs.

Hearst (1998) presents a method to automate the discovery of WordNet relations, by searching for the corresponding patterns in large text corpora. She explores several patterns for the hyponymy relation, including "*X such as Y*" "*X and/or other Y*", "*X including / especially Y*" and so on. The use of Hearst's style patterns can be seen for the reference resolution task. Modjeska et al. (2003) explore the use of the Web to do the *other*-anaphora resolution. In their approach, a pattern "*X and other Y*" is used. Given an anaphor and a candidate antecedent, the pattern is instantiated with the two NPs and forms a query. The query is submitted to the Google searching engine, and the returned hit number is utilized to compute the semantic relatedness between the two NPs. In their work, the semantic information is used as a feature for the learner. Markert et al. (2003) and Poesio et al. (2004) adopt a similar strategy for the *bridging* anaphora resolution.

In (Hearst, 1998), the author also proposes to discover new patterns instead of using the manually designed ones. She employs a bootstrapping algorithm to learn new patterns from the word pairs with a known relation. Based on Hearst's work, Pantel and Pennacchiotti (2006) further give a method

which measures the reliability of the patterns based on the strength of association between patterns and instances, employing the pointwise mutual information (PMI).

3 Framework of Coreference Resolution

Our coreference resolution system adopts the common learning-based framework as employed by Soon et al. (2001) and Ng and Cardie (2002).

In the learning framework, a training or testing instance has the form of $\boldsymbol{i}\{NP_i, NP_j\}$, in which NP_j is a possible anaphor and NP_i is one of its antecedent candidates. An instance is associated with a vector of features, which is used to describe the properties of the two noun phrases as well as their relationships. In our baseline system, we adopt the common features for coreference resolution such as lexical property, distance, string-matching, name-alias, apposition, grammatical role, number/gender agreement and so on. The same feature set is described in (Ng and Cardie, 2002) for reference.

During training, for each encountered anaphor NP_j, one single positive training instance is created for its closest antecedent. And a group of negative training instances is created for every intervening noun phrases between NP_j and the antecedent.

Based on the training instances, a binary classifier can be generated using any discriminative learning algorithm, like C5 in our study. For resolution, an input document is processed from the first NP to the last. For each encountered NP_j, a test instance is formed for each antecedent candidate, NP_i[1]. This instance is presented to the classifier to determine the coreference relationship. NP_j will be resolved to the candidate that is classified as positive (if any) and has the highest confidence value.

In our study, we augment the common framework by incorporating non-anaphors into training. We focus on the non-anaphors that the original classifier fails to identify. Specifically, we apply the learned classifier to all the non-anaphors in the training documents. For each non-anaphor that is classified as positive, a negative instance is created by pairing the non-anaphor and its false antecedent. These negative instances are added into the original training instance set for learning, which will generate a classifier with the capability of not only antecedent identification, but also non-anaphorically identification. The new classier is applied to the testing document to do coreference resolution as usual.

[1]For resolution of pronouns, only the preceding NPs in current and previous two sentences are considered as antecedent candidates. For resolution of non-pronouns, all the preceding non-pronouns are considered.

4 Patterned Based Semantic Relatedness

4.1 Acquiring the Patterns

To derive patterns to indicate a specific semantic relation, a set of seed NP pairs that have the relation of interest is needed. As described in the previous section, we have a set of training instances formed by NP pairs with known coreference relationships. We can just use this set of NP pairs as the seeds. That is, an instance $\boldsymbol{i}\{NP_i, NP_j\}$ will become a seed pair (E_i:E_j) in which NP_i corresponds to E_i and NP_j corresponds to E_j. In creating the seed, for a common noun, only the head word is retained while for a proper name, the whole string is kept. For example, instance $\boldsymbol{i}$\{"Bill Clinton", "the former president"\} will be converted to a NP pair ("Bill Clinton":"president").

We create the seed pair for every training instance $\boldsymbol{i}\{NP_i, NP_j\}$, except when (1) NP_i or NP_j is a pronoun; or (2) NP_i and NP_j have the same head word. We denote S+ and S- the set of seed pairs derived from the positive and the negative training instances, respectively. Note that a seed pair may possibly belong to S+ can S- at the same time.

For each of the seed NP pairs (E_i:E_j), we search in a large corpus for the strings that match the regular expression "E_i * * * E_j" or "E_j * * * E_i", where * is a wildcard for any word or symbol. The regular expression is defined as such that all the co-occurrences of E_i and E_j with at most three words (or symbols) in between are retrieved.

For each retrieved string, we extract a surface pattern by replacing expression E_i with a mark <#t1#> and E_j with <#t2#>. If the string is followed by a symbol, the symbol will be also included in the pattern. This is to create patterns like "X * * * Y [, . ?]" where *Y*, with a high possibility, is the head word, but not a modifier of another noun phrase.

As an example, consider the pair ("Bill Clinton":"president"). Suppose that two sentences in a corpus can be matched by the regular expressions:

(S1) " ***Bill Clinton*** *is elected* ***President*** *of the United States.*"

(S2) "*The US* ***President****, Mr* ***Bill Clinton****, today advised India to move towards nuclear non-proliferation and begin a dialogue with Pakistan to ...* ".

The patterns to be extracted for (S1) and (S2), respectively, are

P1: <#t1#> ***is elected*** <#t2#>

P2: <#t2#> **, *Mr*** <#t1#> **,**

We record the number of strings matched by a pattern p instantiated with (E_i:E_j), noted $|(E_i, p, E_j)|$, for later use.

For each seed pair, we generate a list of surface patterns in the above way. We collect all the patterns derived from the positive seed pairs as a set of reference patterns, which will be scored and used to evaluate the semantic relatedness for any new NP pair.

4.2 Scoring the Patterns

4.2.1 Frequency

One possible scoring scheme is to evaluate a pattern based on its commonality to positive seed pairs. The intuition here is that the more often a pattern is seen for the positive seed pairs, the more indicative the pattern is to find positive coreferential NP pairs. Based on this idea, we score a pattern by calculating the number of positive seed pairs whose pattern list contains the pattern. Formally, supposing the pattern list associated with a seed pair s is PList(s), the frequency score of a pattern p is defined as

$$Freqency(p) = |\{s|s \in S+, p \in PList(s)\}| \quad (1)$$

4.2.2 Reliability

Another possible way to evaluate a pattern is based on its reliability, i.e., the degree that the pattern is associated with the positive coreferential NPs. In our study, we use pointwise mutual information (Cover and Thomas, 1991) to measure association strength, which has been proved effective in the task of semantic relation identification (Pantel and Pennacchiotti, 2006). Under pointwise mutual information (PMI), the strength of association between two events x and y is defined as follows:

$$pmi(x, y) = \log \frac{P(x, y)}{P(x)P(y)} \quad (2)$$

Thus the association between a pattern p and a positive seed pair s:(E_i:E_j) is:

$$pmi(p, (E_i : E_j)) = \log \frac{\frac{|(E_i,p,E_j)|}{|(*,*,*)|}}{\frac{|(E_i,*,E_j)|}{|(*,*,*)|}\frac{|(*,p,*)|}{|(*,*,*)|}} \quad (3)$$

where $|(E_i$,p,$E_j)|$ is the count of strings matched by pattern p instantiated with E_i and E_j. Asterisk * represents a wildcard, that is:

$$|(E_i, *, E_j)| = \sum_{p \in PList(E_i:E_j)} |(E_i, p, E_j)| \quad (4)$$

$$|(*, p, *)| = \sum_{(E_i:E_j) \in S+ \cup S-} |(E_i, p, E_j)| \quad (5)$$

$$|(*, *, *)| = \sum_{(E_i:E_j) \in S+ \cup S-; p \in Plist(E_i:E_j)} |(E_i, p, E_j)| \quad (6)$$

The reliability of pattern is the average strength of association across each positive seed pair:

$$r(p) = \frac{\sum_{s \in S+} \frac{pmi(p,s)}{max\_pmi}}{|S+|} \quad (7)$$

Here *max_pmi* is used for the normalization purpose, which is the maximum PMI between all patterns and all positive seed pairs.

4.3 Exploiting the Patterns

4.3.1 Patterns Features

One strategy is to directly use the reference patterns as a set of features for classifier learning and testing. To select the most effective patterns for the learner, we rank the patterns according to their scores and then choose the top patterns (first 100 in our study) as the features.

As mentioned, the frequency score is based on the commonality of a pattern to the positive seed pairs. However, if a pattern also occurs frequently for the negative seed pairs, it should be not deemed a good feature as it may lead to many false positive pairs during real resolution. To take this factor into account, we filter the patterns based on their accuracy, which is defined as follows:

$$Accuracy(p) = \frac{|\{s|s \in S+, p \in PList(s)\}|}{|\{s|s \in S+ \cup S-, p \in PList(s)\}|} \quad (8)$$

A pattern with an accuracy below threshold 0.5 is eliminated from the reference pattern set. The remaining patterns are sorted as normal, from which the top 100 patterns are selected as features.

		NWire			NPaper			BNews

Table 1: The results of different systems for coreference resolution

Each selected pattern p is used as a single feature, PF_p. For an instance $\boldsymbol{i}\{\text{NP}_i, \text{NP}_j\}$, a list of patterns is generated for (E_i:E_j) in the same way as described in Section 4.1. The value of PF_p for the instance is simply $|(\text{E}_i, \text{p}, \text{E}_j)|$.

The set of pattern features is used together with the other normal features to do the learning and testing. Thus, the actual importance of a pattern in coreference resolution is automatically determined in a supervised learning way.

4.3.2 Semantic Relatedness Feature

Another strategy is to use only one semantic feature which is able to reflect the reliability that a NP pair is related in semantics. Intuitively, a NP pair with strong semantic relatedness should be highly associated with as many reliable patterns as possible. Based on this idea, we define the semantic relatedness feature (SRel) as follows:

$$SRel(\boldsymbol{i}\{NP_i, NP_j\}) = 1000 * \sum_{p \in PList(E_i:E_j)} pmi(p, (E_i : E_j)) * r(p) \quad (9)$$

where pmi(p, (E_i:E_j)) is the pointwise mutual information between pattern p and a NP pair (E_i:E_j), as defined in Eq. 3. $r(p)$ is the reliability score of p (Eq. 7). As a relatedness value is always below 1, we multiple it by 1000 so that the feature value will be of integer type with a range from 0 to 1000. Note that among PList(E_i:E_j), only the reference patterns are involved in the feature computing.

5 Experiments and Discussion

5.1 Experimental setup

In our study we did evaluation on the ACE-2 V1.0 corpus (NIST, 2003), which contains two data set, training and devtest, used for training and testing respectively. Each of these sets is further divided by three domains: newswire (NWire), newspaper (NPaper), and broadcast news (BNews).

An input raw text was preprocessed automatically by a pipeline of NLP components, including sentence boundary detection, POS-tagging, Text Chunking and Named-Entity Recognition. Two different classifiers were learned respectively for resolving pronouns and non-pronouns. As mentioned, the pattern based semantic information was only applied to the non-pronoun resolution. For evaluation, Vilain et al. (1995)'s scoring algorithm was adopted to compute the recall and precision of the whole coreference resolution.

For pattern extraction and feature computing, we used Wikipedia, a web-based free-content encyclopedia, as the text corpus. We collected the English Wikipedia database dump in November 2006 (refer to http://download.wikimedia.org/). After all the hyperlinks and other html tags were removed, the whole pure text contains about 220 Million words.

5.2 Results and Discussion

Table 1 lists the performance of different coreference resolution systems. The first line of the table shows the baseline system that uses only the common features proposed in (Ng and Cardie, 2002). From the table, our baseline system can

NO	Frequency	Frequency (Filtered)	PMI_Reliabilty

Table 2: Top patterns chosen under different scoring schemes

achieve a good precision (above 75%-80%) with a recall around 50%-60%. The overall F-measure for NWire, NPaper and BNews is 64.9%, 64.9% and 62.0% respectively. The results are comparable to those reported in (Ng, 2005) which uses similar features and gets an F-measure of about 62% for the same data set.

The rest lines of Table 1 are for the systems using the pattern based information. In all the systems, we examine the utility of the semantic information in resolving different types of NP Pairs: (1) NP Pairs containing proper names (i.e., Name:Name or Name:Definites), and (2) NP Pairs of all types.

In Table 1 (Line 2-5), we also list the results of incorporating two commonly used patterns, "X(s) such as Y" and "X and other Y(s)". We can find that neither of the manually designed patterns has significant impact on the resolution performance. For all the domains, the manual patterns just achieve slight improvement in recall (below 0.6%), indicating that coverage of the patterns is not broad enough.

5.2.1 Pattern Features

In Section 4.3.1 we propose a strategy that directly uses the patterns as features. Table 2 lists the top patterns that are sorted based on *frequency*, *filtered frequency (by accuracy)*, and *PMI_reliability*, on the NWire domain for illustration.

From the table, evaluated only based on *frequency*, the top patterns are those that indicate the appositive structure like "*X*, *an/a/the Y*". However, if filtered by *accuracy*, patterns of such a kind will be removed. Instead, the top patterns with both high frequency and high accuracy are those for the copula structure, like "*X is/was/are Y*". Sorted by PMI reliability, patterns for the above two structures can be seen in the top of the list. These results are consistent with the findings in (Cimiano and Staab, 2004) that the appositive and copula structures are indicative to find the *is-a* relation. Also, the two commonly used patterns "X(s) such as Y" and "X and other Y(s)" were found in the feature lists (not shown in the table). Their importance for coreference resolution will be determined automatically by the learning algorithm.

An interesting pattern seen in the lists is "$X \mid\mid Y \mid$", which represents the cases when Y and X appear in the same of line of a table in Wikipedia. For example, the following text
"*American* || *United States* | *Washington D.C.* | ..."
is found in the table "list of empires". Thus the pair "American:United States", which is deemed coreferential in ACE, can be identified by the pattern.

The sixth till the eleventh lines of Table 1 list the results of the system with pattern features. From the table, adding the pattern features brings the improvement of the recall against the baseline. Take the system based on *filtered frequency* as an example. We can observe that the recall increases by up to 3.3% (for NWire). However, we see the precision drops (up to 1.2% for NWire) at the same time. Overall the system achieves an F-measure better than the baseline in NWire (1.9%), while equal ($\pm$0.2%) in NPaper and BNews.

Among the three ranking schemes, simply using *frequency* leads to the lowest precision. By contrast, using *filtered frequency* yields the highest precision with nevertheless the lowest recall. It is reasonable since the low_accuracy features prone to false posi-

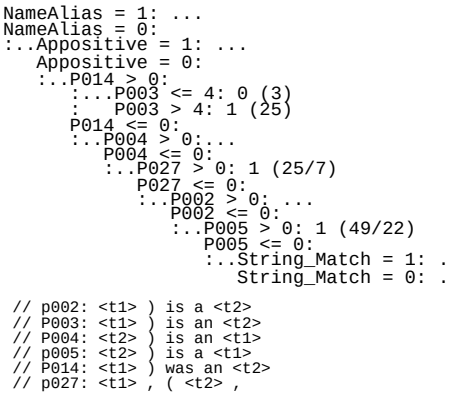

Figure 1: The decision tree (NWire domain) for the system using pattern features (filtered frequency)
(feature *String_Match* records whether the string of anaphor NP_j matches that of a candidate antecedent NP_i)

tive NP pairs are eliminated, at the price of recall. Using *PMI_Reliability* can achieve the highest recall with a medium level of precision. However, we do not find significant difference in the overall F-measure for all these three schemes. This should be due to the fact that the pattern features need to be further chosen by the learning algorithm, and only those patterns deemed effective by the learner will really matter in the real resolution.

From the table, the pattern features only work well for NP pairs containing proper names. Applied on all types of NP pairs, the pattern features further boost the recall of the systems, but in the meanwhile degrade the precision significantly. The F-measure of the systems is even worse than that of the baseline. Our error analysis shows that a non-anaphor is often wrongly resolved to a false antecedent once the two NPs happen to satisfy a pattern feature, which affects precision largely (as an evidence, the decrease of precision is less significant when using *filtered_frequency* than using *frequency*). Still, these results suggest that we just apply the pattern based semantic information in resolving proper names which, in fact, is more compelling as the semantic information of common nouns could be more easily retrieved from WordNet.

We also notice that the patterned based semantic information seems more effective in the NWire domain than the other two. Especially for NPaper, the improvement in F-measure is less than 0.1% for all the systems tested. The error analysis indicates it may be because (1) there are less NP pairs in NPaper than in NWire that require the external semantic knowledge for resolution; and (2) For many NP pairs that require the semantic knowledge, no co-occurrence can be found in the Wikipedia corpus. To address this problem, we could resort to the Web which contains a larger volume of texts and thus could lead to more informative patterns. We would like to explore this issue in our future work.

In Figure 1, we plot the decision tree learned with the pattern features for non-pronoun resolution (NWire domain, *filtered_frequency*), which visually illustrates which features are useful in the reference determination. We can find the pattern features occur in the top of the decision tree, among the features for *name_alias*, *apposition* and *string-matching* that are crucial for coreference resolution as reported in previous work (Soon et al., 2001). Most of the pattern features deemed important by the learner are for the copula structure.

5.2.2 Single Semantic Relatedness Feature

Section 4.3.2 presents another strategy to exploit the patterns, which uses a single feature to reflect the semantic relatedness between NP pairs. The last two lines of Table 1 list the results of such a system.

Observed from the table, the system with the single semantic relatedness feature beats those with other solutions. Compared with the baseline, the system can get improvement in recall (up to 2.9% as in NWire), with a similar or even higher precision. The overall F-measure it produces is 67.1%, 65.0% and 62.7%, better than the baseline in all the domains. Especially in the NWire domain, we can see the significant (t-test, $p \leq 0.05$) improvement of 2.1% in F-measure. When applied on All-Type NP pairs, the degrade of performance is less significant as using pattern features. The resulting performance is better than the baseline or equal. Compared with the systems using the pattern features, it can still achieve a higher precision and F-measure (with a little loss in recall) .

There are several reasons why the single semantic relatedness feature (*SRel*) can perform better than the set of pattern features. Firstly, the feature value of *SRel* takes into consideration the information of all the patterns, instead of only the selected patterns. Secondly, since the *SRel* feature is computed based on all the patterns, it reduces the risk of false posi-

          String_Match = 0: ...
```

Figure 2: The decision tree (Nwire) for the system using the single semantic relatedness feature

tive when a NP pair happens to satisfy one or several pattern features. Lastly, from the point of view of machine learning, using only one semantic feature, instead of hundreds of pattern features, can avoid overfitting and thus benefit the classifier learning.

In Figure 2, we also show the decision tree learned with the semantic relatedness feature. We observe that the decision tree is simpler than that with pattern features as depicted in Figure 1. After feature *name-alias* and *apposite*, the classifier checks different ranges of the *SRel* value and make different resolution decision accordingly. This figure further illustrates the importance of the semantic feature.

6 Conclusions

In this paper we present a pattern based approach to coreference resolution. Different from the previous work which utilizes manually designed patterns, our approach can automatically discover the patterns effective for the coreference resolution task. In our study, we explore how to acquire and evaluate patterns, and investigate how to exploit the patterns to mine semantic relatedness information for coreference resolution. The evaluation on ACE data set shows that the patterned based features, when applied on NP pairs containing proper names, can effectively help the performance of coreference resolution in the recall (up to 4.3%) and the overall F-measure (up to 2.1%). The results also indicate that using the single semantic relatedness feature has more advantages than using a set of pattern features.

For future work, we intend to investigate our approach in more difficult tasks like the bridging anaphora resolution, in which the semantic relations involved are more complicated. Also, we would like to explore the approach in technical (e.g., biomedical) domains, where jargons are frequently seen and the need for external knowledge is more compelling.

Abstract

This paper examines whether a learning-based coreference resolver can be improved using semantic class knowledge that is automatically acquired from a version of the Penn Treebank in which the noun phrases are labeled with their semantic classes. Experiments on the ACE test data show that a resolver that employs such induced semantic class knowledge yields a statistically significant improvement of 2% in F-measure over one that exploits heuristically computed semantic class knowledge. In addition, the induced knowledge improves the accuracy of common noun resolution by 2-6%.

1 Introduction

In the past decade, *knowledge-lean* approaches have significantly influenced research in noun phrase (NP) coreference resolution — the problem of determining which NPs refer to the same real-world entity in a document. In knowledge-lean approaches, coreference resolvers employ only morpho-syntactic cues as knowledge sources in the resolution process (e.g., Mitkov (1998), Tetreault (2001)). While these approaches have been reasonably successful (see Mitkov (2002)), Kehler et al. (2004) speculate that deeper linguistic knowledge needs to be made available to resolvers in order to reach the next level of performance. In fact, semantics plays a crucially important role in the resolution of common NPs, allowing us to identify the coreference relation between two lexically dissimilar common nouns (e.g., *talks* and *negotiations*) and to eliminate *George W. Bush* from the list of candidate antecedents of *the city*, for instance. As a result, researchers have re-adopted the once-popular *knowledge-rich* approach, investigating a variety of semantic knowledge sources for common noun resolution, such as the *semantic relations* between two NPs (e.g., Ji et al. (2005)), their *semantic similarity* as computed using WordNet (e.g., Poesio et al. (2004)) or Wikipedia (Ponzetto and Strube, 2006), and the *contextual role* played by an NP (see Bean and Riloff (2004)).

Another type of semantic knowledge that has been employed by coreference resolvers is the *semantic class* (SC) of an NP, which can be used to disallow coreference between semantically incompatible NPs. However, learning-based resolvers have not been able to benefit from having an SC agreement feature, presumably because the method used to compute the SC of an NP is too simplistic: while the SC of a proper name is computed fairly accurately using a named entity (NE) recognizer, many resolvers simply assign to a common noun the first (i.e., most frequent) WordNet sense as its SC (e.g., Soon et al. (2001), Markert and Nissim (2005)). It is not easy to measure the accuracy of this heuristic, but the fact that the SC agreement feature is not used by Soon et al.'s decision tree coreference classifier seems to suggest that the SC values of the NPs are not computed accurately by this first-sense heuristic.

Motivated in part by this observation, we examine whether automatically induced semantic class knowledge can improve the performance of a learning-based coreference resolver, reporting evaluation results on the commonly-used ACE corefer-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 536–543,
Prague, Czech Republic, June 2007.

ence corpus. Our investigation proceeds as follows.

Train a classifier for labeling the SC of an NP. In ACE, we are primarily concerned with classifying an NP as belonging to one of the ACE semantic classes. For instance, part of the ACE Phase 2 evaluation involves classifying an NP as PERSON, ORGANIZATION, GPE (a geographical-political region), FACILITY, LOCATION, or OTHERS. We adopt a corpus-based approach to SC determination, recasting the problem as a six-class classification task.

Derive two knowledge sources for coreference resolution from the induced SCs. The first knowledge source (KS) is *semantic class agreement* (SCA). Following Soon et al. (2001), we represent SCA as a binary value that indicates whether the induced SCs of the two NPs involved are the same or not. The second KS is *mention*, which is represented as a binary value that indicates whether an NP belongs to one of the five ACE SCs mentioned above. Hence, the *mention* value of an NP can be readily derived from its induced SC: the value is NO if its SC is OTHERS, and YES otherwise. This KS could be useful for ACE coreference, since ACE is concerned with resolving only NPs that are mentions.

Incorporate the two knowledge sources in a coreference resolver. Next, we investigate whether these two KSs can improve a learning-based baseline resolver that employs a fairly standard feature set. Since (1) the two KSs can each be represented in the resolver as a *constraint* (for filtering non-mentions or disallowing coreference between semantically incompatible NPs) or as a *feature*, and (2) they can be applied to the resolver in *isolation* or in *combination*, we have eight ways of incorporating these KSs into the baseline resolver.

In our experiments on the ACE Phase 2 coreference corpus, we found that (1) our SC induction method yields a significant improvement of 2% in accuracy over Soon et al.'s first-sense heuristic method as described above; (2) the coreference resolver that incorporates our induced SC knowledge by means of the two KSs mentioned above yields a significant improvement of 2% in F-measure over the resolver that exploits the SC knowledge computed by Soon et al.'s method; (3) the *mention* KS, when used in the baseline resolver as a *constraint*, improves the resolver by approximately 5-7% in F-measure; and (4) *SCA*, when employed as a *feature* by the baseline resolver, improves the accuracy of common noun resolution by about 5-8%.

2 Related Work

Mention detection. Many ACE participants have also adopted a corpus-based approach to SC determination that is investigated as part of the *mention detection* (MD) task (e.g., Florian et al. (2006)). Briefly, the goal of MD is to identify the boundary of a mention, its mention type (e.g., pronoun, name), and its semantic type (e.g., person, location). Unlike them, (1) we do not perform the full MD task, as our goal is to investigate the role of SC knowledge in coreference resolution; and (2) we do not use the ACE training data for acquiring our SC classifier; instead, we use the *BBN Entity Type Corpus* (Weischedel and Brunstein, 2005), which consists of all the Penn Treebank Wall Street Journal articles with the ACE mentions manually identified and annotated with their SCs. This provides us with a training set that is approximately five times bigger than that of ACE. More importantly, the ACE participants do not evaluate the role of *induced* SC knowledge in coreference resolution: many of them evaluate coreference performance on perfect mentions (e.g., Luo et al. (2004)); and for those that do report performance on automatically extracted mentions, they do not explain whether or how the induced SC information is used in their coreference algorithms.

Joint probabilistic models of coreference. Recently, there has been a surge of interest in improving coreference resolution by jointly modeling coreference with a related task such as MD (e.g., Daumé and Marcu (2005)). However, joint models typically need to be trained on data that is *simultaneously* annotated with information required by all of the underlying models. For instance, Daumé and Marcu's model assumes as input a corpus annotated with both MD and coreference information. On the other hand, we tackle coreference and SC induction separately (rather than jointly), since we train our SC determination model on the BBN Entity Type Corpus, where coreference information is absent.

3 Semantic Class Induction

This section describes how we train and evaluate a classifier for determining the SC of an NP.

3.1 Training the Classifier

Training corpus. As mentioned before, we use the BBN Entity Type Corpus for training the SC classifier. This corpus was originally developed to support the ACE and AQUAINT programs and consists of annotations of 12 named entity types and nine nominal entity types. Nevertheless, we will only make use of the annotations of the five ACE semantic types that are present in our ACE Phase 2 coreference corpus, namely, PERSON, ORGANIZATION, GPE, FACILITY, and LOCATION.

Training instance creation. We create one training instance for each proper or common NP (extracted using an NP chunker and an NE recognizer) in each training text. Each instance is represented by a set of lexical, syntactic, and semantic features, as described below. If the NP under consideration is annotated as one of the five ACE SCs in the corpus, then the classification of the associated training instance is simply the ACE SC value of the NP. Otherwise, the instance is labeled as OTHERS. This results in 310063 instances in the training set.

Features. We represent the training instance for a noun phrase, NP_i, using seven types of features:

(1) WORD: For each word w in NP_i, we create a WORD feature whose value is equal to w. No features are created from stopwords, however.

(2) SUBJ_VERB: If NP_i is involved in a subject-verb relation, we create a SUBJ_VERB feature whose value is the verb participating in the relation. We use Lin's (1998b) MINIPAR dependency parser to extract grammatical relations. Our motivation here is to coarsely model subcategorization.

(3) VERB_OBJ: A VERB_OBJ feature is created in a similar fashion as SUBJ_VERB if NP_i participates in a verb-object relation. Again, this represents our attempt to coarsely model subcategorization.

(4) NE: We use BBN's IdentiFinder (Bikel et al., 1999), a MUC-style NE recognizer to determine the NE type of NP_i. If NP_i is determined to be a PERSON or ORGANIZATION, we create an NE feature whose value is simply its MUC NE type. However, if NP_i is determined to be a LOCATION, we create a feature with value GPE (because most of the MUC LOCATION NEs are ACE GPE NEs). Otherwise, no NE feature will be created (because we are not interested in the other MUC NE types).

ACE SC	Keywords
PERSON	person
ORGANIZATION	social group
FACILITY	establishment, construction, building, facility, workplace
GPE	country, province, government, town, city, administration, society, island, community
LOCATION	dry land, region, landmass, body of water, geographical area, geological formation

Table 1: List of keywords used in WordNet search for generating WN_CLASS features.

(5) WN_CLASS: For each keyword w shown in the right column of Table 1, we determine whether the head noun of NP_i is a hyponym of w in WordNet, using only the first WordNet sense of NP_i.[1] If so, we create a WN_CLASS feature with w as its value. These keywords are potentially useful features because some of them are subclasses of the ACE SCs shown in the left column of Table 1, while others appear to be correlated with these ACE SCs.[2]

(6) INDUCED_CLASS: Since the first-sense heuristic used in the previous feature may not be accurate in capturing the SC of an NP, we employ a corpus-based method for inducing SCs that is motivated by research in lexical semantics (e.g., Hearst (1992)). Given a large, unannotated corpus[3], we use IdentiFinder to label each NE with its NE type and MINIPAR to extract all the appositive relations. An example extraction would be <*Eastern Airlines*, *the carrier*>, where the first entry is a proper noun labeled with either one of the seven MUC-style NE types[4] or OTHERS[5] and the second entry is a common noun. We then infer the SC of a common noun as follows: (1) we compute the probability that the common noun co-occurs with each of the eight NE types[6] based on the extracted appositive relations, and (2) if the most likely NE type has a co-occurrence probability above a certain threshold (we set it to 0.7), we create a INDUCED_CLASS fea-

[1] This is motivated by Lin's (1998c) observation that a coreference resolver that employs only the first WordNet sense performs slightly better than one that employs more than one sense.

[2] The keywords are obtained via our experimentation with WordNet and the ACE SCs of the NPs in the ACE training data.

[3] We used (1) the BLLIP corpus (30M words), which consists of WSJ articles from 1987 to 1989, and (2) the Reuters Corpus (3.7GB data), which has 806,791 Reuters articles.

[4] Person, organization, location, date, time, money, percent.

[5] This indicates the proper noun is not a MUC NE.

[6] For simplicity, OTHERS is viewed as an NE type here.

ture for NP_i whose value is the most likely NE type.
(7) NEIGHBOR: Research in lexical semantics suggests that the SC of an NP can be inferred from its distributionally similar NPs (see Lin (1998a)). Motivated by this observation, we create for each of NP_i's ten most semantically similar NPs a NEIGHBOR feature whose value is the surface string of the NP. To determine the ten nearest neighbors, we use the semantic similarity values provided by Lin's dependency-based thesaurus, which is constructed using a distributional approach combined with an information-theoretic definition of similarity.

Learning algorithms. We experiment with four learners commonly employed in language learning:
Decision List (DL): We use the DL learner as described in Collins and Singer (1999), motivated by its success in the related tasks of word sense disambiguation (Yarowsky, 1995) and NE classification (Collins and Singer, 1999). We apply add-one smoothing to smooth the class posteriors.
1-Nearest Neighbor (1-NN): We use the 1-NN classifier as implemented in TiMBL (Daelemans et al., 2004), employing *dot product* as the similarity function (which defines similarity as the number of common feature-value pairs between two instances). All other parameters are set to their default values.
Maximum Entropy (ME): We employ Lin's ME implementation[7], using a Gaussian prior for smoothing and running the algorithm until convergence.
Naive Bayes (NB): We use an in-house implementation of NB, using add-one smoothing to smooth the class priors and the class-conditional probabilities.

In addition, we train an SVM classifier for SC determination by combining the output of five classification methods: DL, 1-NN, ME, NB, and Soon et al.'s method as described in the introduction,[8] with the goal of examining whether SC classification accuracy can be improved by combining the output of individual classifiers in a supervised manner. Specifically, we (1) use 80% of the instances generated from the BBN Entity Type Corpus to train the four classifiers; (2) apply the four classifiers and Soon et al.'s method to independently make predictions for the remaining 20% of the instances; and (3) train an SVM classifier (using the LIBSVM package (Chang and Lin, 2001)) on these 20% of the instances, where each instance, i, is represented by a set of 31 binary features. More specifically, let $L_i = \{l_{i1}, l_{i2}, l_{i3}, l_{i4}, l_{i5}\}$ be the set of predictions that we obtained for i in step (2). To represent i, we generate one feature from each non-empty subset of L_i.

[7] See http://www.cs.ualberta.ca/∼lindek/downloads.htm

[8] In our implementation of Soon's method, we label an instance as OTHERS if no NE or WN_CLASS feature is generated; otherwise its label is the value of the NE feature or the ACE SC that has the WN_CLASS features as its keywords (see Table 1).

Table 2: Distribution of SCs in the ACE corpus.

3.2 Evaluating the Classifiers

For evaluation, we use the ACE Phase 2 coreference corpus, which comprises 422 training texts and 97 test texts. Each text has its mentions annotated with their ACE SCs. We create our test instances from the ACE texts in the same way as the training instances described in Section 3.1. Table 2 shows the percentages of instances corresponding to each SC.

Table 3 shows the accuracy of each classifier (see row 1) for the ACE training set (54641 NPs, with 16414 proper NPs and 38227 common NPs) and the ACE test set (13444 NPs, with 3713 proper NPs and 9731 common NPs), as well as their performance on the proper NPs (row 2) and the common NPs (row 3). We employ as our baseline system the Soon et al. method (see Footnote 8), whose accuracy is shown under the Soon column. As we can see, DL, 1-NN, and SVM show a statistically significant improvement over the baseline for both data sets, whereas ME and NB perform significantly worse.[9] Additional experiments are needed to determine the reason for ME and NB's poor performance.

In an attempt to gain additional insight into the performance contribution of each type of features, we conduct feature ablation experiments using the DL classifier (DL is chosen simply because it is the best performer on the ACE training set). Results are shown in Table 4, where each row shows the accuracy of the DL trained on all types of features except for the one shown in that row (All), as well as accuracies on the proper NPs (PN) and the common NPs (CN). For easy reference, the accuracy of the DL

[9] We use Noreen's (1989) Approximate Randomization test for significance testing, with p set to .05 unless otherwise stated.

Table 5: Accuracies of single-feature classifiers.

classifier trained on all types of features is shown in row 1 of the table. As we can see, accuracy drops significantly with the removal of NE and NEIGHBOR. As expected, removing NE precipitates a large drop in proper NP accuracy; somewhat surprisingly, removing NEIGHBOR also causes proper NP accuracy to drop significantly. To our knowledge, there are no prior results on using distributionally similar neighbors as features for supervised SC induction.

Note, however, that these results do not imply that the remaining feature types are not useful for SC classification; they simply suggest, for instance, that WORD is not important in the presence of other feature types. To get a better idea of the utility of each feature type, we conduct another experiment in which we train seven classifiers, each of which employs exactly one type of features. The accuracies of these classifiers are shown in Table 5. As we can see, NEIGHBOR has the largest contribution. This again demonstrates the effectiveness of a distributional approach to semantic similarity. Its superior performance to WORD, the second largest contributor, could be attributed to its ability to combat data sparseness. The NE feature, as expected, is crucial to the classification of proper NPs.

4 Application to Coreference Resolution

We can now derive from the induced SC information two KSs — *semantic class agreement* and *mention* — and incorporate them into our learning-based coreference resolver in eight different ways, as described in the introduction. This section examines whether our coreference resolver can benefit from any of the eight ways of incorporating these KSs.

4.1 Experimental Setup

As in SC induction, we use the ACE Phase 2 coreference corpus for evaluation purposes, acquiring the coreference classifiers on the 422 training texts and evaluating their output on the 97 test texts. We report performance in terms of two metrics: (1) the *F-measure* score as computed by the commonly-used MUC scorer (Vilain et al., 1995), and (2) the *accuracy* on the anaphoric references, computed as the fraction of anaphoric references correctly resolved. Following Ponzetto and Strube (2006), we consider an anaphoric reference, NP_i, correctly resolved if NP_i and its closest antecedent are in the same coreference chain in the resulting partition. In all of our experiments, we use NPs automatically extracted by an in-house NP chunker and IdentiFinder.

4.2 The Baseline Coreference System

Our baseline coreference system uses the C4.5 decision tree learner (Quinlan, 1993) to acquire a classifier on the training texts for determining whether two NPs are coreferent. Following previous work (e.g., Soon et al. (2001) and Ponzetto and Strube (2006)), we generate training instances as follows: a positive instance is created for each anaphoric NP, NP_j, and its closest antecedent, NP_i; and a negative instance is created for NP_j paired with each of the intervening NPs, NP_{i+1}, NP_{i+2}, ..., NP_{j-1}. Each instance is represented by 33 lexical, grammatical, semantic, and

positional features that have been employed by high-performing resolvers such as Ng and Cardie (2002) and Yang et al. (2003), as described below.

Lexical features. Nine features allow different types of string matching operations to be performed on the given pair of NPs, NP_x and NP_y[10], including (1) exact string match for pronouns, proper nouns, and non-pronominal NPs (both before and after determiners are removed); (2) substring match for proper nouns and non-pronominal NPs; and (3) head noun match. In addition, one feature tests whether all the words that appear in one NP also appear in the other NP. Finally, a nationality matching feature is used to match, for instance, *British* with *Britain*.

Grammatical features. 22 features test the grammatical properties of one or both of the NPs. These include ten features that test whether each of the two NPs is a pronoun, a definite NP, an indefinite NP, a nested NP, and a clausal subject. A similar set of five features is used to test whether both NPs are pronouns, definite NPs, nested NPs, proper nouns, and clausal subjects. In addition, five features determine whether the two NPs are compatible with respect to gender, number, animacy, and grammatical role. Furthermore, two features test whether the two NPs are in apposition or participate in a predicate nominal construction (i.e., the IS-A relation).

Semantic features. Motivated by Soon et al. (2001), we have a semantic feature that tests whether one NP is a name alias or acronym of the other.

Positional feature. We have a feature that computes the distance between the two NPs in sentences.

After training, the decision tree classifier is used to select an antecedent for each NP in a test text. Following Soon et al. (2001), we select as the antecedent of each NP, NP_j, the *closest* preceding NP that is classified as coreferent with NP_j. If no such NP exists, no antecedent is selected for NP_j.

Row 1 of Table 6 and Table 7 shows the results of the baseline system in terms of F-measure (F) and accuracy in resolving 4599 anaphoric references (All), respectively. For further analysis, we also report the corresponding recall (R) and precision (P) in Table 6, as well as the accuracies of the system in resolving 1769 pronouns (PRO), 1675 proper NPs (PN), and 1155 common NPs (CN) in Table 7. As we can see, the baseline achieves an F-measure of 57.0 and a resolution accuracy of 48.4.

To get a better sense of how strong our baseline is, we re-implement the Soon et al. (2001) coreference resolver. This simply amounts to replacing the 33 features in the baseline resolver with the 12 features employed by Soon et al.'s system. Results of our Duplicated Soon et al. system are shown in row 2 of Tables 6 and 7. In comparison to our baseline, the Duplicated Soon et al. system performs worse according to both metrics, and although the drop in F-measure seems moderate, the performance difference is in fact highly significant (p=0.002).[11]

4.3 Coreference with Induced SC Knowledge

Recall from the introduction that our investigation of the role of induced SC knowledge in learning-based coreference resolution proceeds in three steps:

Label the SC of each NP in each ACE document. If a noun phrase, NP_i, is a proper or common NP, then its SC value is determined using an SC classifier that we acquired in Section 3. On the other hand, if NP_i is a pronoun, then we will be conservative and posit its SC value as UNCONSTRAINED (i.e., it is semantically compatible with all other NPs).[12]

Derive two KSs from the induced SCs. Recall that our first KS, *Mention*, is defined on an NP; its value is YES if the induced SC of the NP is not OTHERS, and NO otherwise. On the other hand, our second KS, *SCA*, is defined on a pair of NPs; its value is YES if the two NPs have the same induced SC that is not OTHERS, and NO otherwise.

Incorporate the two KSs into the baseline resolver. Recall that there are eight ways of incorporating these two KSs into our resolver: they can each be represented as a *constraint* or as a *feature*, and they can be applied to the resolver in *isolation* and in *combination*. Constraints are applied during the antecedent selection step. Specifically, when employed as a constraint, the *Mention* KS disallows coreference between two NPs if at least one of them has a *Mention* value of NO, whereas the *SCA* KS disallows coreference if the *SCA* value of the two NPs involved is NO. When encoded as a feature for the resolver, the *Mention* feature for an NP pair has the

[10] We assume that NP_x precedes NP_y in the associated text.

[11] Again, we use Approximate Randomization with p=.05.

[12] The only exception is pronouns whose SC value can be easily determined to be PERSON (e.g., *he*, *him*, *his*, *himself*).

	System Variation	R	P	F	R	P	F	R	P	F	R	P	F

Table 7: Resolution accuracies for the ACE test set.

value YES if and only if the *Mention* value for both NPs is YES, whereas the *SCA* feature for an NP pair has its value taken from the *SCA* KS.

Now, we can evaluate the impact of the two KSs on the performance of our baseline resolver. Specifically, rows 3-6 of Tables 6 and 7 show the F-measure and the resolution accuracy, respectively, when exactly one of the two KSs is employed by the baseline as either a constraint (C) or a feature (F), and rows 7-10 of the two tables show the results when both KSs are applied to the baseline. Furthermore, each row of Table 6 contains four sets of results, each of which corresponds to a different method for determining the SC value of an NP. For instance, the first set is obtained by using Soon et al.'s method as described in Footnote 8 to compute SC values, serving as sort of a baseline for our results using induced SC values. The second and third sets are obtained based on the SC values computed by the DL and the SVM classifier, respectively.[13] The last set corresponds to an oracle experiment in which the resolver has access to perfect SC information. Rows 3-10 of Table 7 can be interpreted in a similar manner.

From Table 6, we can see that (1) in comparison to the baseline, F-measure increases significantly in the five cases where at least one of the KSs is employed as a constraint by the resolver, and such improvements stem mainly from significant gains in precision; (2) in these five cases, the resolvers that use SCs induced by DL and SVM achieve significantly higher F-measure scores than their counterparts that rely on Soon's method for SC determination; and (3) none of the resolvers appears to benefit from *SCA* information whenever *mention* is used as a constraint.

Moreover, note that even with perfectly computed SC information, the performance of the baseline system does not improve when neither *MD* nor *SCA* is employed as a constraint. These results provide further evidence that the decision tree learner is not exploiting these two semantic KSs in an optimal manner, whether they are computed automatically or perfectly. Hence, in machine learning for coreference resolution, it is important to determine not only *what* linguistic KSs to use, but also *how* to use them.

While the coreference results in Table 6 seem to suggest that *SCA* and *mention* should be employed as constraints, the resolution results in Table 7 sug-

[13] Results using other learners are not shown due to space limitations. DL and SVM are chosen simply because they achieve the highest SC classification accuracies on the ACE training set.

gest that *SCA* is better encoded as a feature. Specifically, (1) in comparison to the baseline, the accuracy of common NP resolution improves by about 5-8% when *SCA* is encoded as a feature; and (2) whenever *SCA* is employed as a feature, the overall resolution accuracy is significantly higher for resolvers that use SCs induced by DL and SVM than those that rely on Soon's method for SC determination, with improvements in resolution observed on all three NP types.

Overall, these results provide suggestive evidence that both KSs are useful for learning-based coreference resolution. In particular, *mention* should be employed as a constraint, whereas *SCA* should be used as a feature. Interestingly, this is consistent with the results that we obtained when the resolver has access to perfect SC information (see Table 6), where the highest F-measure is achieved by employing *mention* as a constraint and *SCA* as a feature.

5 Conclusions

We have shown that (1) both *mention* and *SCA* can be usefully employed to improve the performance of a learning-based coreference system, and (2) employing SC knowledge induced in a supervised manner enables a resolver to achieve better performance than employing SC knowledge computed by Soon et al.'s simple method. In addition, we found that the MUC scoring program is unable to reveal the usefulness of the *SCA* KS, which, when encoded as a feature, substantially improves the accuracy of common NP resolution. This underscores the importance of reporting both resolution accuracy and clustering-level accuracy when analyzing the performance of a coreference resolver.

Generating a Table-of-Contents

Abstract

This paper presents a method for the automatic generation of a table-of-contents. This type of summary could serve as an effective navigation tool for accessing information in long texts, such as books. To generate a coherent table-of-contents, we need to capture both global dependencies across different titles in the table and local constraints within sections. Our algorithm effectively handles these complex dependencies by factoring the model into local and global components, and incrementally constructing the model's output. The results of automatic evaluation and manual assessment confirm the benefits of this design: our system is consistently ranked higher than non-hierarchical baselines.

1 Introduction

Current research in summarization focuses on processing short articles, primarily in the news domain. While in practice the existing summarization methods are not limited to this material, they are not universal: texts in many domains and genres cannot be summarized using these techniques. A particularly significant challenge is the summarization of longer texts, such as books. The requirement for high compression rates and the increased need for the preservation of contextual dependencies between summary sentences places summarization of such texts beyond the scope of current methods.

In this paper, we investigate the automatic generation of *tables-of-contents*, a type of indicative summary particularly suited for accessing information in long texts. A typical table-of-contents lists topics described in the source text and provides information about their location in the text. The hierarchical organization of information in the table further refines information access by specifying the relations between different topics and providing rich contextual information during browsing. Commonly found in books, tables-of-contents can also facilitate access to other types of texts. For instance, this type of summary could serve as an effective navigation tool for understanding a long, unstructured transcript for an academic lecture or a meeting.

Given a text, our goal is to generate a tree wherein a node represents a segment of text and a title that summarizes its content. This process involves two tasks: the hierarchical segmentation of the text, and the generation of informative titles for each segment. The first task can be addressed by using the hierarchical structure readily available in the text (e.g., chapters, sections and subsections) or by employing existing topic segmentation algorithms (Hearst, 1994). In this paper, we take the former approach. As for the second task, a naive approach would be to employ existing methods of title generation to each segment, and combine the results into a tree structure.

However, the latter approach cannot guarantee that the generated table-of-contents forms a coherent representation of the entire text. Since titles of different segments are generated in isolation, some of the generated titles may be repetitive. Even non-repetitive titles may not provide sufficient information to discriminate between the content of one seg-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 544–551,
Prague, Czech Republic, June 2007.

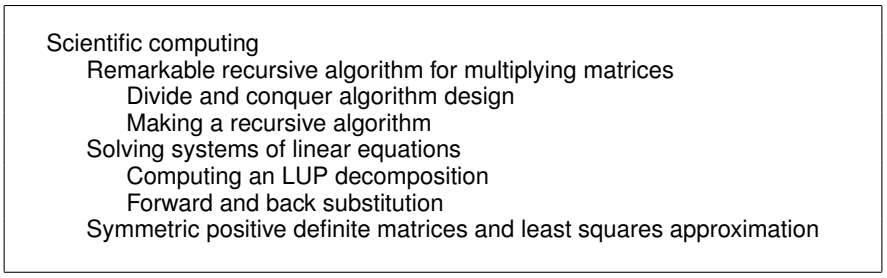

Figure 1: A fragment of a table-of-contents generated by our method.

ment and another. Therefore, it is essential to generate an entire table-of-contents tree in a concerted fashion.

This paper presents a hierarchical discriminative approach for table-of-contents generation. Figure 1 shows a fragment of a table-of-contents automatically generated by this algorithm. Our method has two important points of departure from existing techniques. First, we introduce a structured discriminative model for table-of-contents generation that accounts for a wide range of phrase-based and collocational features. The flexibility of this model results in improved summary quality. Second, our model captures both global dependencies across different titles in the tree and local dependencies within sections. We decompose the model into local and global components that handle different classes of dependencies. We further reduce the search space through incremental construction of the model's output by considering only the promising parts of the decision space.

We apply our method to process a 1,180 page algorithms textbook. To assess the contribution of our hierarchical model, we compare our method with state-of-the-art methods that generate each segment title independently.[1] The results of automatic evaluation and manual assessment of title quality show that the output of our system is consistently ranked higher than that of non-hierarchical baselines.

2 Related Work

Although most current research in summarization focuses on newspaper articles, a number of approaches have been developed for processing longer texts. Most of these approaches are tailored to a particular domain, such as medical literature or scientific articles. By making strong assumptions about the input structure and the desired format of the output, these methods achieve a high compression rate while preserving summary coherence. For instance, Teufel and Moens (2002) summarize scientific articles by selecting rhetorical elements that are commonly present in scientific abstracts. Elhadad and McKeown (2001) generate summaries of medical articles by following a certain structural template in content selection and realization.

Our work, however, is closer to domain-independent methods for summarizing long texts. Typically, these approaches employ topic segmentation to identify a list of topics described in a document, and then produce a summary for each part (Boguraev and Neff, 2000; Angheluta et al., 2002). In contrast to our method, these approaches perform either sentence or phrase extraction, rather than summary generation. Moreover, extraction for each segment is performed in isolation, and global constraints on the summary are not enforced.

Finally, our work is also related to research on title generation (Banko et al., 2000; Jin and Hauptmann, 2001; Dorr et al., 2003). Since work in this area focuses on generating titles for one article at a time (e.g., newspaper reports), the issue of hierarchical generation, which is unique to our task, does not arise. However, this is not the only novel aspect of the proposed approach. Our model learns title generation in a fully discriminative framework, in contrast to the commonly used noisy-channel model. Thus, instead of independently modeling the selection and grammaticality constraints, we learn both types of features in a single framework. This joint training regime supports greater flexibility in modeling feature interaction.

[1] The code and feature vector data for our model and the baselines are available at http://people.csail.mit.edu/branavan/code/toc.

3 Problem Formulation

We formalize the problem of table-of-contents generation as a supervised learning task where the goal is to map a tree of text segments S to a tree of titles T. A segment may correspond to a chapter, section or subsection.

Since the focus of our work is on the generation aspect of table-of-contents construction, we assume that the hierarchical segmentation of a text is provided in the input. This division can either be automatically computed using one of the many available text segmentation algorithms (Hearst, 1994), or it can be based on demarcations already present in the input (e.g., paragraph markers).

During training, the algorithm is provided with a set of pairs (S^i, T^i) for $i = 1, \ldots, p$, where S^i is the i^{th} tree of text segments, and T^i is the table-of-contents for that tree. During testing, the algorithm generates tables-of-contents for unseen trees of text segments.

We also assume that during testing the desired title length is provided as a parameter to the algorithm.

4 Algorithm

To generate a coherent table-of-contents, we need to take into account multiple constraints: the titles should be grammatical, they should adequately represent the content of their segments, and the table-of-contents as a whole should clearly convey the relations between the segments. Taking a discriminative approach for modeling this task would allow us to achieve this goal: we can easily integrate a range of constraints in a flexible manner. Since the number of possible labels (i.e., tables-of-contents) is prohibitively large and the labels themselves exhibit a rich internal structure, we employ a structured discriminative model that can easily handle complex dependencies. Our solution relies on two orthogonal strategies to balance the tractability and the richness of the model. First, we factor the model into local and global components. Second, we incrementally construct the output of each component using a search-based discriminative algorithm. Both of these strategies have the effect of intelligently pruning the decision space.

Our model factorization is driven by the different types of dependencies which are captured by the two components. The first model is *local*: for each segment, it generates a list of candidate titles ranked by their individual likelihoods. This model focuses on grammaticality and word selection constraints, but it does not consider relations among different titles in the table-of-contents. These latter dependencies are captured in the *global* model that constructs a table-of-contents by selecting titles for each segment from the available candidates. Even after this factorization, the decision space for each model is large: for the local model, it is exponential in the length of the segment title, and for the global model it is exponential in the size of the tree.

Therefore, we construct the output for each of these models *incrementally* using beam search. The algorithm maintains the most promising partial output structures, which are extended at every iteration. The model incorporates this decoding procedure into the training process, thereby learning model parameters best suited for the specific decoding algorithm. Similar models have been successfully applied in the past to other tasks including parsing (Collins and Roark, 2004), chunking (Daumé and Marcu, 2005), and machine translation (Cowan et al., 2006).

4.1 Model Structure

The model takes as input a tree of text segments S. Each segment $s \in S$ and its title z are represented as a *local feature vector* $\Phi_{\mathbf{loc}}(s, z)$. Each component of this vector stores a numerical value. This feature vector can track any feature of the segment s together with its title z. For instance, the i^{th} component of this vector may indicate whether the bigram $(z[j]z[j+1])$ occurs in s, where $z[j]$ is the j^{th} word in z:

$$(\Phi_{\mathbf{loc}}(s, z))_i = \begin{cases} 1 & \text{if } (z[j]z[j+1]) \in s \\ 0 & \text{otherwise} \end{cases}$$

In addition, our model captures dependencies among *multiple titles* that appear in the same table-of-contents. We represent a tree of segments S paired with titles T with the *global feature vector* $\Phi_{\mathbf{glob}}(S, T)$. The components here are also numerical features. For example, the i^{th} component of the vector may indicate whether a title is repeated in the table-of-contents T:

$$(\Phi_{\mathbf{glob}}(S,T))_i = \begin{cases} 1 & \text{repeated title} \\ 0 & \text{otherwise} \end{cases}$$

Our model constructs a table-of-contents in two basic steps:

Step One The goal of this step is to generate a list of k candidate titles for each segment $s \in S$. To do so, for each possible title z, the model maps the feature vector $\Phi_{\mathbf{loc}}(s,z)$ to a real number. This mapping can take the form of a linear model,

$$\Phi_{\mathbf{loc}}(s,z) \cdot \alpha_{\text{loc}}$$

where α_{loc} is the local parameter vector.

Since the number of possible titles is exponential, we cannot consider all of them. Instead, we prune the decision space by incrementally constructing promising titles. At each iteration j, the algorithm maintains a beam Q of the top k partially generated titles of length j. During iteration $j+1$, a new set of candidates is grown by appending a word from s to the right of each member of the beam Q. We then sort the entries in Q: $z_1, z_2, \ldots$ such that $\Phi_{\mathbf{loc}}(s,z_i) \cdot \alpha_{\text{loc}} \geq \Phi_{\mathbf{loc}}(s,z_{i+1}) \cdot \alpha_{\text{loc}}, \forall i$. Only the top k candidates are retained, forming the beam for the next iteration. This process continues until a title of the desired length is generated. Finally, the list of k candidates is returned.

Step Two Given a set of candidate titles $z_1, z_2, \ldots, z_k$ for each segment $s \in S$, our goal is to construct a table-of-contents T by selecting the most appropriate title from each segment's candidate list. To do so, our model computes a score for the pair (S,T) based on the global feature vector $\Phi_{\mathbf{glob}}(S,T)$:

$$\Phi_{\mathbf{glob}}(S,T) \cdot \alpha_{\text{glob}}$$

where α_{glob} is the global parameter vector.

As with the local model (step one), the number of possible tables-of-contents is too large to be considered exhaustively. Therefore, we incrementally construct a table-of-contents by traversing the tree of segments in a pre-order walk (i.e., the order in which segments appear in the text). In this case, the beam contains partially generated tables-of-contents, which are expanded by one segment title at a time. To further reduce the search space, during decoding only the top five candidate titles for a segment are given to the global model.

4.2 Training the Model

Training for Step One We now describe how the local parameter vector α_{loc} is estimated from training data. We are given a set of training examples (s^i, y^i) for $i = 1, \ldots, l$, where s^i is the i^{th} text segment, and y^i is the title of this segment.

This linear model is learned using a variant of the incremental perceptron algorithm (Collins and Roark, 2004; Daumé and Marcu, 2005). This online algorithm traverses the training set multiple times, updating the parameter vector α_{loc} after each training example in case of mis-predictions. The algorithm encourages a setting of the parameter vector α_{loc} that assigns the highest score to the feature vector associated with the correct title.

The pseudo-code of the algorithm is shown in Figure 2. Given a text segment s and the corresponding title y, the training algorithm maintains a beam Q containing the top k partial titles of length j. The beam is updated on each iteration using the functions GROW and PRUNE. For every word in segment s and for every partial title in Q, GROW creates a new title by appending this word to the title. PRUNE retains only the top ranked candidates based on the scoring function $\Phi_{\mathbf{loc}}(s,z) \cdot \alpha_{\text{loc}}$. If $y[1 \ldots j]$ (i.e., the prefix of y of length j) is not in the modified beam Q, then α_{loc} is updated[2] as shown in line 4 of the pseudo-code in Figure 2. In addition, Q is replaced with a beam containing only $y[1 \ldots j]$ (line 5). This process is performed $|y|$ times. We repeat this process for all training examples over 50 training iterations. [3]

Training for Step Two To train the global parameter vector α_{glob}, we are given training examples (S^i, T^i) for $i = 1, \ldots, p$, where S^i is the i^{th} tree of text segments, and T^i is the table-of-contents for that tree. However, we cannot directly use these tables-of-contents for training our global model: since this model selects one of the candidate titles $z_1^i, \ldots, z_k^i$ returned by the local model, the true title of the segment may not be among these candidates. Therefore, to determine a new target title for the segment, we need to identify the title in the set of candidates

[2] If the word in the j^{th} position of y does not occur in s, then the parameter update is not performed.

[3] For decoding, α_{loc} is averaged over the training iterations as in Collins and Roark (2004).

s – segment text.
y – segment title.
$y[1 \dots j]$ – prefix of y of length j.
Q – beam containing partial titles.

1. for $j = 1 \dots |y|$
2. $\quad Q = \text{PRUNE}(\text{GROW}(s, Q))$
3. $\quad$ if $y[1 \dots j] \notin Q$
4. $\quad\quad \alpha_{\text{loc}} = \alpha_{\text{loc}} + \Phi_{\mathbf{loc}}(s, y[1 \dots j]) - \sum_{z \in Q} \frac{\Phi_{\mathbf{loc}}(s,z)}{|Q|}$
5. $\quad\quad Q = \{y[1 \dots j]\}$

Figure 2: The training algorithm for the local model.

that is closest to the true title.

We employ the L_1 distance measure to compare the content word overlap between two titles.[4] For each input (S, T), and each segment $s \in S$, we identify the segment title closest in the L_1 measure to the true title y[5]:

$$z^* = \arg\min_i L_1(z_i, y)$$

Once all the training targets in the corpus have been identified through this procedure, the global linear model $\Phi_{\mathbf{glob}}(S, T) \cdot \alpha_{\text{glob}}$ is learned using the same perceptron algorithm as in step one. Rather than maintaining the beam of partially generated titles, the beam Q holds partially generated tables-of-contents. Also, the loop in line 1 of Figure 2 iterates over segment titles rather than words. The global model is trained over 200 iterations.

5 Features

Local Features Our local model aims to generate titles which adequately represent the meaning of the segment and are grammatical. Selection and contextual preferences are encoded in the local features. The features that capture selection constraints are specified at the word level, and contextual features are expressed at the word sequence level.

The selection features capture the position of the word, its TF*IDF, and part-of-speech information. In addition, they also record whether the word occurs in the body of neighboring segments. We also generate conjunctive features by combining features of different types.

The contextual features record the bigram and trigram language model scores, both for words and for part-of-speech tags. The trigram scores are averaged over the title. The language models are trained using the SRILM toolkit. Another type of contextual feature models the collocational properties of noun phrases in the title. This feature aims to eliminate generic phrases, such as *"the following section"* from the generated titles.[6] To achieve this effect, for each noun phrase in the title, we measure the ratio of their frequency in the segment to their frequency in the corpus.

Segment has the same title as its sibling
Segment has the same title as its parent
Two adjacent sibling titles have the same head
Two adjacent sibling titles start with the same word
Rank given to the title by the local model

Table 1: Examples of global features.

Global Features Our global model describes the interaction between different titles in the tree (See Table 1). These interactions are encoded in three types of global features. The first type of global feature indicates whether titles in the tree are redundant at various levels of the tree structure. The second type of feature encourages parallel constructions within the same tree. For instance, titles of adjoining segments may be verbalized as noun phrases with the same head (e.g., *"Bubble sort algorithm"*, *"Merge sort algorithm"*). We capture this property by comparing words that appear in certain positions in adjacent sibling titles. Finally, our global model also uses the rank of the title provided by the local model. This feature enables the global model to account for the preferences of the local model in the title selection process.

6 Evaluation Set-Up

Data We apply our method to an undergraduate algorithms textbook. For detailed statistics on the data see Table 2. We split its table-of-contents into a set

[4] This measure is close to ROUGE-1 which in addition considers the overlap in auxiliary words.

[5] In the case of ties, one of the titles is picked arbitrarily.

[6] Unfortunately, we could not use more sophisticated syntactic features due to the low accuracy of statistical parsers on our corpus.

Number of Titles	540
Number of Trees	39
Tree Depth	4
Number of Words	269,650
Avg. Title Length	3.64
Avg. Branching	3.29
Avg. Title Duplicates	21

Table 2: Statistics on the corpus used in the experiments.

of independent subtrees. Given a table-of-contents of depth n with a root branching factor of r, we generate r subtrees, with a depth of at most $n-1$. We randomly select 80% of these trees for training, and the rest are used for testing. In our experiments, we use ten different randomizations to compensate for the small number of available trees.

Admittedly, this method of generating training and testing data omits some dependencies at the level of the table-of-contents as a whole. However, the subtrees used in our experiments still exhibit a sufficiently deep hierarchical structure, rich with contextual dependencies.

Baselines As an alternative to our hierarchical discriminative method, we consider three baselines that build a table-of-contents by generating a title for each segment individually, without taking into account the tree structure, and one hierarchical generative baseline. The first method generates a title for a segment by selecting the noun phrase from that segment with the highest TF*IDF. This simple method is commonly used to generate keywords for browsing applications in information retrieval, and has been shown to be effective for summarizing technical content (Wacholder et al., 2001).

The second baseline is based on the noisy-channel generative (flat generative, FG) model proposed by Banko et al., (2000). Similar to our local model, this method captures both selection and grammatical constraints. However, these constraints are modeled separately, and then combined in a generative framework.

We use our local model (Flat Discriminative model, FD) as the third baseline. Like the second baseline, this model omits global dependencies, and only focuses on features that capture relations within individual segments.

In the hierarchical generative (HG) baseline we run our global model on the ranked list of titles produced for each section by the noisy-channel generative model.

The last three baselines and our algorithm are provided with the title length as a parameter. In our experiments, the algorithms use the reference title length.

Experimental Design: Comparison with reference tables-of-contents Reference based evaluation is commonly used to assess the quality of machine-generated headlines (Wang et al., 2005). We compare our system's output with the table-of-contents from the textbook using ROUGE metrics. We employ a publicly available software package,[7] with all the parameters set to default values.

Experimental Design: Human assessment The judges were each given 30 segments randomly selected from a set of 359 test segments. For each test segment, the judges were presented with its text, and 3 alternative titles consisting of the reference and the titles produced by the hierarchical discriminative model, and the best performing baseline. In addition, the judges had access to all of the segments in the book. A total of 498 titles for 166 unique segments were ranked. The system identities were hidden from the judges, and the titles were presented in random order. The judges ranked the titles based on how well they represent the content of the segment. Titles were ranked equal if they were judged to be equally representative of the segment.

Six people participated in this experiment. All the participants were graduate students in computer science who had taken the algorithms class in the past and were reasonably familiar with the material.

7 Results

Figure 3 shows fragments of the tables-of-contents generated by our method and the four baselines along with the reference counterpart. These extracts illustrate three general phenomena that we observed in the test corpus. First, the titles produced by keyword extraction exhibit a high degree of redundancy. In fact, 40% of the titles produced by this method are repeated more than once in the table-of-contents. In

contrast, our method yields 5.5% of the titles as duplicates, as compared to 9% in the reference table-of-contents.[8]

Second, the fragments show that the two discriminative models — Flat and Hierarchical — have a number of common titles. However, adding global dependencies to rerank titles generated by the local model changes 30% of the titles in the test set.

Comparison with reference tables-of-contents Table 3 shows the average ROUGE scores over the ten randomizations for the five automatic methods. The hierarchical discriminative method consistently outperforms the four baselines according to all ROUGE metrics.

At the same time, these results also show that only a small ratio of the automatically generated titles are identical to the reference ones. In some cases, the machine-generated titles are very close in meaning to the reference, but are verbalized differently. Examples include pairs such as *("Minimum Spanning Trees", "Spanning Tree Problem")* and *("Wallace Tree", "Multiplication Circuit").*[9] While measures like ROUGE can capture the similarity in the first pair, they cannot identify semantic proximity

[8]Titles such as *"Analysis"* and *"Chapter Outline"* are repeated multiple times in the text.

[9]A Wallace Tree is a circuit that multiplies two integers.

between the titles in the second pair. Therefore, we supplement the results of this experiment with a manual assessment of title quality as described below.

Human assessment We analyze the human ratings by considering pairwise comparisons between the models. Given two models, A and B, three outcomes are possible: A is better than B, B is better than A, or they are of equal quality. The results of the comparison are summarized in Table 4. These results indicate that using hierarchical information yields statistically significant improvement (at $p \leq 0.0002$ based on the Sign test) over a flat counterpart.

8 Conclusion and Future Work

This paper presents a method for the automatic generation of a table-of-contents. The key strength of our method lies in its ability to track dependencies between generation decisions across different levels of the tree structure. The results of automatic evaluation and manual assessment confirm the benefits of joint tree learning: our system is consistently ranked higher than non-hierarchical baselines.

We also plan to expand our method for the task of slide generation. Like tables-of-contents, slide bullets are organized in a hierarchical fashion and are written in relatively short phrases. From the language viewpoint, however, slides exhibit more variability and complexity than a typical table-of-contents. To address this challenge, we will explore more powerful generation methods that take into account syntactic information.

Abstract

Though both document summarization and keyword extraction aim to extract concise representations from documents, these two tasks have usually been investigated independently. This paper proposes a novel iterative reinforcement approach to simultaneously extracting summary and keywords from single document under the assumption that the summary and keywords of a document can be mutually boosted. The approach can naturally make full use of the reinforcement between sentences and keywords by fusing three kinds of relationships between sentences and words, either homogeneous or heterogeneous. Experimental results show the effectiveness of the proposed approach for both tasks. The corpus-based approach is validated to work almost as well as the knowledge-based approach for computing word semantics.

1 Introduction

Text summarization is the process of creating a compressed version of a given document that delivers the main topic of the document. Keyword extraction is the process of extracting a few salient words (or phrases) from a given text and using the words to represent the text. The two tasks are similar in essence because they both aim to extract concise representations for documents. Automatic text summarization and keyword extraction have drawn much attention for a long time because they both are very important for many text applications, including document retrieval, document clustering, etc. For example, keywords of a document can be used for document indexing and thus benefit to improve the performance of document retrieval, and document summary can help to facilitate users to browse the search results and improve users' search experience.

Text summaries and keywords can be either query-relevant or generic. Generic summary and keyword should reflect the main topics of the document without any additional clues and prior knowledge. In this paper, we focus on generic document summarization and keyword extraction for single documents.

Document summarization and keyword extraction have been widely explored in the natural language processing and information retrieval communities. A series of workshops and conferences on automatic text summarization (e.g. SUMMAC, DUC and NTCIR) have advanced the technology and produced a couple of experimental online systems. In recent years, graph-based ranking algorithms have been successfully used for document summarization (Mihalcea and Tarau, 2004, 2005; ErKan and Radev, 2004) and keyword extraction (Mihalcea and Tarau, 2004). Such algorithms make use of "voting" or "recommendations" between sentences (or words) to extract sentences (or keywords). Though the two tasks essentially share much in common, most algorithms have been developed particularly for either document summarization or keyword extraction.

Zha (2002) proposes a method for simultaneous keyphrase extraction and text summarization by using only the heterogeneous sentence-to-word relationships. Inspired by this, we aim to take into account all the three kinds of relationships among sentences and words (i.e. the homogeneous relationships between words, the homogeneous relationships between sentences, and the heterogeneous relationships between words and sentences) in

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 552–559,
Prague, Czech Republic, June 2007.

a unified framework for both document summarization and keyword extraction. The importance of a sentence (word) is determined by both the importance of related sentences (words) and the importance of related words (sentences). The proposed approach can be considered as a generalized form of previous graph-based ranking algorithms and Zha's work (Zha, 2002).

In this study, we propose an iterative reinforcement approach to realize the above idea. The proposed approach is evaluated on the DUC2002 dataset and the results demonstrate its effectiveness for both document summarization and keyword extraction. Both knowledge-based approach and corpus-based approach have been investigated to compute word semantics and they both perform very well.

The rest of this paper is organized as follows: Section 2 introduces related works. The details of the proposed approach are described in Section 3. Section 4 presents and discusses the evaluation results. Lastly we conclude our paper in Section 5.

2 Related Works

2.1 Document Summarization

Generally speaking, single document summarization methods can be either extraction-based or abstraction-based and we focus on extraction-based methods in this study.

Extraction-based methods usually assign a saliency score to each sentence and then rank the sentences in the document. The scores are usually computed based on a combination of statistical and linguistic features, including term frequency, sentence position, cue words, stigma words, topic signature (Hovy and Lin, 1997; Lin and Hovy, 2000), etc. Machine learning methods have also been employed to extract sentences, including unsupervised methods (Nomoto and Matsumoto, 2001) and supervised methods (Kupiec et al., 1995; Conroy and O'Leary, 2001; Amini and Gallinari, 2002; Shen et al., 2007). Other methods include maximal marginal relevance (MMR) (Carbonell and Goldstein, 1998), latent semantic analysis (LSA) (Gong and Liu, 2001). In Zha (2002), the mutual reinforcement principle is employed to iteratively extract key phrases and sentences from a document.

Most recently, graph-based ranking methods, including TextRank ((Mihalcea and Tarau, 2004, 2005) and LexPageRank (ErKan and Radev, 2004) have been proposed for document summarization. Similar to Kleinberg's HITS algorithm (Kleinberg, 1999) or Google's PageRank (Brin and Page, 1998), these methods first build a graph based on the similarity between sentences in a document and then the importance of a sentence is determined by taking into account global information on the graph recursively, rather than relying only on local sentence-specific information.

2.2 Keyword Extraction

Keyword (or keyphrase) extraction usually involves assigning a saliency score to each candidate keyword by considering various features. Krulwich and Burkey (1996) use heuristics to extract keyphrases from a document. The heuristics are based on syntactic clues, such as the use of italics, the presence of phrases in section headers, and the use of acronyms. Muñoz (1996) uses an unsupervised learning algorithm to discover two-word keyphrases. The algorithm is based on Adaptive Resonance Theory (ART) neural networks. Steier and Belew (1993) use the mutual information statistics to discover two-word keyphrases.

Supervised machine learning algorithms have been proposed to classify a candidate phrase into either keyphrase or not. GenEx (Turney, 2000) and Kea (Frank et al., 1999; Witten et al., 1999) are two typical systems, and the most important features for classifying a candidate phrase are the frequency and location of the phrase in the document. More linguistic knowledge (such as syntactic features) has been explored by Hulth (2003). More recently, Mihalcea and Tarau (2004) propose the TextRank model to rank keywords based on the co-occurrence links between words.

3 Iterative Reinforcement Approach

3.1 Overview

The proposed approach is intuitively based on the following assumptions:

Assumption 1: A sentence should be salient if it is heavily linked with other salient sentences, and a word should be salient if it is heavily linked with other salient words.

Assumption 2: A sentence should be salient if it contains many salient words, and a word should be salient if it appears in many salient sentences.

The first assumption is similar to PageRank which makes use of mutual "recommendations"

between homogeneous objects to rank objects. The second assumption is similar to HITS if words and sentences are considered as authorities and hubs respectively. In other words, the proposed approach aims to fuse the ideas of PageRank and HITS in a unified framework.

In more detail, given the heterogeneous data points of sentences and words, the following three kinds of relationships are fused in the proposed approach:

SS-Relationship: It reflects the homogeneous relationships between sentences, usually computed by their content similarity.

WW-Relationship: It reflects the homogeneous relationships between words, usually computed by knowledge-based approach or corpus-based approach.

SW-Relationship: It reflects the heterogeneous relationships between sentences and words, usually computed as the relative importance of a word in a sentence.

Figure 1 gives an illustration of the relationships.

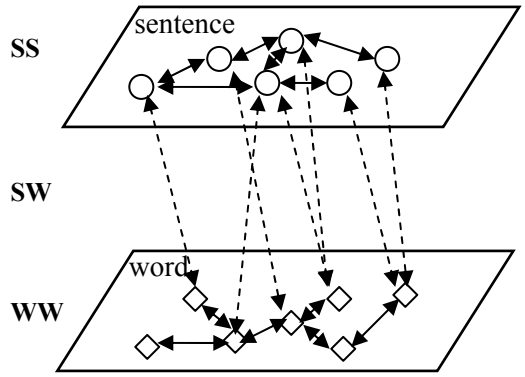

Figure 1. Illustration of the Relationships

The proposed approach first builds three graphs to reflect the above relationships respectively, and then iteratively computes the saliency scores of the sentences and words based on the graphs. Finally, the algorithm converges and each sentence or word gets its saliency score. The sentences with high saliency scores are chosen into the summary, and the words with high saliency scores are combined to produce the keywords.

3.2 Graph Building

3.2.1 Sentence-to-Sentence Graph (SS-Graph)

Given the sentence collection $S=\{s_i \mid 1\le i\le m\}$ of a document, if each sentence is considered as a node, the sentence collection can be modeled as an undirected graph by generating an edge between two sentences if their content similarity exceeds 0, i.e. an undirected link between s_i and s_j ($i\neq j$) is constructed and the associated weight is their content similarity. Thus, we construct an undirected graph G_{SS} to reflect the homogeneous relationship between sentences. The content similarity between two sentences is computed with the cosine measure. We use an adjacency matrix $\boldsymbol{U}$ to describe G_{SS} with each entry corresponding to the weight of a link in the graph. $\boldsymbol{U}=[U_{ij}]_{m\times m}$ is defined as follows:

$$U_{ij}=\begin{cases}\dfrac{\vec{s}_i \times \vec{s}_j}{\|\vec{s}_i\| \times \|\vec{s}_j\|}, & if\ i \neq j \\ 0, & otherwise\end{cases} \quad (1)$$

where s_i and $\vec{s}_j$ are the corresponding term vectors of sentences s_i and s_j respectively. The weight associated with term t is calculated with $tf_t.isf_t$, where tf_t is the frequency of term t in the sentence and isf_t is the inverse sentence frequency of term t, i.e. $1+\log(N/n_t)$, where N is the total number of sentences and n_t is the number of sentences containing term t in a background corpus. Note that other measures (e.g. Jaccard, Dice, Overlap, etc.) can also be explored to compute the content similarity between sentences, and we simply choose the cosine measure in this study.

Then $\boldsymbol{U}$ is normalized to $\widetilde{\boldsymbol{U}}$ as follows to make the sum of each row equal to 1:

$$\widetilde{U}_{ij}=\begin{cases}U_{ij} \Big/ \sum_{j=1}^{m} U_{ij}, & if \sum_{j=1}^{m} U_{ij} \neq 0 \\ 0, & otherwise\end{cases} \quad (2)$$

3.2.2 Word-to-Word Graph (WW-Graph)

Given the word collection $T=\{t_j \mid 1\le j\le n\}$ of a document[1], the semantic similarity between any two words t_i and t_j can be computed using approaches that are either knowledge-based or corpus-based (Mihalcea et al., 2006).

Knowledge-based measures of word semantic similarity try to quantify the degree to which two words are semantically related using information drawn from semantic networks. WordNet (Fellbaum, 1998) is a lexical database where each

[1] The stopwords defined in the Smart system have been removed from the collection.

unique meaning of a word is represented by a synonym set or *synset*. Each synset has a gloss that defines the concept that it represents. Synsets are connected to each other through explicit semantic relations that are defined in WordNet. Many approaches have been proposed to measure semantic relatedness based on WordNet. The measures vary from simple edge-counting to attempt to factor in peculiarities of the network structure by considering link direction, relative path, and density, such as *vector*, *lesk*, *hso, lch*, *wup*, *path*, *res, lin* and *jcn* (Pedersen et al., 2004). For example, "cat" and "dog" has higher semantic similarity than "cat" and "computer". In this study, we implement the *vector* measure to efficiently evaluate the similarities of a large number of word pairs. The *vector* measure (Patwardhan, 2003) creates a co–occurrence matrix from a corpus made up of the WordNet glosses. Each content word used in a WordNet gloss has an associated context vector. Each gloss is represented by a gloss vector that is the average of all the context vectors of the words found in the gloss. Relatedness between concepts is measured by finding the cosine between a pair of gloss vectors.

Corpus-based measures of word semantic similarity try to identify the degree of similarity between words using information exclusively derived from large corpora. Such measures as mutual information (Turney 2001), latent semantic analysis (Landauer et al., 1998), log-likelihood ratio (Dunning, 1993) have been proposed to evaluate word semantic similarity based on the co-occurrence information on a large corpus. In this study, we simply choose the mutual information to compute the semantic similarity between word t_i and t_j as follows:

$$sim(t_i,t_j) = \log \frac{N \times p(t_i,t_j)}{p(t_i) \times p(t_j)} \qquad (3)$$

which indicates the degree of statistical dependence between t_i and t_j. Here, N is the total number of words in the corpus and $p(t_i)$ and $p(t_j)$ are respectively the probabilities of the occurrences of t_i and t_j, i.e. $count(t_i)/N$ and $count(t_j)/N$, where $count(t_i)$ and $count(t_j)$ are the frequencies of t_i and t_j. $p(t_i, t_j)$ is the probability of the co-occurrence of t_i and t_j within a window with a predefined size k, i.e. $count(t_i, t_j)/N$, where $count(t_i, t_j)$ is the number of the times t_i and t_j co-occur within the window.

Similar to the SS-Graph, we can build an undirected graph G_{WW} to reflect the homogeneous relationship between words, in which each node corresponds to a word and the weight associated with the edge between any different word t_i and t_j is computed by either the WordNet-based *vector* measure or the corpus-based mutual information measure. We use an adjacency matrix $\boldsymbol{V}$ to describe G_{WW} with each entry corresponding to the weight of a link in the graph. $\boldsymbol{V}= [V_{ij}]_{n\times n}$, where $V_{ij} = sim(t_i, t_j)$ if $i \neq j$ and $V_{ij}=0$ if $i=j$.

Then $\boldsymbol{V}$ is similarly normalized to $\widetilde{\boldsymbol{V}}$ to make the sum of each row equal to 1.

3.2.3 Sentence-to-Word Graph (SW-Graph)

Given the sentence collection $S=\{s_i \mid 1\le i\le m\}$ and the word collection $T=\{t_j \mid 1\le j\le n\}$ of a document, we can build a weighted bipartite graph G_{SW} from S and T in the following way: if word t_j appears in sentence s_i, we then create an edge between s_i and t_j. A nonnegative weight $aff(s_i,t_j)$ is specified on the edge, which is proportional to the importance of word t_j in sentence s_i, computed as follows:

$$aff(s_i,t_j) = \frac{tf_{t_j} \times isf_{t_j}}{\sum_{t \in s_i} tf_t \times isf_t} \qquad (4)$$

where t represents a unique term in s_i and tf_t, isf_t are respectively the term frequency in the sentence and the inverse sentence frequency.

We use an adjacency (affinity) matrix $\boldsymbol{W}=[W_{ij}]_{m\times n}$ to describe G_{SW} with each entry W_{ij} corresponding to $aff(s_i,t_j)$. Similarly, $\boldsymbol{W}$ is normalized to $\widetilde{\boldsymbol{W}}$ to make the sum of each row equal to 1. In addition, we normalize the transpose of $\boldsymbol{W}$, i.e. $\boldsymbol{W}^{\mathrm{T}}$, to $\hat{\boldsymbol{W}}$ to make the sum of each row in $\boldsymbol{W}^{\mathrm{T}}$ equal to 1.

3.3 Reinforcement Algorithm

We use two column vectors $\boldsymbol{u}=[u(s_i)]_{m\times 1}$ and $\boldsymbol{v}=[v(t_j)]_{n\times 1}$ to denote the saliency scores of the sentences and words in the specified document. The assumptions introduced in Section 3.1 can be rendered as follows:

$$u(s_i) \propto \sum_j \widetilde{U}_{ji} u(s_j) \qquad (5)$$

$$v(t_j) \propto \sum_i \widetilde{V}_{ij} v(t_i) \qquad (6)$$

$$u(s_i) \propto \sum_j \hat{W}_{ji} v(t_j) \qquad (7)$$

$$v(t_j) \propto \sum_i \widetilde{W}_{ij} u(s_i) \quad (8)$$

After fusing the above equations, we can obtain the following iterative forms:

$$u(s_i) = \alpha \sum_{j=1}^{m} \widetilde{U}_{ji} u(s_j) + \beta \sum_{j=1}^{n} \hat{W}_{ji} v(t_j) \quad (9)$$

$$v(t_j) = \alpha \sum_{i=1}^{n} \widetilde{V}_{ij} v(t_i) + \beta \sum_{i=1}^{m} \widetilde{W}_{ij} u(s_i) \quad (10)$$

And the matrix form is:

$$\boldsymbol{u} = \alpha \widetilde{\boldsymbol{U}}^T \boldsymbol{u} + \beta \hat{\boldsymbol{W}}^T \boldsymbol{v} \quad (11)$$

$$\boldsymbol{v} = \alpha \widetilde{\boldsymbol{V}}^T \boldsymbol{v} + \beta \widetilde{\boldsymbol{W}}^T \boldsymbol{u} \quad (12)$$

where α and β specify the relative contributions to the final saliency scores from the homogeneous nodes and the heterogeneous nodes and we have $\alpha+\beta=1$. In order to guarantee the convergence of the iterative form, $\boldsymbol{u}$ and $\boldsymbol{v}$ are normalized after each iteration.

For numerical computation of the saliency scores, the initial scores of all sentences and words are set to 1 and the following two steps are alternated until convergence,

1. Compute and normalize the scores of sentences:
$$\boldsymbol{u}^{(n)} = \alpha \widetilde{\boldsymbol{U}}^T \boldsymbol{u}^{(n-1)} + \beta \hat{\boldsymbol{W}}^T \boldsymbol{v}^{(n-1)},$$
$$\boldsymbol{u}^{(n)} = \boldsymbol{u}^{(n)} / \left\| \boldsymbol{u}^{(n)} \right\|_1$$
2. Compute and normalize the scores of words:
$$\boldsymbol{v}^{(n)} = \alpha \widetilde{\boldsymbol{V}}^T \boldsymbol{v}^{(n-1)} + \beta \widetilde{\boldsymbol{W}}^T \boldsymbol{u}^{(n-1)},$$
$$\boldsymbol{v}^{(n)} = \boldsymbol{v}^{(n)} / \left\| \boldsymbol{v}^{(n)} \right\|_1$$

where $\boldsymbol{u}^{(n)}$ and $\boldsymbol{v}^{(n)}$ denote the vectors computed at the n-th iteration.

Usually the convergence of the iteration algorithm is achieved when the difference between the scores computed at two successive iterations for any sentences and words falls below a given threshold (0.0001 in this study).

4 Empirical Evaluation

4.1 Summarization Evaluation

4.1.1 Evaluation Setup

We used task 1 of DUC2002 (DUC, 2002) for evaluation. The task aimed to evaluate generic summaries with a length of approximately 100 words or less. DUC2002 provided 567 English news articles collected from TREC-9 for single-document summarization task. The sentences in each article have been separated and the sentence information was stored into files.

In the experiments, the background corpus for using the mutual information measure to compute word semantics simply consisted of all the documents from DUC2001 to DUC2005, which could be easily expanded by adding more documents. The stopwords were removed and the remaining words were converted to the basic forms based on WordNet. Then the semantic similarity values between the words were computed.

We used the ROUGE (Lin and Hovy, 2003) toolkit (i.e.ROUGEeval-1.4.2 in this study) for evaluation, which has been widely adopted by DUC for automatic summarization evaluation. It measured summary quality by counting overlapping units such as the n-gram, word sequences and word pairs between the candidate summary and the reference summary. ROUGE toolkit reported separate scores for 1, 2, 3 and 4-gram, and also for longest common subsequence co-occurrences. Among these different scores, unigram-based ROUGE score (ROUGE-1) has been shown to agree with human judgment most (Lin and Hovy, 2003). We showed three of the ROUGE metrics in the experimental results: ROUGE-1 (unigram-based), ROUGE-2 (bigram-based), and ROUGE-W (based on weighted longest common subsequence, weight=1.2).

In order to truncate summaries longer than the length limit, we used the "-l" option [2] in the ROUGE toolkit.

4.1.2 Evaluation Results

For simplicity, the parameters in the proposed approach are simply set to $\alpha=\beta=0.5$, which means that the contributions from sentences and words are equally important. We adopt the WordNet-based *vector* measure (WN) and the corpus-based mutual information measure (MI) for computing the semantic similarity between words. When using the mutual information measure, we heuristically set the window size k to 2, 5 and 10, respectively.

The proposed approaches with different word similarity measures (WN and MI) are compared

[2] The "-l" option is very important for fair comparison. Some previous works not adopting this option are likely to overestimate the ROUGE scores.

with two solid baselines: SentenceRank and MutualRank. SentenceRank is proposed in Mihalcea and Tarau (2004) to make use of only the sentence-to-sentence relationships to rank sentences, which outperforms most popular summarization methods. MutualRank is proposed in Zha (2002) to make use of only the sentence-to-word relationships to rank sentences and words. For all the summarization methods, after the sentences are ranked by their saliency scores, we can apply a variant form of the MMR algorithm to remove redundancy and choose both the salient and novel sentences to the summary. Table 1 gives the comparison results of the methods before removing redundancy and Table 2 gives the comparison results of the methods after removing redundancy.

System	ROUGE-1	ROUGE-2	ROUGE-W
Our Approach (WN)	**0.47100**$^{*\#}$	**0.20424**$^{*\#}$	**0.16336**$^{\#}$
Our Approach (MI:k=2)	0.46711$^{\#}$	0.20195$^{\#}$	0.16257$^{\#}$
Our Approach (MI:k=5)	0.46803$^{\#}$	0.20259$^{\#}$	0.16310$^{\#}$
Our Approach (MI:k=10)	0.46823$^{\#}$	0.20301$^{\#}$	0.16294$^{\#}$
SentenceRank	0.45591	0.19201	0.15789
MutualRank	0.43743	0.17986	0.15333

Table 1. Summarization Performance before Removing Redundancy (w/o MMR)

System	ROUGE-1	ROUGE-2	ROUGE-W
Our Approach (WN)	**0.47329**$^{*\#}$	0.20249$^{\#}$	0.16352$^{\#}$
Our Approach (MI:k=2)	0.47281$^{\#}$	**0.20281**$^{\#}$	**0.16373**$^{\#}$
Our Approach (MI:k=5)	0.47282$^{\#}$	0.20249$^{\#}$	0.16343$^{\#}$
Our Approach (MI:k=10)	0.47223$^{\#}$	0.20225$^{\#}$	0.16308$^{\#}$
SentenceRank	0.46261	0.19457	0.16018
MutualRank	0.43805	0.17253	0.15221

Table 2. Summarization Performance after Removing Redundancy (w/ MMR)

(* indicates that the improvement over SentenceRank is significant and $^{\#}$ indicates that the improvement over MutualRank is significant, both by comparing the 95% confidence intervals provided by the ROUGE package.)

Seen from Tables 1 and 2, the proposed approaches always outperform the two baselines over all three metrics with different word semantic measures. Moreover, no matter whether the MMR algorithm is applied or not, almost all performance improvements over MutualRank are significant and the ROUGE-1 performance improvements over SentenceRank are significant when using WordNet-based measure (WN). Word semantics can be naturally incorporated into the computation process, which addresses the problem that SentenceRank cannot take into account word semantics, and thus improves the summarization performance. We also observe that the corpus-based measure (MI) works almost as well as the knowledge-based measure (WN) for computing word semantic similarity.

In order to better understand the relative contributions from the sentence nodes and the word nodes, the parameter α is varied from 0 to 1. The larger α is, the more contribution is given from the sentences through the SS-Graph, while the less contribution is given from the words through the SW-Graph. Figures 2-4 show the curves over three ROUGE scores with respect to α. Without loss of generality, we use the case of k=5 for the MI measure as an illustration. The curves are similar to Figures 2-4 when k=2 and k=10.

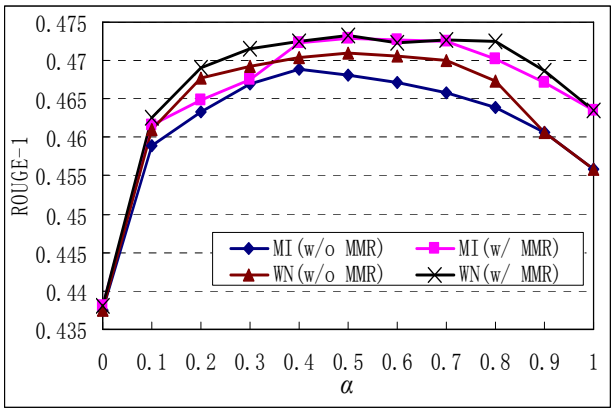

Figure 2. ROUGE-1 vs. α

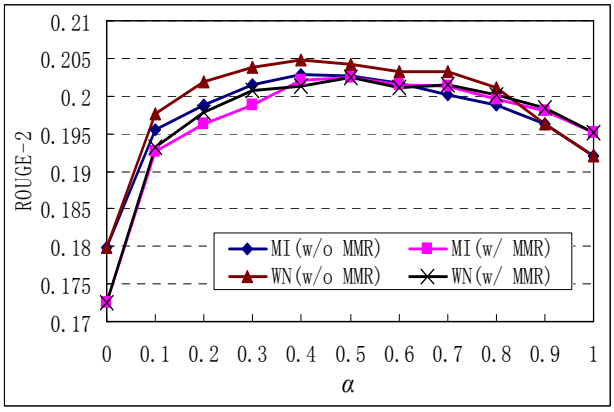

Figure 3. ROUGE-2 vs. α

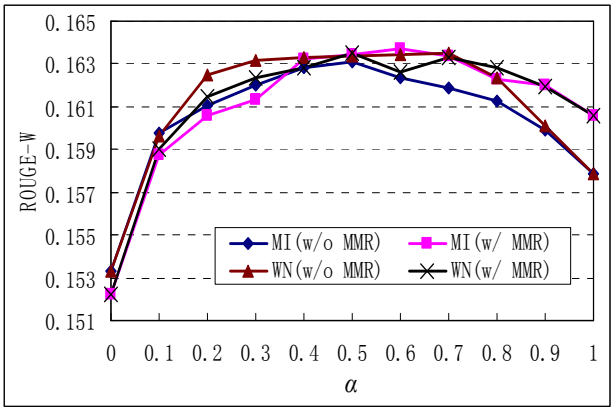

Figure 4. ROUGE-W vs. α

Seen from Figures 2-4, no matter whether the MMR algorithm is applied or not (i.e. w/o MMR or w/ MMR), the ROUGE scores based on either word semantic measure (MI or WN) achieves the peak when α is set between 0.4 and 0.6. The performance values decrease sharply when α is very large (near to 1) or very small (near to 0). The curves demonstrate that both the contribution from the sentences and the contribution from the words are important for ranking sentences; moreover, the contributions are almost equally important. Loss of either contribution will much deteriorate the final performance.

Similar results and observations have been obtained on task 1 of DUC2001 in our study and the details are omitted due to page limit.

4.2 Keyword Evaluation

4.1.1 Evaluation Setup

In this study we performed a preliminary evaluation of keyword extraction. The evaluation was conducted on the single word level instead of the multi-word phrase (n-gram) level, in other words, we compared the automatically extracted unigrams (words) and the manually labeled unigrams (words). The reasons were that: 1) there existed partial matching between phrases and it was not trivial to define an accurate measure to evaluate phrase quality; 2) each phrase was in fact composed of a few words, so the keyphrases could be obtained by combining the consecutive keywords.

We used 34 documents in the first five document clusters in DUC2002 dataset (i.e. d061-d065). At most 10 salient words were manually labeled for each document to represent the document and the average number of manually assigned keywords was 6.8. Each approach returned 10 words with highest saliency scores as the keywords. The extracted 10 words were compared with the manually labeled keywords. The words were converted to their corresponding basic forms based on WordNet before comparison. The precision p, recall r, F-measure (F=2pr/(p+r)) were obtained for each document and then the values were averaged over all documents for evaluation purpose.

4.1.2 Evaluation Results

Table 3 gives the comparison results. The proposed approaches are compared with two baselines: WordRank and MutualRank. WordRank is proposed in Mihalcea and Tarau (2004) to make use of only the co-occurrence relationships between words to rank words, which outperforms traditional keyword extraction methods. The window size k for WordRank is also set to 2, 5 and 10, respectively.

System	Precision	Recall	F-measure
Our Approach (WN)	0.413	**0.504**	0.454
Our Approach (MI:k=2)	**0.428**	0.485	0.455
Our Approach (MI:k=5)	0.425	0.491	**0.456**
Our Approach (MI:k=10)	0.393	0.455	0.422
WordRank (k=2)	0.373	0.412	0.392
WordRank (k=5)	0.368	0.422	0.393
WordRank (k=10)	0.379	0.407	0.393
MutualRank	0.355	0.397	0.375

Table 3. The Performance of Keyword Extraction

Seen from the table, the proposed approaches significantly outperform the baseline approaches. Both the corpus-based measure (MI) and the knowledge-based measure (WN) perform well on the task of keyword extraction.

A running example is given below to demonstrate the results:

Document ID: *D062/AP891018-0301*

Labeled keywords:

insurance earthquake insurer damage california Francisco pay

Extracted keywords:

WN: *insurance earthquake insurer quake california spokesman cost million wednesday damage*

MI(k=5): *insurance insurer earthquake percent benefit california property damage estimate rate*

5 Conclusion and Future Work

In this paper we propose a novel approach to simultaneously document summarization and keyword extraction for single documents by fusing the sentence-to-sentence, word-to-word, sentence-to-word relationships in a unified framework. The semantics between words computed by either corpus-based approach or knowledge-based approach can be incorporated into the framework in a natural way. Evaluation results demonstrate the performance improvement of the proposed approach over the baselines for both tasks.

In this study, only the mutual information measure and the *vector* measure are employed to compute word semantics, and in future work many other measures mentioned earlier will be investigated in the framework in order to show the robustness of the framework. The evaluation of keyword extraction is preliminary in this study, and we will conduct more thorough experiments to make the results more convincing. Furthermore, the proposed approach will be applied to multi-document summarization and keyword extraction, which are considered more difficult than single document summarization and keyword extraction.

Abstract

We describe a novel neural network architecture for the problem of *semantic role labeling*. Many current solutions are complicated, consist of several stages and hand-built features, and are too slow to be applied as part of real applications that require such semantic labels, partly because of their use of a syntactic parser (Pradhan et al., 2004; Gildea and Jurafsky, 2002). Our method instead learns a direct mapping from source sentence to semantic tags for a given predicate without the aid of a parser *or* a chunker. Our resulting system obtains accuracies comparable to the current state-of-the-art at a fraction of the computational cost.

1 Introduction

Semantic understanding plays an important role in many end-user applications involving text: for information extraction, web-crawling systems, question and answer based systems, as well as machine translation, summarization and search. Such applications typically have to be *computationally cheap* to deal with an enormous quantity of data, e.g. web-based systems process large numbers of documents, whilst interactive human-machine applications require almost instant response. Another issue is the cost of producing labeled training data required for statistical models, which is exacerbated when those models also depend on syntactic features which must themselves be learnt.

To achieve the goal of semantic understanding, the current consensus is to divide and conquer the problem. Researchers tackle several layers of processing tasks ranging from the syntactic, such as part-of-speech labeling and parsing, to the semantic: word-sense disambiguation, semantic role-labeling, named entity extraction, co-reference resolution and entailment. None of these tasks are end goals in themselves but can be seen as layers of feature extraction that can help in a language-based end application, such as the ones described above. Unfortunately, the state-of-the-art solutions of many of these tasks are simply too slow to be used in the applications previously described. For example, state-of-the-art syntactic parsers theoretically have cubic complexity in the sentence length (Younger, 1967)[1] and several semantic extraction algorithms use the parse tree as an initial feature.

[The company]$_{\text{ARG0}}$ [bought]$_{\text{REL}}$ [sugar]$_{\text{ARG1}}$ [on the world market]$_{\text{ARGM-LOC}}$ [to meet export commitments]$_{\text{ARGM-PNC}}$

Figure 1: Example of *Semantic Role Labeling* from the PropBank dataset (Palmer et al., 2005). ARG0 is typically an actor, REL an action, ARG1 an object, and ARGM describe various modifiers such as location (LOC) and purpose (PNC).

In this work, we describe a novel type of neural network architecture that could help to solve some of these issues. We focus our experimental study on the *semantic role labeling* problem (Palmer et al., 2005): being able to give a semantic role to a syn-

[1] Even though some parsers effectively exhibit linear behavior in sentence length (Ratnaparkhi, 1997), fast statistical parsers such as (Henderson, 2004) still take around 1.5 seconds for sentences of length 35 in tests that we made.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 560–567,
Prague, Czech Republic, June 2007.

tactic constituent of a sentence, i.e. annotating the predicate argument structure in text (see for example Figure 1). Because of its nature, role labeling seems to require the syntactic analysis of a sentence before attributing semantic labels. Using this intuition, state-of-the-art systems first build a *parse tree*, and syntactic constituents are then labeled by feeding hand-built features extracted from the parse tree to a machine learning system, e.g. the ASSERT system (Pradhan et al., 2004). This is rather slow, taking a few seconds per sentence at test time, partly because of the parse tree component, and partly because of the use of Support Vector Machines (Boser et al., 1992), which have linear complexity in testing time with respect to the number of training examples. This makes it hard to apply this method to interesting end user applications.

Here, we propose a radically different approach that avoids the more complex task of building a full parse tree. From a machine learning point of view, a human does not need to be taught about parse trees to talk. It is possible, however, that our brains may implicitly learn features highly correlated with those extracted from a parse tree. We propose to develop an architecture that implements this kind of implicit learning, rather than using explicitly engineered features. In practice, our system also provides semantic tags at a fraction of the computational cost of other methods, taking on average 0.02 seconds to label a sentence from the Penn Treebank, with almost no loss in accuracy.

The rest of the article is as follows. First, we describe the problem of shallow semantic parsing in more detail, as well as existing solutions to this problem. We then detail our algorithmic approach – the neural network architecture we employ – followed by experiments that evaluate our method. Finally, we conclude with a summary and discussion of future work.

2 Shallow Semantic Parsing

FrameNet (Baker et al., 1998) and the Proposition Bank (Palmer et al., 2005), or PropBank for short, are the two main systems currently developed for semantic role-labeling annotation. We focus here on PropBank. PropBank encodes role labels by semantically tagging the syntactic structures of hand annotated parses of sentences. The current version of the dataset gives semantic tags for the same sentences as in the Penn Treebank (Marcus et al., 1993), which are excerpts from the Wall Street Journal. The central idea is that each verb in a sentence is labeled with its propositional arguments, where the abstract numbered arguments are intended to fill typical roles. For example, ARG0 is typically the actor, and ARG1 is typically the thing acted upon. The precise usage of the numbering system is labeled for each particular verb as so-called frames. Additionally, semantic roles can also be labeled with one of 13 ARGM adjunct labels, such as ARGM-LOC or ARGM-TMP for additional locational or temporal information relative to some verb.

Shallow semantic parsing has immediate applications in tasks such as meta-data extraction (e.g. from web documents) and question and answer based systems (e.g. call center systems), amongst others.

3 Previous Work

Several authors have already attempted to build machine learning approaches for the semantic role-labeling problem. In (Gildea and Jurafsky, 2002) the authors presented a statistical approach to learning (for FrameNet), with some success. They proposed to take advantage of the syntactic tree structure that can be predicted by a parser, such as Charniak's parser (Charniak, 2000). Their aim is, given a node in the parse tree, to assign a semantic role label to the words that are the children of that node. They extract several key types of features from the parse tree to be used in a statistical model for prediction. These same features also proved crucial to subsequent approaches, e.g. (Pradhan et al., 2004). These features include:

- The parts of speech and syntactic labels of words and nodes in the tree.
- The node's position (left or right) in relation to the verb.
- The syntactic path to the verb in the parse tree.
- Whether a node in the parse tree is part of a noun or verb phrase (by looking at the parent nodes of that node).

- The voice of the sentence: active or passive (part of the PropBank gold annotation);

as well as several other features (predicate, head word, verb sub-categorization, ...).

The authors of (Pradhan et al., 2004) used a similar structure, but added more features, notably head word part-of-speech, the predicted named entity class of the argument, word sense disambiguation of the verb and verb clustering, and others (they add 25 variants of 12 new feature types overall.) Their system also uses a parser, as before, and then a polynomial Support Vector Machine (SVM) (Boser et al., 1992) is used in two further stages: to classify each node in the tree as being a semantic argument or not for a given verb; and then to classify each semantic argument into one of the classes (ARG1, ARG2, etc.). The first SVM solves a two-class problem, the second solves a multi-class problem using a one-vs-the-rest approach. The final system, called ASSERT, gives state-of-the-art performance and is also freely available at: `http://oak.colorado.edu/assert/`. We compare to this system in our experimental results in Section 5. Several other competing methods exist, e.g. the ones that participated in the CONLL 2004 and 2005 challenges (`http://www.lsi.upc.edu/~srlconll/st05/st05.html`). In this paper we focus on a comparison with ASSERT because software to re-run it is available online. This also gives us a timing result for comparison purposes.

The three-step procedure used in ASSERT (calculating a parse tree and then applying SVMs twice) leads to good classification performance, but has several drawbacks. First in speed: predicting a parse tree is extremely demanding in computing resources. Secondly, choosing the features necessary for SVM classification requires extensive research. Finally, the SVM classification algorithm used in existing approaches is rather slow: SVM training is at least quadratic in time with respect to the number of training examples. The number of support vectors involved in the SVM decision function also increases linearly with the number of training examples. This makes SVMs slow on large-scale problems, both during training and testing phases.

To alleviate the burden of parse tree computation, several attempts have been made to remove the full parse tree information from the semantic role labeling system, in fact the shared task of CONLL 2004 was devoted to this goal, but the results were not completely satisfactory. Previously, in (Gildea and Palmer, 2001), the authors tried to show that the parse tree is necessary for good generalization by showing that segments derived from a shallow syntactic parser *or* chunker do not perform as well for this goal. A further analysis of using chunkers, with improved results was also given in (Punyakanok et al., 2005), but still concluded the full parse tree is most useful.

4 Neural Network Architecture

Ideally, we want an end-to-end *fast* learning system to output semantic roles for syntactic constituents without using a time consuming parse tree.

Also, as explained before, we are interesting in exploring whether machine learning approaches can learn structure implicitly. Hence, even if there is a deep relationship between syntax and semantics, we prefer to avoid hand-engineered features that exploit this, and see if we can develop a model that can learn these features instead. We are thus not interested in chunker-based techniques, even though they are faster than parser-based techniques.

We propose here a *neural network based architecture* which achieves these two goals.

4.1 Basic Architecture

The type of neural network that we employ is a Multi Layer Perceptron (MLP). MLPs have been used for many years in the machine learning field and slowly abandoned for several reasons: partly because of the difficulty of solving the non-convex optimization problems associated with learning (LeCun et al., 1998), and partly because of the difficulty of their theoretical analysis compared to alternative convex approaches.

An MLP works by successively projecting the data to be classified into different spaces. These projections are done in what is called *hidden layers*. Given an input vector $\boldsymbol{z}$, a hidden layer applies a linear transformation (matrix M) followed by a squashing function h:

$$\boldsymbol{z} \mapsto M\boldsymbol{z} \mapsto h(M\boldsymbol{z})\,. \qquad (1)$$

A typical squashing function is the hyperbolic tangent $h(\cdot) = \tanh(\cdot)$. The last layer (the output layer) linearly separates the classes. The composition of the projections in the hidden layers could be viewed as the work done by the kernel in SVMs. However there is a very important difference: the kernel in SVM is fixed and arbitrarily chosen, while the hidden layers in an MLP are *trained* and *adapted* to the classification task. This allows us to create much more flexible classification architectures.

Our method for semantic role labeling classifies each word of a sentence separately. We do not use any semantic constituent information: if the model is powerful enough, words in the same semantic constituent should have the same class label. This means we also do not separate the problem into an identification and classification phase, but rather solve in a single step.

4.1.1 Notation

We represent words as indices. We consider a finite dictionary of words $\mathcal{D} \subset \mathbb{N}$. Let us represent a sentence of n_w words to be analyzed as a function $s(\cdot)$. The i^{th} word in the sentence is given by the index $s(i)$:

$$1 \leq i \leq n_w \quad s(i) \in \mathcal{D}\,.$$

We are interested in predicting the semantic role label of the word at position pos_w, given a verb at position pos_v ($1 \leq pos_w, pos_v \leq n_w$). A mathematical description of our network architecture schematically shown in Figure 2 follows.

4.1.2 Transforming words into feature vectors

Our first concern in semantic role labeling is that we have to deal with words, and that a simple index $i \in \mathcal{D}$ does not carry any information specific to a word: for each word we need a set of features relevant for the task. As described earlier, previous methods construct a parse tree, and then compute hand-built features which are then fed to a classification algorithm. In order to bypass the use of a parse tree, we convert each word $i \in \mathcal{D}$ into a particular vector $\boldsymbol{w}_i \in \mathbb{R}^d$ *which is going to be learnt* for the task we are interested in. This approach has already been used with great success in the domain of language models (Bengio and Ducharme, 2001; Schwenk and Gauvain, 2002).

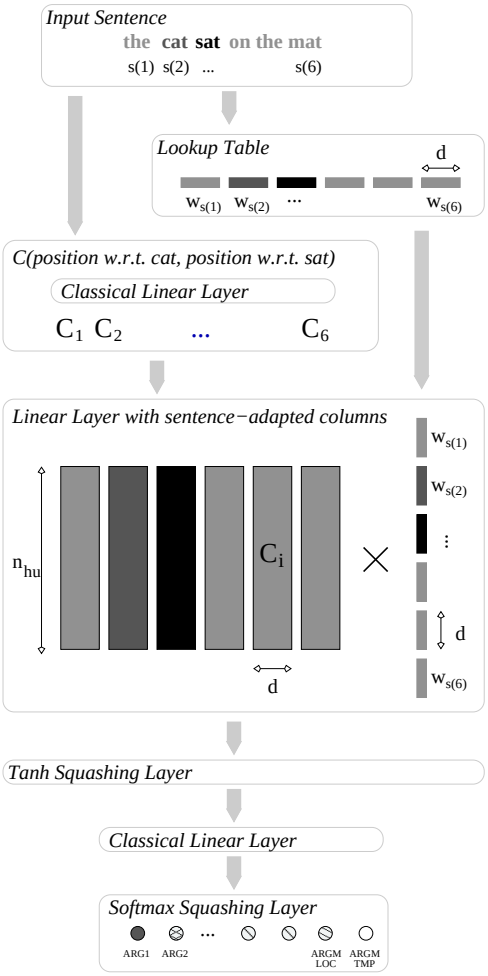

Figure 2: MLP architecture for shallow semantic parsing. The input sequence is at the top. The output class probabilities for the word of interest ("cat") given the verb of interest ("sat") are given at the bottom.

The first layer of our MLP is thus a lookup table which replaces the word indices into a concatenation of vectors:

$$\begin{aligned}\{s(1), \ldots, s(n_w)\} \\ \mapsto (\boldsymbol{w}_{s(1)} \ \ldots \ \boldsymbol{w}_{s(n_w)}) \in \mathbb{R}^{n_w\, d}\,.\end{aligned} \tag{2}$$

The weights $\{\boldsymbol{w}_i \,|\, i \in \mathcal{D}\}$ for this layer are considered during the backpropagation phase of the MLP, and thus adapted automatically for the task we are interested in.

4.1.3 Integrating the verb position

Feeding word vectors alone to a linear classification layer as in (Bengio and Ducharme, 2001) leads

to very poor accuracy because the semantic classification of a given word also depends on the verb in question. We need to provide the MLP with information about the verb position within the sentence. For that purpose we use a kind of linear layer which is *adapted* to the sentence considered. It takes the form:

$$(\boldsymbol{w}_{s(1)} \ \dots \ \boldsymbol{w}_{s(n_w)}) \mapsto M \begin{pmatrix} \boldsymbol{w}_{s(1)}^{\mathrm{T}} \\ \vdots \\ \boldsymbol{w}_{s(n_w)}^{\mathrm{T}} \end{pmatrix} ,$$

where $M \in \mathbb{R}^{n_{hu} \times n_w \, d}$, and n_{hu} is the number of hidden units. The specific nature of this layer is that the matrix M has a special block-column form which depends on the sentence:

$$M = (C_1 | \dots | C_{n_w}) ,$$

where each column $C_i \in \mathbb{R}^{n_{hu} \times d}$ depends on the position of the i^{th} word in $s(\cdot)$, with respect to the position pos_w of the word of interest, and with respect to the position pos_v of the verb of interest:

$$C_i = \mathcal{C}(i - pos_w, \, i - pos_v) ,$$

where $\mathcal{C}(\cdot, \cdot)$ is a function to be chosen.

In our experiments $\mathcal{C}(\cdot, \cdot)$ was a linear layer with discretized inputs $(i - pos_w, \, i - pos_v)$ which were transformed into two binary vectors of size wsz, where a bit is set to 1 if it corresponds to the position to encode, and 0 otherwise. These two binary vectors are then concatenated and fed to the linear layer. We chose the "window size" $wsz = 11$. If a position lies outside the window, then we still set the leftmost or rightmost bit to 1. The parameters involved in this function are also considered during the backpropagation. With such an architecture we allow our MLP to automatically adapt the importance of a word in the sentence given its distance to the word we want to classify, and to the verb we are interested in.

This idea is the major novelty in this work, and is crucial for the success of the entire architecture, as we will see in the experiments.

4.1.4 Learning class probabilities

The last layer in our MLP is a classical linear layer as described in (1), with a *softmax* squashing function (Bridle, 1990). Considering (1) and given $\tilde{\boldsymbol{z}} = M\boldsymbol{z}$, we have

$$h_i(\tilde{\boldsymbol{z}}) = \frac{\exp \tilde{z}_i}{\sum_j \exp \tilde{z}_j} .$$

This allows us to interpret outputs as probabilities for each semantic role label. The training of the whole system is achieved using a normal stochastic gradient descent.

4.2 Word representation

As we have seen, in our model we are *learning* one d dimensional vector to represent each word. If the dataset were large enough, this would be an elegant solution. In practice many words occur infrequently within PropBank, so (independent of the size of d) we can still only learn a very poor representation for words that only appear a few times. Hence, to control the capacity of our model we take the original word and replace it with its part-of-speech if it is a verb, noun, adjective, adverb or number as determined by a part-of-speech classifier, and keep the words for all other parts of speech. This classifier is itself a neural network. This way we keep linking words which are important for this task. We do not do this replacement for the predicate itself.

5 Experiments

We used Sections 02-21 of the PropBank dataset version 1 for training and validation and Section 23 for testing as standard in all our experiments. We first describe the part-of-speech tagger we employ, and then describe our semantic role labeling experiments. Software for our method, SENNA (Semantic Extraction using a Neural Network Architecture), more details on its implementation, an online applet and test set predictions of our system in comparison to ASSERT can be found at `http://ml.nec-labs.com/software/senna`.

Part-Of-Speech Tagger The part-of-speech classifier we employ is a neural network architecture of the same type as in Section 4, where the function $C_i = C(i - pos_w)$ depends now only on the word position, and not on a verb. More precisely:

$$C_i = \begin{cases} 0 & \text{if } 2\,|i - pos_w| > wsz - 1 \\ W_{i - pos_w} & \text{otherwise} , \end{cases}$$

where $W_k \in \mathbb{R}^{n_{hu} \times d}$ and wsz is a window size. We chose $wsz = 5$ in our experiments. The d-dimensional vectors learnt take into account the capitalization of a word, and the prefix and suffix calculated using Porter-Stemmer. See `http://ml.nec-labs.com/software/senna` for more details. We trained on the training set of PropBank supplemented with the Brown corpus, resulting in a test accuracy on the test set of PropBank of 96.85% which compares to 96.66% using the Brill tagger (Brill, 1992).

Semantic Role Labeling In our experiments we considered a 23-class problem of NULL (no label), the core arguments ARG0-5, REL, ARGA, and ARGM- along with the 13 secondary modifier labels such as ARGM-LOC and ARGM-TMP. We simplified R-ARGn and C-ARGn to be written as ARGn, and post-processed ASSERT to do this as well.

We compared our system to the freely available ASSERT system (Pradhan et al., 2004). Both systems are fed only the input sentence during testing, with traces removed, so they cannot make use of many PropBank features such as frameset identitifier, person, tense, aspect, voice, and form of the verb. As our algorithm outputs a semantic tag for each word of a sentence, we directly compare this per-word accuracy with ASSERT. Because ASSERT uses a parser, and because PropBank was built by labeling the nodes of a hand-annotated parse tree, per-node accuracy is usually reported in papers such as (Pradhan et al., 2004). Unfortunately our approach is based on a completely different premise: we tag words, not syntactic constituents coming from the parser. We discuss this further in Section 5.2.

The per-word accuracy comparison results can be seen in Table 5. Before labeling the semantic roles of each predicate, one must first identify the predicates themselves. If a predicate is not identified, NULL tags are assigned to each word for that predicate. The first line of results in the table takes into account this identification process. For the neural network, we used our part-of-speech tagger to perform this as a verb-detection task.

We noticed ASSERT failed to identify relatively many predicates. In particular, it seems predicates such as "is" are sometimes labeled as AUX by the part-of-speech tagger, and subsequently ignored. We informed the authors of this, but we did not receive a response. To deal with this, we considered the additional accuracy (second row in the table) measured over only those sentences where the predicate was identified by ASSERT.

Timing results The per-sentence compute time is also given in Table 5, averaged over all sentences in the test set. Our method is around 250 times faster than ASSERT. It is not really feasible to run ASSERT for most applications.

Measurement	NN	ASSERT
Per-word accuracy (all verbs)	83.64%	83.46%
Per-word accuracy (ASSERT verbs)	84.09%	86.06%
Per-sentence compute time (secs)	0.02 secs	5.08 secs

Table 1: Experimental comparison with ASSERT

5.1 Analysis of our MLP

While we gave an intuitive justification of the architecture choices of our model in Section 4, we now give a systematic empirical study of those choices. First of all, providing the position of the word *and* the predicate in function $C(\cdot, \cdot)$ is essential: the best model we obtained with a window around the word only gave 51.3%, assuming correct identification of all predicates. Our best model achieves 83.95% in this setting.

If we do not cluster the words according to their part-of-speech, we also lose some performance, obtaining 78.6% at best. On the other hand, clustering *all* words (such as CC, DT, IN part-of-speech tags) also gives weaker results (81.1% accuracy at best). We believe that including all words would give very good performance if the dataset was large enough, but training only on PropBank leads to overfitting, many words being infrequent. Clustering is a way to fight against overfitting, by grouping infrequent words: for example, words with the label NNP, JJ, RB (which we cluster) appear on average 23, 22 and 72 times respectively in the training set, while CC, DT, IN (which we do not cluster) appear 2420, 5659 and 1712 times respectively.

Even though some verbs are infrequent, one cannot cluster all verbs into a single group, as each verb dictates the types of semantic roles in the sentence, depending on its frame. Clustering all words into their part-of-speech, including the predicate, gives a poor 73.8% compared with 81.1%, where everything is clustered apart from the predicate.

Figure 3 gives some anecdotal examples of test set predictions of our final model compared to ASSERT.

5.2 Argument Classification Accuracy

So far we have not used the same accuracy measures as in previous work (Gildea and Jurafsky, 2002; Pradhan et al., 2004). Currently our architecture is designed to label on a per-word basis, while existing systems perform a segmentation process, and then label segments. While we do not optimize our model for the same criteria, it is still possible to measure the accuracy using the same metrics. We measured the argument classification accuracy of our network, assuming the correct segmentation is given to our system, as in (Pradhan et al., 2004), by post-processing our per-word tags to form a majority vote over each segment. This gives 83.18% accuracy for our network when we suppose the predicate must also be identified, and 80.53% for the ASSERT software. Measuring only on predicates identified by ASSERT we instead obtain 84.32% accuracy for our network, and 87.02% for ASSERT.

TRUTH: He camped out at a high-tech nerve center on the floor of [the Big Board, where]$_{\text{ARGM-LOC}}$ [he]$_{\text{ARG0}}$ [could]$_{\text{ARGM-MOD}}$ [watch]$_{\text{REL}}$ [updates on prices and pending stock orders]$_{\text{ARG1}}$.
ASSERT (68.7%): He camped out at a high-tech nerve center on the floor of the Big Board, [where]$_{\text{ARGM-LOC}}$ [he]$_{\text{ARG0}}$ [could]$_{\text{ARGM-MOD}}$ [watch]$_{\text{REL}}$ [updates]$_{\text{ARG1}}$ on prices and pending stock orders.
NN (100%): He camped out at a high-tech nerve center on the floor of [the Big Board, where]$_{\text{ARGM-LOC}}$ [he]$_{\text{ARG0}}$ [could]$_{\text{ARGM-MOD}}$ [watch]$_{\text{REL}}$ [updates on prices and pending stock orders]$_{\text{ARG1}}$.

TRUTH: [United Auto Workers Local 1069, which]$_{\text{ARG0}}$ [represents]$_{\text{REL}}$ [3,000 workers at Boeing's helicopter unit in Delaware County, Pa.]$_{\text{ARG1}}$, said it agreed to extend its contract on a day-by-day basis, with a 10-day notification to cancel, while it continues bargaining.
ASSERT (100%): [United Auto Workers Local 1069, which]$_{\text{ARG0}}$ [represents]$_{\text{REL}}$ [3,000 workers at Boeing's helicopter unit in Delaware County, Pa.]$_{\text{ARG1}}$, said it agreed to extend its contract on a day-by-day basis, with a 10-day notification to cancel, while it continues bargaining.
NN (89.1%): [United Auto Workers Local 1069, which]$_{\text{ARG0}}$ [represents]$_{\text{REL}}$ [3,000 workers at Boeing's helicopter unit]$_{\text{ARG1}}$ [in Delaware County]$_{\text{ARGM-LOC}}$, Pa. , said it agreed to extend its contract on a day-by-day basis, with a 10-day notification to cancel, while it continues bargaining.

Figure 3: Two examples from the PropBank test set, showing Neural Net and ASSERT and gold standard labelings, with per-word accuracy in brackets. Note that even though our labeling does not match the hand-annotated one in the second sentence it still seems to make some sense as "in Delaware County" is labeled as a location modifier. The complete set of predictions on the test set can be found at `http://ml.nec-labs.com/software/senna`.

6 Discussion

We have introduced a neural network architecture that can provide computationally efficient semantic role tagging. It is also a general architecture that could be applied to other problems as well. Because our network currently outputs labels on a per-word basis it is difficult to assess existing accuracy measures. However, it should be possible to combine our approach with a shallow parser to enhance performance, and make comparisons more direct.

We consider this work as a starting point for different research directions, including the following areas:

- *Incorporating hand-built features* Currently, the only prior knowledge our system encodes comes from part-of-speech tags, in stark contrast to other methods. Of course, performance would improve with more hand-built features. For example, simply adding whether each word is part of a noun or verb phrase using the hand-annotated parse tree (the so-called "GOV" feature from (Gildea and Jurafsky, 2002)) improves the performance of our system from 83.95% to 85.8%. One must trade the generality of the model with its specificity, and also take into account how long the features take to compute.

- *Incorporating segment information* Our system has no prior knowledge about segmentation in text. This could be encoded in many ways: most obviously by using a chunker, but also by

designing a different network architecture, e.g. by encoding contiguity constraints. To show the latter is useful, using hand-annotated segments to force contiguity by majority vote leads to an improvement from 83.95% to 85.6%.

- *Incorporating known invariances via virtual training data.* In image recognition problems it is common to create artificial training data by taking into account invariances in the images, e.g. via rotation and scale. Such data improves generalization substantially. It may be possible to achieve similar results for text, by "warping" training data to create new sentences, or by constructing sentences from scratch using a hand-built grammar.

- *Unlabeled data.* Our representation of words is as d dimensional vectors. We could try to improve this representation by learning a language model from unlabeled data (Bengio and Ducharme, 2001). As many words in PropBank only appear a few times, the representation might improve, even though the learning is unsupervised. This may also make the system generalize better to types of data other than the Wall Street Journal.

- *Transductive Inference.* Finally, one can also use unlabeled data as part of the supervised training process, which is called transduction or semi-supervised learning.

In particular, we find the possibility of using unlabeled data, invariances and the use of transduction exciting. These possibilities naturally fit into our framework, whereas scalability issues will limit their application in competing methods.

Improving the Interpretation of Noun Phrases with Cross-linguistic Information

Roxana Girju
University of Illinois at Urbana-Champaign
girju@uiuc.edu

Abstract

This paper addresses the automatic classification of semantic relations in noun phrases based on cross-linguistic evidence from a set of five Romance languages. A set of novel semantic and contextual English–Romance NP features is derived based on empirical observations on the distribution of the syntax and meaning of noun phrases on two corpora of different genre (Europarl and CLUVI). The features were employed in a Support Vector Machines algorithm which achieved an accuracy of 77.9% (Europarl) and 74.31% (CLUVI), an improvement compared with two state-of-the-art models reported in the literature.

1 Introduction

Semantic knowledge is very important for any application that requires a deep understanding of natural language. The automatic acquisition of semantic information in text has become increasingly important in ontology development, information extraction, question answering, and other advanced natural language processing applications.

In this paper we present a model for the automatic semantic interpretation of noun phrases (NPs), which is the task of determining the semantic relation among the noun constituents. For example, *family estate* encodes a POSSESSION relation, while *dress of silk* refers to PART-WHOLE. The problem, while simple to state is hard to solve. The reason is that the meaning of these constructions is most of the time ambiguous or implicit. Interpreting NPs correctly requires various types of information from world knowledge to complex context features. Moreover, the extension of this task to other natural languages brings forward new issues and problems. For instance, *beer glass* translates into *tarro de cerveza* in Spanish, *bicchiere da birra* in Italian, *verre à bière* in French, and *pahar de bere* in Romanian. Thus, an important research question is how do the syntactic constructions in the target language contribute to the preservation of meaning in context.

In this paper we investigate noun phrases based on cross-linguistic evidence and present a domain independent model for their semantic interpretation. We aim at uncovering the general aspects that govern the semantics of NPs in English based on a set of five Romance languages: Spanish, Italian, French, Portuguese, and Romanian. The focus on Romance languages is well motivated. It is mostly true that English noun phrases translate into constructions of the form *N P N* in Romance languages where, as we will show below, the *P* (preposition) varies in ways that correlate with the semantics. Thus Romance languages will give us another source of evidence for disambiguating the semantic relations in English NPs. We also present empirical observations on the distribution of the syntax and meaning of noun phrases on two different corpora based on two state-of-the-art classification tag sets: Lauer's set of 8 prepositions (Lauer, 1995) and our list of 22 semantic relations. We show that various crosslingual cues can help in the NP interpretation task when employed in an SVM model. The results are compared against two state of the art approaches: a su-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 568–575,
Prague, Czech Republic, June 2007.

pervised machine learning model, Semantic Scattering (Moldovan and Badulescu, 2005), and a web-based probabilistic model (Lapata and Keller, 2004).

The paper is organized as follows. In Section 2 we present a summary of the previous work. Section 3 lists the syntactic and semantic interpretation categories used along with observations regarding their distribution on the two different cross-lingual corpora. Sections 4 and 5 present a learning model and results for the interpretation of English noun phrases. Finally, in Section 6 we offer some discussion and conclusions.

2 Related Work

Currently, the best-performing NP interpretation methods in computational linguistics focus mostly on two consecutive noun instances (noun compounds) and rely either on rather ad-hoc, domain-specific semantic taxonomies, or on statistical models on large collections of unlabeled data. Recent results have shown that symbolic noun compound interpretation systems using machine learning techniques coupled with a large lexical hierarchy perform with very good accuracy, but they are most of the time tailored to a specific domain (Rosario and Hearst, 2001). On the other hand, the majority of corpus statistics approaches to noun compound interpretation collect statistics on the occurrence frequency of the noun constituents and use them in a probabilistic model (Lauer, 1995). More recently, (Lapata and Keller, 2004) showed that simple unsupervised models perform significantly better when the frequencies are obtained from the web, rather than from a large standard corpus. Other researchers (Pantel and Pennacchiotti, 2006), (Snow et al., 2006) use clustering techniques coupled with syntactic dependency features to identify IS-A relations in large text collections. (Kim and Baldwin, 2006) and (Turney, 2006) focus on the lexical similarity of unseen noun compounds with those found in training.

However, although the web-based solution might overcome the data sparseness problem, the current probabilistic models are limited by the lack of deep linguistic information. In this paper we investigate the role of cross-linguistic information in the task of English NP semantic interpretation and show the importance of a set of novel linguistic features.

3 Corpus Analysis

For a better understanding of the meaning of the N N and N P N instances, we analyzed the semantic behavior of these constructions on a large cross-linguistic corpora of examples. We are interested in what syntactic constructions are used to translate the English instances to the target Romance languages and vice-versa, what semantic relations do these constructions encode, and what is the corpus distribution of the semantic relations.

3.1 Lists of semantic classification relations

Although the NP interpretation problem has been studied for a long time, researchers haven't agreed on the number and the level of abstraction of these semantic categories. They can vary from a few prepositions (Lauer, 1995) to hundreds or thousands specific semantic relations (Finin, 1980). The more abstract the categories, the more noun phrases are covered, but also the more room for variation as to which category a phrase should be assigned.

In this paper we experiment with two state of the art classification sets used in NP interpretation. The first is a core set of 22 semantic relations (22 SRs) identified by us from the computational linguistics literature. This list, presented in Table 1 along with examples is general enough to cover a large majority of text semantics while keeping the semantic relations to a manageable number. The second set is Lauer's list of 8 prepositions (8 PP) and can be applied only to noun compounds (*of, for, with, in, on, at, about*, and *from* – e.g., according to this classification, *love story* can be classified as *story* `about` *love*). We selected these sets as they are of different size and contain semantic classification categories at different levels of abstraction. Lauer's list is more abstract and, thus capable of encoding a large number of noun compound instances, while the 22-SR list contains finer grained semantic categories. We show below the coverage of these semantic lists on two different corpora and how well they solve the interpretation problem of noun phrases.

3.2 The data

The data was collected from two text collections with different distributions and of different genre,

POSSESSION (family estate); KINSHIP (sister of the boy); PROPERTY (lubricant viscosity); AGENT (return of the natives); THEME (acquisition of stock); TEMPORAL (morning news); DEPICTION-DEPICTED (a picture of my niece); PART-WHOLE (brush hut); HYPERNYMY (IS-A) (daisy flower); CAUSE (scream of pain); MAKE/PRODUCE (chocolate factory); INSTRUMENT (laser treatment); LOCATION (castle in the desert); PURPOSE (cough syrup); SOURCE (grapefruit oil); TOPIC (weather report); MANNER (performance with passion); beneficiary (rights of citizens); MEANS (bus service); EXPERIENCER (fear of the girl); MEASURE (cup of sugar); TYPE (framework law);

Table 1: The list of 22 semantic relations (22-SRs).

Europarl[1] and CLUVI[2]. The Europarl data was assembled by combining the Spanish-English, Italian-English, French-English and Portuguese-English corpora which were automatically aligned based on exact matches of English translations. Then, we considered only the English sentences which appeared verbatim in all four language pairs. The resulting English corpus contained 10,000 sentences which were syntactically parsed (Charniak, 2000). From these we extracted the first 3,000 NP instances (N N: 48.82% and N P N: 51.18%).

CLUVI is an open text repository of parallel corpora of contemporary oral and written texts in some of the Romance languages. Here, we focused only on the English-Portuguese and English-Spanish parallel texts from the works of John Steinbeck, H. G. Wells, J. Salinger, and others. Using the CLUVI search interface we created a sentence-aligned parallel corpus of 2,800 English-Spanish and English-Portuguese sentences. The English versions were automatically parsed after which each N N and N P N instance thus identified was manually mapped to the corresponding translations. The resulting corpus contains 2,200 English instances with a distribution of 26.77% N N and 73.23% N P N.

3.3 Corpus Annotation

For each corpus, each NP instance was presented separately to two experienced annotators in a web interface in context along with the English sentence and its translations. Since the corpora do not cover some of the languages (Romanian in Europarl and CLUVI, and Italian and French in CLUVI), three other native speakers of these languages and fluent in English provided the translations which were added to the list. The two computational semantics annotators had to tag each English constituent noun with its corresponding WordNet sense and each instance with the corresponding semantic category. If the word was not found in WordNet the instance was not considered. Whenever the annotators found an example encoding a semantic category other than those provided or they didn't know what interpretation to give, they had to tag it as "OTHER-SR", and respectively "OTHER-PP"[3]. The details of the annotation task and the observations drawn from there are presented in a companion paper (Girju, 2007).

The corpus instances used in the corpus analysis phase have the following format: $<$NP$_{En}$;NP$_{Es}$; NP$_{It}$; NP$_{Fr}$; NP$_{Port}$; NP$_{Ro}$; target$>$. The word *target* is one of the 23 (22 + OTHER-SR) semantic relations and one of the eight prepositions considered or OTHER-PP (with the exception of those N P N instances that already contain a preposition). For example, $<$*development cooperation; cooperación para el desarrollo; cooperazione allo sviluppo; coopération au développement; cooperare pentru dezvoltare;* PURPOSE / FOR$>$.

The annotators' agreement was measured using Kappa statistics: $K = \frac{Pr(A)-Pr(E)}{1-Pr(E)}$, where $Pr(A)$ is the proportion of times the annotators agree and $Pr(E)$ is the probability of agreement by chance. The Kappa values were obtained on Europarl (N N: 0.80 for 8-PP and 0.61 for 22-SR; N P N: 0.67 for 22-SR) and CLUVI (N N: 0.77 for 8-PP and 0.56 for 22-SR; N P N: 0.68 for 22-SR). We also computed the number of pairs that were tagged with OTHER by both annotators for each semantic relation and preposition paraphrase, over the number of examples classified in that category by at least one of the judges (in Europarl: 91% for 8-PP and 78% for 22-SR; in CLUVI: 86% for 8-PP and 69% for 22-SR).

The agreement obtained on the Europarl corpus is

[1]http://www.isi.edu/koehn/europarl/. This corpus contains over 20 million words in eleven official languages of the European Union covering the proceedings of the European Parliament from 1996 to 2001.

[2]CLUVI - Linguistic Corpus of the University of Vigo - Parallel Corpus 2.1 - http://sli.uvigo.es/CLUVI/

[3]The annotated corpora resulted in this research is available at http://apfel.ai.uiuc.edu.

higher than the one on CLUVI on both classification sets. This is partially explained by the distribution of semantic relations in both corpora, as will be shown in the next subsection.

3.4 Cross-linguistic distribution of Syntactic Constructions

From the sets of 2,954 (Europarl) and 2,168 (CLUVI) instances resulted after annotation, the data show that over 83% of the translation patterns for both text corpora on all languages were of the type N N and N P N. However, while their distribution is balanced in the Europarl corpus (about 45%, with a 64% N P N – 26% N N ratio for Romanian), in CLUVI the N P N constructions occur in more than 85% of the cases (again, with the exception of Romanian – 50%). It is interesting to note here that some of the English NPs are translated into both noun–noun and noun–adjective compounds in the target languages. For example, *love affair* translates in Italian as *storia d'amore* or the noun–adjective compound *relazione amorosa*. There are also instances that have just one word correspondent in the target language (e.g., *ankle boot* is *bottine* in French). The rest of the data is encoded by other syntactic paraphrases (e.g., *bomb site* is *luogo dove è esplosa la bomba* (It.)). [4].

From the initial corpus we considered those English instances that had all the translations encoded only by N N and N P N. Out of these, we selected only 1,023 Europarl and 1,008 CLUVI instances encoded by N N and N P N in all languages considered and resulted after agreement.

4 Model

4.1 Feature space

We have identified and experimented with 13 NP features presented below. With the exceptions of features F1-F5 (Girju et al., 2005), all the other features are novel.

A. English Features

F1 and **F2.** *Noun semantic class* specifies the WordNet sense of the head (F1) and modifier noun (F2) and implicitly points to all its hypernyms. For example, the hypernyms of *car#1* are: {*motor vehicle*}, .. {*entity*}. This feature helps generalize over the semantic classes of the two nouns in the corpus.

F3 and **F4.** *WordNet derivationally related form* specifies if the head (F3) and the modifier (F4) nouns are related to a corresponding WordNet verb (e.g. *statement* derived from *to state*; *cry* from *to cry*).

F5. *Prepositional cues* that link the two nouns in an NP. These can be either simple or complex prepositions such as "*of*" or "*according to*". In case of N N instances, this feature is "–" (e.g., *framework law*).

F6 and F7. *Type of nominalized noun* indicates the specific class of nouns the head (F6) or modifier (F7) belongs to depending on the verb it derives from. First, we check if the noun is a nominalization. For English we used NomLex-Plus (Meyers et al., 2004) to map nouns to corresponding verbs.[5] For example, "*destruction of the city*", where *destruction* is a nominalization. F6 and F7 may overlap with features F3 and F4 which are used in case the noun to be checked does not have an entry in the NomLex-Plus dictionary. These features are of particular importance since they impose some constraints on the possible set of relations the instance can encode. They take the following values (identified based on list of verbs extracted from VerbNet (Kipper et al., 2000)):

a. Active form nouns which have an intrinsic active voice predicate-argument structure. (Giorgi and Longobardi, 1991) argue that in English this is a necessary restriction. Most of the time, they represent states of emotion, such as fear, desire, etc. These nouns mark their internal argument through *of* and require most of the time prepositions like *por* and not *de* when translated in Romance. Our observations on the Romanian translations (captured by features F12 and F13 below) show that the possible cases of ambiguity are solved by the type of syntactic construction used. For example, N N genitive-marked constructions are used for EXPERIENCER–encoding instances, while *N de N* or *N pentru N* (N for N) are used for other relations. Such examples are *the love of children* – THEME (and not *the love by the children*). (Giorgi and Longobardi, 1991) mention that with such nouns that resist passivisation,

[4] "*the place where the bomb is exploded*" (It.)

[5] NomLex-Plus is a hand-coded database of 5,000 verb nominalizations, de-adjectival, and de-adverbial nouns including the corresponding subcategorization frames (verb-argument structure information).

the preposition introducing the internal argument, even if it is *of*, has always a semantic content, and is not a bare case-marker realizing the genitive case.

b. Unaccusative (ergative) nouns which are derived from ergative verbs that take only internal arguments (e.g., not agentive ones). For example, the transitive verb *to disband* allows the subject to be deleted as in the following sentences (1) "*The lead singer disbanded the group in 1991.*" and (2) "*The group disbanded.*". Thus, the corresponding ergative nominalization *the disbandment of the group* encodes a THEME relation and not AGENT.

c. Unergative (intransitive) nouns are derived from intransitive verbs and take only AGENT semantic relations. For example, *the departure of the girl*.

d. Inherently passive nouns such as *the capture of the soldier*. These nouns, like the verbs they are derived from, assume a default AGENT (subject) and being transitive, associate to their internal argument (introduced by "of" in the example above) the THEME relation.

B. Romance Features

F8, F9, F10, F11 and **F12.** *Prepositional cues* that link the two nouns are extracted from each translation of the English instance: F8 (Es.), F9 (Fr.), F10 (It.), F11 (Port.), and F12 (Ro.). These can be either simple or complex prepositions (e.g., *de*, *in materia de* (Es.)) in all five Romance languages, or the Romanian genitival article *a/ai/ale*. In Romanian the genitive case is assigned by the definite article of the first noun to the second noun, case realized as a suffix if the second noun is preceded by the definite article or as one of the genitival articles *a/ai/ale*. For example, the noun phrase *the beauty of the girl* is translated as *frumuseţea fetei* (*beauty*-the *girl*-gen), and *the beauty of a girl* as *frumuseţea unei fete* (*beauty*-the gen *girl*). For N N instances, this feature is "–".

F13. *Noun inflection* is defined only for Romanian and shows if the modifier noun is inflected (indicates the genitive case). This feature is used to help differentiate between instances encoding IS-A and other semantic relations in N N compounds in Romanian. It also helps in features F6 and F7, case a) when the choice of syntactic construction reflects different semantic content. For example, *iubirea pentru copii* (N P N) (*the love for children*) and not *iubirea copiilor* (N N) (*love expressed by the children*).

4.2 Learning Models

We have experimented with the support vector machines (SVM) model[6] and compared the results against two state-of-the-art models: a supervised model, Semantic Scattering (SS), (Moldovan and Badulescu, 2005), and a web-based unsupervised model (Lapata and Keller, 2004). The SVM and SS models were trained and tested on the Europarl and CLUVI corpora using a 8:2 ratio. The test dataset was randomly selected from each corpus and the test nouns (only for English) were tagged with the corresponding sense in context using a state of the art WSD tool (Mihalcea and Faruque, 2004).

After the initial NP instances in the training and test corpora were expanded with the corresponding features, we had to prepare them for SVM and SS. The method consists of a set of automatic iterative procedures of specialization of the English nouns on the WordNet IS-A hierarchy. Thus, after a set of necessary specialization iterations, the method produces specialized examples which through supervised machine learning are transformed into sets of semantic rules. This specialization procedure improves the system's performance since it efficiently separates the positive and negative noun-noun pairs in the WordNet hierarchy.

Initially, the training corpus consists of examples in the format exemplified by the feature space. Note that for the English NP instances, each noun constituent was expanded with the corresponding WordNet top semantic class. At this point, the generalized training corpus contains two types of examples: unambiguous and ambiguous. The second situation occurs when the training corpus classifies the same noun – noun pair into more than one semantic category. For example, both relationships "*chocolate cake*"-PART-WHOLE and "*chocolate article*"-TOPIC are mapped into the more general type <*entity#1, entity#1,* PART-WHOLE/TOPIC>[7]. We recursively specialize these examples to eliminate the ambiguity. By specialization, the semantic class is replaced with the corresponding hyponym for that particular sense, i.e. the concept immediately below in the hierarchy. These steps are repeated until there are no

[6] We used the package LIBSVM with a radial-based kernel *http://www.csie.ntu.edu.tw/∼cjlin/libsvm/*

[7] The specialization procedure applies only to features 1, 2.

more ambiguous examples. For the example above, the specialization stops at the first hyponym of *entity*: *physical entity* (for *cake*) and *abstract entity* (for *article*). For the unambiguous examples in the generalized training corpus (those that are classified with a single semantic relation), constraints are determined using cross validation on SVM.

A. Semantic Scattering uses a training data set to establish a boundary G^* on WordNet noun hierarchies such that each feature pair of noun – noun senses f_{ij} on this boundary maps uniquely into one of a predefined list of semantic relations, and any feature pair above the boundary maps into more than one semantic relation. For any new pair of noun–noun senses, the model finds the closest WordNet boundary pair.

The authors define with $SC^m = \{f_i^m\}$ and $SC^h = \{f_j^h\}$ the sets of semantic class features for modifier noun and, respectively head noun. A pair of <modifier – head> nouns maps uniquely into a semantic class feature pair $< f_i^m, f_j^h >$, denoted as f_{ij}. The probability of a semantic relation *r* given feature pair f_{ij}, $P(r|f_{ij}) = \frac{n(r,f_{ij})}{n(f_{ij})}$, is defined as the ratio between the number of occurrences of a relation *r* in the presence of feature pair f_{ij} over the number of occurrences of feature pair f_{ij} in the corpus. The most probable semantic relation $\hat{r}$ is $\arg\max_{r \in R} P(r|f_{ij}) = \arg\max_{r \in R} P(f_{ij}|r)P(r)$.

B. (Lapata and Keller, 2004)'s web-based unsupervised model classifies noun - noun instances based on Lauer's list of 8 prepositions and uses the web as training corpus. They show that the best performance is obtained with the trigram model $f(n_1, p, n_2)$. The count used for a given trigram is the number of pages returned by Altavista on the trigram corresponding queries. For example, for the test instance *war stories*, the best number of hits was obtained with the query *stories about war*.

For the Europarl and CLUVI test sets, we replicated Lapata & Keller's experiments using Google[8]. We formed inflected queries with the patterns they proposed and searched the web.

[8]As Google limits the number of queries to 1,000 per day, we repeated the experiment for a number of days. Although (Lapata and Keller, 2004) used Altavista in their experiments, they showed there is almost no difference between the correlations achieved using Google and Altavista counts.

5 Experimental results

Table 2 shows the results obtained against SS and Lapata & Keller's model on both corpora and the contribution the features exemplified in one baseline and six versions of the SVM model. The baseline is defined only for the English part of the NP feature set and measures the the contribution of the WordNet IS-A lexical hierarchy specialization. The baseline does not differentiate between unambiguous and ambiguous training examples (after just one level specialization) and thus, does not specialize the ambiguous ones. Moreover, here we wanted to see what is the difference between SS and SVM, and what is the contribution of the other English features, such as preposition and nominalization (F1–F7).

The table shows that, overall the performance is better for the Europarl corpus than for CLUVI. For the Baseline and SVM_1, SS [F1 + F2] gives better results than SVM. The inclusion of other English features (SVM [F1–F7]) adds more than 15% (with a higher increase in Europarl) for SVM_1.

The contribution of Romance linguistic features. Since our intuition is that the more translations are provided for an English noun phrase instance, the better the results, we wanted to see what is the impact of each Romance language on the overall performance. Thus, SVM_2 shows the results obtained for English and the Romance language that contributed the least to the performance (F1–F12). Here we computed the performance on all five English – Romance language combinations and chose the Romance language that provided the best result. Thus, SVM #2, #3, #4, #5, and #6 add Spanish, French, Italian, Portuguese, and Romanian in this order and show the contribution of each Romance preposition and all features for English.

The language ranking in Table 2 shows that Romance languages considered here have a different contribution to the overall performance. While the addition of Italian in Europarl decreases the performance, Portuguese doesn't add anything. However, a closer analysis of the data shows that this is mostly due to the distribution of the corpus instances. For example, French, Italian, Spanish, and Portuguese are most of the time consistent in the choice of preposition (e.g. most of the time, if the preposition 'de' ('of') is used in French, then the

corresponding preposition is used in the other four language translations). A notable exception here is Romanian which provides two possible constructions: the N P N and the genitive-marked N N. The table shows (in the increase in performance between SVM_5 and SVM_6) that this choice is not random, but influenced by the meaning of the instances (features F12, F13). This observation is also supported by the contribution of each feature to the overall performance. For example, in Europarl, the WordNet verb and nominalization features of the head noun (F3, F6) have a contribution of 4.08%, while for the modifier nouns it decreases by about 2%. The preposition (F5) contributes 4.41% (Europarl) and 5.24% (CLUVI) to the overall performance.

A closer analysis of the data shows that in Europarl most of the N N instances were naming noun compounds such as *framework law* (TYPE) and, most of the time, are encoded by N N patterns in the target languages (e.g., *legge quadro* (It.)). In the CLUVI corpus, on the other hand, the N N Romance translations represented only 1% of the data. A notable exception here is Romanian where most NPs are represented as genitive–marked noun compounds. However, there are instances that are encoded mostly or only as N P N constructions and this choice correlates with the meaning of the instance. For example, *the milk glass* (PURPOSE) translates as *paharul de lapte* (*glass*-the *of milk*) and not as *paharul laptelui* (*glass*-the *milk*-gen), *the olive oil* (SOURCE) translates as *uleiul de măsline* (*oil*-the *of olive*) and not as *uleiul măslinei* (*oil*-the *olive*-gen). Other examples include CAUSE and TOPIC.

Lauer's set of 8 prepositions represents 94.5% (Europarl) and 97% (CLUVI) of the N P N instances. From these, the most frequent preposition is "of" with a coverage of 70.31% (Europarl) and 85.08% (CLUVI). Moreover, in the Europarl corpus, 26.39% of the instances are synthetic phrases (where one of the nouns is a nominalization) encoding AGENT, EXPERIENCER, THEME, BENEFICIARY. Out of these instances, 74.81% use the preposition *of*. In CLUVI, 11.71% of the examples were verbal, from which the preposition *of* has a coverage of 82.20%. The many-to-many mappings of the prepositions (especially *of/de*) to the semantic classes adds to the complexity of the interpretation task. Thus, for the interpretation of these constructions a system must rely on the semantic information of the preposition and two constituent nouns in particular, and on context in general.

In Europarl, the most frequently occurring relations are PURPOSE, TYPE, and THEME that together represent about 57% of the data followed by PART-WHOLE, PROPERTY, TOPIC, AGENT, and LOCATION with an average coverage of about 6.23%. Moreover, other relations such as KINSHIP, DEPICTION, MANNER, MEANS did not occur in this corpus and 5.08% represented OTHER-SR relations. This semantic distribution contrasts with the one in CLUVI, which uses a more descriptive language. Here, the most frequent relation by far

is PART-WHOLE (32.14%), followed by LOCATION (12.40%), THEME (9.23%) and OTHER-SR (7.74%). It is interesting to note here that only 5.70% of the TYPE relation instances in Europarl were unique. This is in contrast with the other relations in both corpora, where instances were mostly unique.

We also report here our observations on Lapata & Keller's unsupervised model. An analysis of these results showed that the order of the constituent nouns in the N P N paraphrase plays an important role. For example, a search for *blood vessels* generated similar frequency counts for *vessels of blood* and *blood in vessels*. About 30% noun - noun paraphrasable pairs preserved the order in the corresponding N P N paraphrases. We also manually checked the first five entries generated by Google for each most frequent prepositional paraphrase for 50 instances and noticed that about 35% of them were wrong due to syntactic and/or semantic ambiguities. Thus, since we wanted to measure the impact of these ambiguities of noun compounds on the interpretation performance, we further tested the probabilistic web-based model on four distinct test sets selected from Europarl, each containing 30 noun - noun pairs encoding different types of ambiguity: in set#1 the noun constituents had only one part of speech and one WordNet sense; in set#2 the nouns had at least two possible parts of speech and were semantically unambiguous, in set#3 the nouns were ambiguous only semantically, and in set#4 they were ambiguous both syntactically and semantically. For unambiguous noun-noun pairs (set#1), the model obtained an accuracy of 35.01%, while for more semantically ambiguous compounds it obtained an accuracy of about 48.8%. This shows that for more semantically ambiguous noun - noun pairs, the web-based probabilistic model introduces a significant number of false positives. Thus, the more abstract the categories, the more noun compounds are covered, but also the more room for variation as to which category a compound should be assigned.

6 Discussion and Conclusions

In this paper we presented a supervised, knowledge-intensive interpretation model which takes advantage of new linguistic information from English and a list of five Romance languages. Our approach to NP interpretation is novel in several ways. We defined the problem in a cross-linguistic framework and provided empirical observations on the distribution of the syntax and meaning of noun phrases on two different corpora based on two state-of-the-art classification tag sets.

As future work we consider the inclusion of other features such as the semantic classes of Romance nouns from aligned EuroWordNets, and other sentence features. Since the results obtained can be seen as an upper bound on NP interpretation due to perfect English - Romance NP alignment, we will experiment with automatic translations generated for the test data. Moreover, we like to extend the analysis to other set of languages whose structures are very different from English and Romance.

Abstract

We present a new approach to relation extraction that requires only a handful of training examples. Given a few pairs of named entities known to exhibit or not exhibit a particular relation, bags of sentences containing the pairs are extracted from the web. We extend an existing relation extraction method to handle this weaker form of supervision, and present experimental results demonstrating that our approach can reliably extract relations from web documents.

1 Introduction

A growing body of recent work in information extraction has addressed the problem of *relation extraction* (RE), identifying relationships between entities stated in text, such as `LivesIn(Person, Location)` or `EmployedBy(Person, Company)`. Supervised learning has been shown to be effective for RE (Zelenko et al., 2003; Culotta and Sorensen, 2004; Bunescu and Mooney, 2006); however, annotating large corpora with examples of the relations to be extracted is expensive and tedious.

In this paper, we introduce a supervised learning approach to RE that requires only a handful of training examples and uses the web as a corpus. Given a few pairs of well-known entities that clearly exhibit or do not exhibit a particular relation, such as `CorpAcquired`(Google, YouTube) and `not`(`CorpAcquired`(Yahoo, Microsoft)), a search engine is used to find sentences on the web that mention both of the entities in each of the pairs. Although not all of the sentences for positive pairs will state the desired relationship, many of them will. Presumably, none of the sentences for negative pairs state the targeted relation. *Multiple instance learning* (MIL) is a machine learning framework that exploits this sort of weak supervision, in which a *positive bag* is a set of instances which is guaranteed to contain at least one positive example, and a *negative bag* is a set of instances all of which are negative. MIL was originally introduced to solve a problem in biochemistry (Dietterich et al., 1997); however, it has since been applied to problems in other areas such as classifying image regions in computer vision (Zhang et al., 2002), and text categorization (Andrews et al., 2003; Ray and Craven, 2005).

We have extended an existing approach to relation extraction using support vector machines and string kernels (Bunescu and Mooney, 2006) to handle this weaker form of MIL supervision. This approach can sometimes be misled by textual features correlated with the specific entities in the few training pairs provided. Therefore, we also describe a method for weighting features in order to focus on those correlated with the target relation rather than with the individual entities. We present experimental results demonstrating that our approach is able to accurately extract relations from the web by learning from such weak supervision.

2 Problem Description

We address the task of learning a relation extraction system targeted to a fixed binary relationship R. The only supervision given to the learning algo-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 576–583,

rithm is a small set of pairs of named entities that are known to belong (positive) or not belong (negative) to the given relationship. Table 1 shows four positive and two negative example pairs for the corporate acquisition relationship. For each pair, a bag of sentences containing the two arguments can be extracted from a corpus of text documents. The corpus is assumed to be sufficiently large and diverse such that, if the pair is positive, it is highly likely that the corresponding bag contains at least one sentence that explicitly asserts the relationship R between the two arguments. In Section 6 we describe a method for extracting bags of relevant sentences from the web.

$+/-$	**Arg** a_1	**Arg** a_2
$+$	Google	YouTube
$+$	Adobe Systems	Macromedia
$+$	Viacom	DreamWorks
$+$	Novartis	Eon Labs
$-$	Yahoo	Microsoft
$-$	Pfizer	Teva

Table 1: Corporate Acquisition Pairs.

Using a limited set of entity pairs (e.g. those in Table 1) and their associated bags as training data, the aim is to induce a relation extraction system that can reliably decide whether two entities mentioned in the same sentence exhibit the target relationship or not. In particular, when tested on the example sentences from Figure 1, the system should classify S_1, S_3,and S_4 as positive, and S_2 and S_5 as negative.

$+/S_1$: Search engine giant **Google** has bought video-sharing website **YouTube** in a controversial $1.6 billion deal.

$-/S_2$: The companies will merge **Google**'s search expertise with **YouTube**'s video expertise, pushing what executives believe is a hot emerging market of video offered over the Internet.

$+/S_3$: **Google** has acquired social media company, **YouTube** for $1.65 billion in a stock-for-stock transaction as announced by Google Inc. on October 9, 2006.

$-/S_5$: He has also received consulting fees from Alpharma, Eli Lilly and Company, **Pfizer**, Wyeth Pharmaceuticals, **Rinat Neuroscience**, Elan Pharmaceuticals, and Forest Laboratories.

Figure 1: Sentence examples.

As formulated above, the learning task can be seen as an instance of *multiple instance learning*. However, there are important properties that set it apart from problems previously considered in MIL. The most distinguishing characteristic is that the number of bags is very small, while the average size of the bags is very large.

3 Multiple Instance Learning

Since its introduction by Dietterich (1997), an extensive and quite diverse set of methods have been proposed for solving the MIL problem. For the task of relation extraction, we consider only MIL methods where the decision function can be expressed in terms of kernels computed between bag instances. This choice was motivated by the comparatively high accuracy obtained by kernel-based SVMs when applied to various natural language tasks, and in particular to relation extraction. Through the use of kernels, SVMs (Vapnik, 1998; Schölkopf and Smola, 2002) can work efficiently with instances that implicitly belong to a high dimensional feature space. When used for classification, the decision function computed by the learning algorithm is equivalent to a hyperplane in this feature space. Overfitting is avoided in the SVM formulation by requiring that positive and negative training instances be maximally separated by the decision hyperplane.

Gartner *et al.* (2002) adapted SVMs to the MIL setting using various multi-instance kernels. Two of these – the normalized set kernel, and the statistic kernel – have been experimentally compared to other methods by Ray and Craven (2005), with competitive results. Alternatively, a simple approach to MIL is to transform it into a standard supervised learning problem by labeling all instances from positive bags as positive. An interesting outcome of the study conducted by Ray and Craven (2005) was that, despite the class noise in the resulting positive examples, such a simple approach often obtains competitive results when compared against other more sophisticated MIL methods.

We believe that an MIL method based on multi-instance kernels is not appropriate for training datasets that contain just a few, very large bags. In a multi-instance kernel approach, only bags (and not instances) are considered as training examples,

which means that the number of support vectors is going to be upper bounded by the number of training bags. Taking the bags from Table 1 as a sample training set, the decision function is going to be specified by at most seven parameters: the coefficients for at most six support vectors, plus an optional bias parameter. A hypothesis space characterized by such a small number of parameters is likely to have insufficient capacity.

Based on these observations, we decided to transform the MIL problem into a standard supervised problem as described above. The use of this approach is further motivated by its simplicity and its observed competitive performance on very diverse datasets (Ray and Craven, 2005). Let $\mathcal{X}$ be the set of bags used for training, $\mathcal{X}_p \subseteq \mathcal{X}$ the set of positive bags, and $\mathcal{X}_n \subseteq \mathcal{X}$ the set of negative bags. For any instance $x \in X$ from a bag $X \in \mathcal{X}$, let $\phi(x)$ be the (implicit) feature vector representation of x. Then the corresponding SVM optimization problem can be formulated as in Figure 2:

minimize:

$$\mathbf{J}(w, b, \xi) = \tfrac{1}{2}\|w\|^2 + \frac{C}{L}\left(c_p \tfrac{L_n}{L} \Xi_p + c_n \tfrac{L_p}{L} \Xi_n\right)$$

$$\Xi_p = \sum_{X \in \mathcal{X}_p} \sum_{x \in X} \xi_x$$

$$\Xi_n = \sum_{X \in \mathcal{X}_n} \sum_{x \in X} \xi_x$$

subject to:

$$w\,\phi(x) + b \geq +1 - \xi_x, \;\; \forall x \in X \in \mathcal{X}_p$$

$$w\,\phi(x) + b \leq -1 + \xi_x, \;\; \forall x \in X \in \mathcal{X}_n$$

$$\xi_x \geq 0$$

Figure 2: SVM Optimization Problem.

The capacity control parameter C is normalized by the total number of instances $L = L_p + L_n = \sum_{X \in \mathcal{X}_p} |X| + \sum_{X \in \mathcal{X}_n} |X|$, so that it remains independent of the size of the dataset. The additional non-negative parameter c_p ($c_n = 1 - c_p$) controls the relative influence that false negative vs. false positive errors have on the value of the objective function. Because not all instances from positive bags are real positive instances, it makes sense to have false negative errors be penalized less than false positive errors (i.e. $c_p < 0.5$).

In the dual formulation of the optimization problem from Figure 2, bag instances appear only inside dot products of the form $K(x_1, x_2) = \phi(x_1)\phi(x_2)$. The kernel K is instantiated to a subsequence kernel, as described in the next section.

4 Relation Extraction Kernel

The training bags consist of sentences extracted from online documents, using the methodology described in Section 6. Parsing web documents in order to obtain a syntactic analysis often gives unreliable results – the type of narrative can vary greatly from one web document to another, and sentences with grammatical errors are frequent. Therefore, for the initial experiments, we used a modified version of the subsequence kernel of Bunescu and Mooney (2006), which does not require syntactic information. This kernel computes the number of common subsequences of tokens between two sentences. The subsequences are constrained to be "anchored" at the two entity names, and there is a maximum number of tokens that can appear in a sequence. For example, a subsequence feature for the sentence S_1 in Figure 1 is $\tilde{s}$ = "$\langle e_1 \rangle$ ... *bought* ... $\langle e_2 \rangle$ ... *in* ... *billion* ... *deal*", where $\langle e_1 \rangle$ and $\langle e_2 \rangle$ are generic placeholders for the two entity names. The subsequence kernel induces a feature space where each dimension corresponds to a sequence of words. Any such sequence that matches a subsequence of words in a sentence example is down-weighted as a function of the total length of the gaps between every two consecutive words. More exactly, let $s = w_1 w_2 \ldots w_k$ be a sequence of k words, and $\tilde{s} = w_1\, g_1\, w_2\, g_2 \ldots w_{k-1}\, g_{k-1}\, w_k$ a matching subsequence in a relation example, where g_i stands for any sequence of words between w_i and w_{i+1}. Then the sequence s will be represented in the relation example as a feature with weight computed as $\tau(s) = \lambda^{g(\tilde{s})}$. The parameter λ controls the magnitude of the gap penalty, where $g(\tilde{s}) = \sum_i |g_i|$ is the total gap.

Many relations, like the ones that we explore in the experimental evaluation, cannot be expressed without using at least one content word. We therefore modified the kernel computation to optionally ignore subsequence patterns formed exclusively of

stop words and punctuation signs. In Section 5.1, we introduce a new weighting scheme, wherein a weight is assigned to every token. Correspondingly, every sequence feature will have an additional multiplicative weight, computed as the product of the weights of all the tokens in the sequence. The aim of this new weighting scheme, as detailed in the next section, is to eliminate the bias caused by the special structure of the relation extraction MIL problem.

5 Two Types of Bias

As already hinted at the end of Section 2, there is one important property that distinguishes the current MIL setting for relation extraction from other MIL problems: the training dataset contains very few bags, and each bag can be very large. Consequently, an application of the learning model described in Sections 3 & 4 is bound to be affected by the following two types of bias:

■ **[Type I Bias]** By definition, all sentences inside a bag are constrained to contain the same two arguments. Words that are semantically correlated with either of the two arguments are likely to occur in many sentences. For example, consider the sentences S_1 and S_2 from the bag associated with "Google" and "YouTube" (as shown in Figure 1). They both contain the words "search" – highly correlated with "Google", and "video" – highly correlated with "YouTube", and it is likely that a significant percentage of sentences in this bag contain one of the two words (or both). The two entities can be mentioned in the same sentence for reasons other than the target relation R, and these noisy training sentences are likely to contain words that are correlated with the two entities, without any relationship to R. A learning model where the features are based on words, or word sequences, is going to give too much weight to words or combinations of words that are correlated with either of individual arguments. This overweighting will adversely affect extraction performance through an increased number of errors. A method for eliminating this type of bias is introduced in Section 5.1.

■ **[Type II Bias]** While Type I bias is due to words that are correlated with the arguments of a relation instance, the Type II bias is caused by words that are specific to the relation instance itself. Using FrameNet terminology (Baker et al., 1998), these correspond to instantiated frame elements. For example, the corporate acquisition frame can be seen as a subtype of the "Getting" frame in FrameNet. The *core* elements in this frame are the *Recipient* (e.g. Google) and the *Theme* (e.g. YouTube), which for the acquisition relationship coincide with the two arguments. They do not contribute any bias, since they are replaced with the generic tags $\langle e_1 \rangle$ and $\langle e_2 \rangle$ in all sentences from the bag. There are however other frame elements – *peripheral*, or *extra-thematic* – that can be instantiated with the same value in many sentences. In Figure 1, for instance, sentence S_3 contains two non-core frame elements: the *Means* element (e.g "in a stock-for-stock transaction") and the *Time* element (e.g. "on October 9, 2006"). Words from these elements, like "stock", or "October", are likely to occur very often in the Google-YouTube bag, and because the training dataset contains only a few other bags, subsequence patterns containing these words will be given too much weight in the learned model. This is problematic, since these words can appear in many other frames, and thus the learned model is likely to make errors. Instead, we would like the model to focus on words that trigger the target relationship (in FrameNet, these are the lexical units associated with the target frame).

5.1 A Solution for Type I Bias

In order to account for how strongly the words in a sequence are correlated with either of the individual arguments of the relation, we modify the formula for the sequence weight $\tau(s)$ by factoring in a weight $\tau(w)$ for each word in the sequence, as illustrated in Equation 1.

$$\tau(s) = \lambda^{g(\bar{s})} \cdot \prod_{w \in s} \tau(w) \qquad (1)$$

Given a predefined set of weights $\tau(w)$, it is straightforward to update the recursive computation of the subsequence kernel so that it reflects the new weighting scheme.

If all the word weights are set to 1, then the new kernel is equivalent to the old one. What we want, however, is a set of weights where words that are correlated with either of the two arguments are given lower weights. For any word, the decrease in weight

should reflect the degree of correlation between that word and the two arguments. Before showing the formula used for computing the word weights, we first introduce some notation:

- Let $X \in \mathcal{X}$ be an arbitrary bag, and let $X.a_1$ and $X.a_2$ be the two arguments associated with the bag.
- Let $C(X)$ be the size of the bag (i.e. the number of sentences in the bag), and $C(X, w)$ the number of sentences in the bag X that contain the word w. Let $P(w|X) = C(X, w)/C(X)$.
- Let $P(w|X.a_1 \vee X.a_2)$ be the probability that the word w appears in a sentence due only to the presence of $X.a_1$ or $X.a_2$, assuming $X.a_1$ and $X.a_2$ are independent causes for w.

The word weights are computed as follows:

$$\begin{aligned}\tau(w) &= \frac{C(X,w) - P(w|X.a_1 \vee X.a_2) \cdot C(X)}{C(X,w)} \\ &= 1 - \frac{P(w|X.a_1 \vee X.a_2)}{P(w|X)} \qquad (2)\end{aligned}$$

The quantity $P(w|X.a_1 \vee X.a_2) \cdot C(X)$ represents the expected number of sentences in which w would occur, if the only causes were $X.a_1$ or $X.a_2$, independent of each other. We want to discard this quantity from the total number of occurrences $C(X, w)$, so that the effect of correlations with $X.a_1$ or $X.a_2$ is eliminated.

We still need to compute $P(w|X.a_1 \vee X.a_2)$. Because in the definition of $P(w|X.a_1 \vee X.a_2)$, the arguments $X.a_1$ and $X.a_2$ were considered independent causes, $P(w|X.a_1 \vee X.a_2)$ can be computed with the *noisy-or* operator (Pearl, 1986):

$$\begin{aligned}P(\cdot) &= 1-(1-P(w|a_1)) \cdot (1-P(w|a_2)) \qquad (3) \\ &= P(w|a_1)+P(w|a_2)-P(w|a_1) \cdot P(w|a_2)\end{aligned}$$

The quantity $P(w|a)$ represents the probability that the word w appears in a sentence due only to the presence of a, and it could be estimated using counts on a sufficiently large corpus. For our experimental evaluation, we used the following approximation: given an argument a, a set of sentences containing a are extracted from web documents (details in Section 6). Then $P(w|a)$ is simply approximated with the ratio of the number of sentences containing w over the total number of sentences, i.e. $P(w|a) = C(w, a)/C(a)$. Because this may be an overestimate (w may appear in a sentence containing a due to causes other than a), and also because of data sparsity, the quantity $\tau(w)$ may sometimes result in a negative value – in these cases it is set to 0, which is equivalent to ignoring the word w in all subsequence patterns.

6 MIL Relation Extraction Datasets

For the purpose of evaluation, we created two datasets: one for corporate acquisitions, as shown in Table 2, and one for the person-birthplace relation, with the example pairs from Table 3. In both tables, the top part shows the training pairs, while the bottom part shows the test pairs.

+/−	**Arg** a_1	**Arg** a_2	**Size**
+	Google	YouTube	1375
+	Adobe Systems	Macromedia	622
+	Viacom	DreamWorks	323
+	Novartis	Eon Labs	311
−	Yahoo	Microsoft	163
−	Pfizer	Teva	247
+	Pfizer	Rinat Neuroscience	50 (41)
+	Yahoo	Inktomi	433 (115)
−	Google	Apple	281
−	Viacom	NBC	231

Table 2: Corporate Acquisition Pairs.

+/−	**Arg** a_1	**Arg** a_2	**Size**
+	Franz Kafka	Prague	552
+	Andre Agassi	Las Vegas	386
+	Charlie Chaplin	London	292
+	George Gershwin	New York	260
−	Luc Besson	New York	74
−	Wolfgang A. Mozart	Vienna	288
+	Luc Besson	Paris	126 (6)
+	Marie Antoinette	Vienna	105 (39)
−	Charlie Chaplin	Hollywood	266
−	George Gershwin	London	104

Table 3: Person-Birthplace Pairs.

Given a pair of arguments (a_1, a_2), the corresponding bag of sentences is created as follows:

■ A query string "$a_1 * * * * * * * a_2$" containing seven wildcard symbols between the two arguments is submitted to Google. The preferences are set to search only for pages written in English, with Safesearch turned on. This type of query will match documents where an occurrence of a_1 is separated from an occurrence of a_2 by at most seven content words. This is an approximation of our actual information

need: "return all documents containing a_1 and a_2 in the same sentence".

■ The returned documents (limited by Google to the first 1000) are downloaded, and then the text is extracted using the HTML parser from the Java Swing package. Whenever possible, the appropriate HTML tags (e.g. *BR, DD, P*, etc.) are used as hard end-of-sentence indicators. The text is further segmented into sentences with the OpenNLP[1] package.

■ Sentences that do not contain both arguments a_1 and a_2 are discarded. For every remaining sentence, we find the occurrences of a_1 and a_2 that are closest to each other, and create a relation example by replacing a_1 with $\langle e_1 \rangle$ and a_2 with $\langle e_2 \rangle$. All other occurrences of a_1 and a_2 are replaced with a null token ignored by the subsequence kernel.

The number of sentences in every bag is shown in the last column of Tables 2 & 3. Because Google also counts pages that are deemed too similar in the first 1000, some of the bags can be relatively small.

As described in Section 5.1, the word-argument correlations are modeled through the quantity $P(w|a) = C(w,a)/C(a)$, estimated as the ratio between the number of sentences containing w and a, and the number of sentences containing a. These counts are computed over a bag of sentences containing a, which is created by querying Google for the argument a, and then by processing the results as described above.

7 Experimental Evaluation

Each dataset is split into two sets of bags: one for training and one for testing. The test dataset was purposefully made difficult by including negative bags with arguments that during training were used in positive bags, and vice-versa. In order to evaluate the relation extraction performance at the sentence level, we manually annotated all instances from the positive test bags. The last column in Tables 2 & 3 shows, between parentheses, how many instances from the positive test bags are real positive instances. The corporate acquisition test set has a total of 995 instances, out of which 156 are positive. The person-birthplace test set has a total of 601 instances, and only 45 of them are positive. Extrapolating from the test set distribution, the positive bags in the person-birthplace dataset are significantly sparser in real positive instances than the positive bags in the corporate acquisition dataset.

The subsequence kernel described in Section 4 was used as a custom kernel for the LibSVM[2] Java package. When run with the default parameters, the results were extremely poor – too much weight was given to the slack term in the objective function. Minimizing the regularization term is essential in order to capture subsequence patterns shared among positive bags. Therefore LibSVM was modified to solve the optimization problem from Figure 2, where the capacity parameter C is normalized by the size of the transformed dataset. In this new formulation, C is set to its default value of 1.0 – changing it to other values did not result in significant improvement. The trade-off between false positive and false negative errors is controlled by the parameter c_p. When set to its default value of 0.5, false-negative errors and false positive errors have the same impact on the objective function. As expected, setting c_p to a smaller value (0.1) resulted in better performance. Tests with even lower values did not improve the results.

We compare the following four systems:

■ **SSK–MIL**: This corresponds to the MIL formulation from Section 3, with the original subsequence kernel described in Section 4.

■ **SSK–T1**: This is the SSK–MIL system augmented with word weights, so that the Type I bias is reduced, as described in Section 5.1.

■ **BW-MIL**: This is a bag-of-words kernel, in which the relation examples are classified based on the unordered words contained in the sentence. This baseline shows the performance of a standard text-classification approach to the problem using a state-of-the art algorithm (SVM).

■ **SSK–SIL**: This corresponds to the original subsequence kernel trained with traditional, single instance learning (SIL) supervision. For evaluation, we train on the manually labeled instances from the test bags. We use a combination of one positive bag and one negative bag for training, while the other two bags are used for testing. The results are averaged over all four possible combinations. Note that the supervision provided to SSK–SIL requires sig-

nificantly more annotation effort, therefore, given a sufficient amount of training examples, we expect this system to perform at least as well as its MIL counterpart.

In Figure 3, precision is plotted against recall by varying a threshold on the value of the SVM decision function. To avoid clutter, we show only the graphs for the first three systems. In Table 4 we show the area under the precision recall curves of all four systems. Overall, the learned relation extractors are able to identify the relationship in novel sentences quite accurately and significantly out-perform a bag-of-words baseline. The new version of the subsequence kernel SSK–T1 is significantly more accurate in the MIL setting than the original subsequence kernel SSK–MIL, and is also competitive with SSK–SIL, which was trained using a reasonable amount of manually labeled sentence examples.

Dataset	SSK–MIL	SSK–T1	BW–MIL	SSK–SIL
(a) CA	76.9%	81.1%	45.9%	80.4%
(b) PB	72.5%	78.2%	69.2%	73.4%

Table 4: Area Under Precision-Recall Curve.

8 Future Work

An interesting potential application of our approach is a web relation-extraction system similar to Google Sets, in which the user provides only a handful of pairs of entities known to exhibit or not to exhibit a particular relation, and the system is used to find other pairs of entities exhibiting the same relation. Ideally, the user would only need to provide positive pairs. Sentences containing one of the relation arguments could be extracted from the web, and likely negative sentence examples automatically created by pairing this entity with other named entities mentioned in the sentence. In this scenario, the training set can contain both false positive and false negative noise. One useful side effect is that Type I bias is partially removed – some bias still remains due to combinations of at least two words, each correlated with a different argument of the relation.

We are also investigating methods for reducing Type II bias, either by modifying the word weights, or by integrating an appropriate measure of word distribution across positive bags directly in the objective function for the MIL problem. Alternatively, implicit negative evidence can be extracted from sentences in positive bags by exploiting the fact that, besides the two relation arguments, a sentence from a positive bag may contain other entity mentions. Any pair of entities different from the relation pair is very likely to be a negative example for that relation. This is similar to the concept of negative *neighborhoods* introduced by Smith and Eisner (2005), and has the potential of eliminating both Type I and Type II bias.

9 Related Work

One of the earliest IE methods designed to work with a reduced amount of supervision is that of Hearst (1992), where a small set of seed patterns is used in a bootstrapping fashion to mine pairs of

hypernym-hyponym nouns. Bootstrapping is actually orthogonal to our method, which could be used as the pattern learner in every bootstrapping iteration. A more recent IE system that works by bootstrapping relation extraction patterns from the web is KNOWITALL (Etzioni et al., 2005). For a given target relation, supervision in KNOWITALL is provided as a *rule template* containing words that describe the class of the arguments (e.g. "company"), and a small set of seed extraction patterns (e.g. "has acquired"). In our approach, the type of supervision is different – we ask only for pairs of entities known to exhibit the target relation or not. Also, KNOWITALL requires large numbers of search engine queries in order to collect and validate extraction patterns, therefore experiments can take weeks to complete. Comparatively, the approach presented in this paper requires only a small number of queries: one query per relation pair, and one query for each relation argument.

Craven and Kumlien (1999) create a noisy training set for the subcellular-localization relation by mining Medline for sentences that contain tuples extracted from relevant medical databases. To our knowledge, this is the first approach that is using a "weakly" labeled dataset for relation extraction. The resulting bags however are very dense in positive examples, and they are also many and small – consequently, the two types of bias are not likely to have significant impact on their system's performance.

10 Conclusion

We have presented a new approach to relation extraction that leverages the vast amount of information available on the web. The new RE system is trained using only a handful of entity pairs known to exhibit and not exhibit the target relationship. We have extended an existing relation extraction kernel to learn in this setting and to resolve problems caused by the minimal supervision provided. Experimental results demonstrate that the new approach can reliably extract relations from web documents.

A Seed-driven Bottom-up Machine Learning Framework for Extracting Relations of Various Complexity

Feiyu Xu, Hans Uszkoreit and Hong Li

Abstract

A minimally supervised machine learning framework is described for extracting relations of various complexity. Bootstrapping starts from a small set of n-ary relation instances as "seeds", in order to automatically learn pattern rules from parsed data, which then can extract new instances of the relation and its projections. We propose a novel rule representation enabling the composition of n-ary relation rules on top of the rules for projections of the relation. The compositional approach to rule construction is supported by a bottom-up pattern extraction method. In comparison to other automatic approaches, our rules cannot only localize relation arguments but also assign their exact target argument roles. The method is evaluated in two tasks: the extraction of Nobel Prize awards and management succession events. Performance for the new Nobel Prize task is strong. For the management succession task the results compare favorably with those of existing pattern acquisition approaches.

1 Introduction

Information extraction (IE) has the task to discover n-tuples of relevant items (entities) belonging to an n-ary relation in natural language documents. One of the central goals of the ACE program[1] is to develop a more systematically grounded approach to IE starting from elementary entities, binary relations to n-ary relations such as events. Current semi- or unsupervised approaches to automatic pattern acquisition are either limited to a certain linguistic representation (e.g., subject-verb-object), or only deal with binary relations, or cannot assign slot filler roles to the extracted arguments, or do not have good selection and filtering methods to handle the large number of tree patterns (Riloff, 1996; Agichtein and Gravano, 2000; Yangarber, 2003; Sudo et al., 2003; Greenwood and Stevenson, 2006; Stevenson and Greenwood, 2006). Most of these approaches do not consider the linguistic interaction between relations and their projections on k dimensional subspaces where $1 \leq k < n$, which is important for scalability and reusability of rules. Stevenson and Greenwood (2006) present a systematic investigation of the pattern representation models and point out that substructures of the linguistic representation and the access to the embedded structures are important for obtaining a good coverage of the pattern acquisition. However, all considered representation models (subject-verb-object, chain model, linked chain model and subtree model) are verb-centered. Relations embedded in non-verb constructions such as a compound noun cannot be discovered:

(1) *the 2005 Nobel Peace Prize*

(1) describes a ternary relation referring to three properties of a prize: year, area and prize name. We also observe that the automatically acquired patterns in Riloff (1996), Yangarber (2003), Sudo et al. (2003), Greenwood and Stevenson (2006) cannot be directly used as relation extraction rules because the relation-specific argument role information is missing. E.g., in the management succession domain that concerns the identification of job changing events, a person can either move into a

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 584–591,
Prague, Czech Republic, June 2007.

job (called Person_In) or leave a job (called Person_Out). (2) is a simplified example of patterns extracted by these systems:

(2) <*subject: person*> *verb* <*object:organisation*>

In (2), there is no further specification of whether the person entity in the subject position is Person_In or Person_Out.

The ambitious goal of our approach is to provide a general framework for the extraction of relations and events with various complexity. Within this framework, the IE system learns extraction patterns automatically and induces rules of various complexity systematically, starting from sample relation instances as seeds. The arity of the seed determines the complexity of extracted relations. The seed helps us to identify the explicit linguistic expressions containing mentionings of relation instances or instances of their *k*-ary projections where $1 \leq k < n$. Because our seed samples are not linguistic patterns, the learning system is not restricted to a particular linguistic representation and is therefore suitable for various linguistic analysis methods and representation formats. The pattern discovery is bottom-up and compositional, i.e., complex patterns can build on top of simple patterns for projections.

We propose a rule representation that supports this strategy. Therefore, our learning approach is seed-driven and bottom-up. Here we use dependency trees as input for pattern extraction. We consider only trees or their subtrees containing seed arguments. Therefore, our method is much more efficient than the subtree model of Sudo et al., (2003), where all subtrees containing verbs are taken into account. Our pattern rule ranking and filtering method considers two aspects of a pattern: its domain relevance and the trustworthiness of its origin. We tested our framework in two domains: Nobel Prize awards and management succession. Evaluations have been conducted to investigate the performance with respect to the seed parameters: the number of seeds and the influence of data size and its redundancy property. The whole system has been evaluated for the two domains considering precision and recall. We utilize the evaluation strategy "Ideal Matrix" of Agichtein and Gravano (2000) to deal with unannotated test data.

The remainder of the paper is organised as follows: Section 2 provides an overview of the system architecture. Section 3 discusses the rule representation. In Section 4, a detailed description of the seed-driven bottom-up pattern acquisition is presented. Section 5 describes our experiments with pattern ranking, filtering and rule induction. Section 6 presents the experiments and evaluations for the two application domains. Section 7 provides a conclusion and an outline of future work.

2 System Architecture

Given the framework, our system architecture can be depicted as follows:

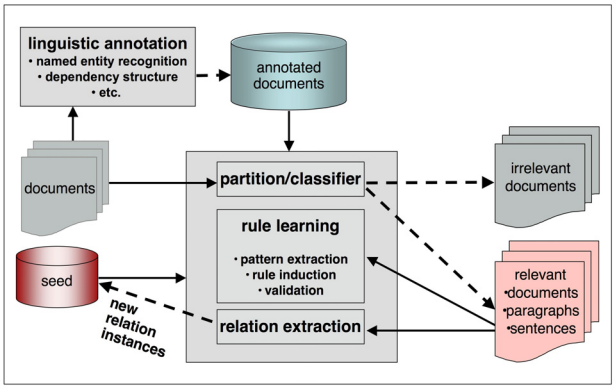

Figure 1. Architecture

This architecture has been inspired by several existing seed-oriented minimally supervised machine learning systems, in particular by Snowball (Agichtein and Gravano, 2000) and ExDisco (Yangarber et al., 2000). We call our system ***DARE***, standing for "***D***omain ***A***daptive ***R***elation ***E***xtraction based on Seeds". ***DARE*** contains four major components: linguistic annotation, classifier, rule learning and relation extraction. The first component only applies once, while the last three components are integrated in a bootstrapping loop. At each iteration, rules will be learned based on the seed and then new relation instances will be extracted by applying the learned rules. The new relation instances are then used as seeds for the next iteration of the learning cycle. The cycle terminates when no new relations can be acquired.

The **linguistic annotation** is responsible for enriching the natural language texts with linguistic information such as named entities and dependency structures. In our framework, the depth of the linguistic annotation can be varied depending on the domain and the available resources.

The **classifier** has the task to deliver relevant paragraphs and sentences that contain seed elements. It has three subcomponents: document re-

trieval, paragraph retrieval and sentence retrieval. The document retrieval component utilizes the open source IR-system Lucene[2]. A translation step is built in to convert the seed into the proper IR query format. As explained in Xu et al. (2006), we generate all possible lexical variants of the seed arguments to boost the retrieval coverage and formulate a boolean query where the arguments are connected via conjunction and the lexical variants are associated via disjunction. However, the translation could be modified. The task of paragraph retrieval is to find text snippets from the relevant documents where the seed relation arguments co-occur. Given the paragraphs, a sentence containing at least two arguments of a seed relation will be regarded as relevant.

As mentioned above, the **rule learning** component constitutes the core of our system. It identifies patterns from the annotated documents inducing extraction rules from the patterns, and validates them. In section 4, we will give a detailed explanation of this component.

The **relation extraction** component applies the newly learned rules to the relevant documents and extracts relation instances. The validated relation instances will then be used as new seeds for the next iteration.

3 *DARE* Rule Representation

Our rule representation is designed to specify the location and the role of the arguments w.r.t. the target relation in a linguistic construction. In our framework, the rules should not be restricted to a particular linguistic representation and should be adaptable to various NLP tools on demand. A ***DARE*** rule is allowed to call further ***DARE*** rules that extract a subset of the arguments. Let us step through some example rules for the prize award domain. One of the target relations in the domain is about a person who obtains a special prize in a certain area in a certain year, namely, a quaternary tuple, see (3). (4) is a domain relevant sentence.

(3) <recipient, prize, area, year>

(4) *Mohamed ElBaradei won the 2005 Nobel Peace Prize on Friday for his efforts to limit the spread of atomic weapons.*

(5) is a rule that extracts a ternary projection instance <*prize, area, year*> from a noun phrase compound, while (6) is a rule which triggers (5) in its object argument and extracts all four arguments. (5) and (6) are useful rules for extracting arguments from (4).

(5)

```
Rule name::  prize_area_year_1
Rule::    (③ year)(① prizename) (② areaname) 'Prize'
Output:: ⟨①Prize, ②Area, ③Year⟩
```

(6)

```
Rule name:: recipient_prize_area_year_1
Rule body:: [ head    [ pos       verb
                        mode      active
                        wordform  "win" ]
              subject [ head  ① Person
                        rule  recipient_1:: ⟨①Person⟩ ]
              object  [ head  [ wordform  "prize" ]
                        rule  prize_area_year_1:: ⟨②Prize, ③Area, ④Year⟩ ] ]
Output:: ⟨①Recipient, ②Prize, ③Area, ④Year⟩
```

Next we provide a definition of a ***DARE*** rule:

A ***DARE*** rule has three components

1. rule name: $\mathbf{r}_i$;
2. output: a set **A** containing the **n** arguments of the n-ary relation**,** labelled with their argument roles;
3. rule body in AVM format containing:
   - specific linguistic labels or attributes (e.g., **subject**, **object**, **head**, **mod**), derived from the linguistic analysis, e.g., dependency structures and the named entity information
   - **rule**: its value is a ***DARE*** rule which extracts a subset of arguments of **A**

The rule in (6) is a typical ***DARE*** rule. Its subject and object descriptions call appropriate ***DARE*** rules that extract a subset of the output relation arguments. The advantages of this rule representation strategy are that (1) it supports the bottom-up rule composition; (2) it is expressive enough for the representation of rules of various complexity; (3) it reflects the precise linguistic relationship among the relation arguments and reduces the template merging task in the later phase; (4) the rules for the subset of arguments may be reused for other relation extraction tasks.

The rule representation models for automatic or unsupervised pattern rule extraction discussed by

[2] http://www.lucene.de

Stevenson and Greenwood (2006) do not account for these considerations.

4 Seed-driven Bottom-up Rule Learning

Two main approaches to seed construction have been discussed in the literature: pattern-oriented (e.g., ExDisco) and semantics-oriented (e.g., Snowball) strategies. The pattern-oriented method suffers from poor coverage because it makes the IE task too dependent on one linguistic representation construction (e.g., *subject-verb-object*) and has moreover ignored the fact that semantic relations and events could be dispersed over different sub-structures of the linguistic representation. In practice, several tuples extracted by different patterns can contribute to one complex relation instance.

The semantics-oriented method uses relation instances as seeds. It can easily be adapted to all relation/event instances. The complexity of the target relation is not restricted by the expressiveness of the seed pattern representation. In Brin (1998) and Agichtein and Gravano (2000), the semantics-oriented methods have proved to be effective in learning patterns for some general binary relations such as *booktitle-author* and *company-headquarter* relations. In Xu et al. (2006), the authors show that at least for the investigated task it is more effective to start with the most complex relation instance, namely, with an n-ary sample for the target n-ary relation as seed, because the seed arguments are often centred in a relevant textual snippet where the relation is mentioned. Given the bottom-up extracted patterns, the task of the rule induction is to cluster and generalize the patterns. In comparison to the bottom-up rule induction strategy (Califf and Mooney, 2004), our method works also in a compositional way. For reasons of space this part of the work will be reported in Xu and Uszkoreit (forthcoming).

4.1 Pattern Extraction

Pattern extraction in ***DARE*** aims to find linguistic patterns which do not only trigger the relations but also locate the relation arguments. In ***DARE***, the patterns can be extracted from a phrase, a clause or a sentence, depending on the location and the distribution of the seed relation arguments.

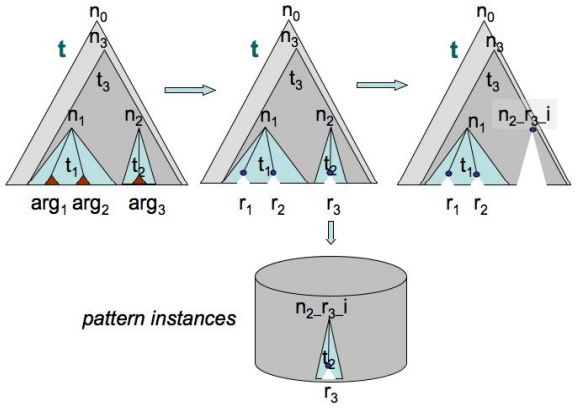

Figure 2. Pattern extraction step 1

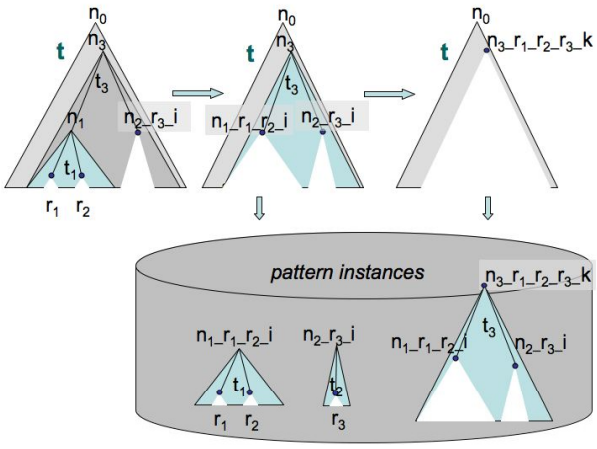

Figure 3. Pattern extraction step 2

Figures 2 and 3 depict the general steps of bottom-up pattern extraction from a dependency tree ***t*** where three seed arguments $\boldsymbol{arg}_1$, $\boldsymbol{arg}_2$ and $\boldsymbol{arg}_3$ are located. All arguments are assigned their relation roles $\boldsymbol{r}_1$, $\boldsymbol{r}_2$ and $\boldsymbol{r}_3$. The pattern-relevant subtrees are trees in which seed arguments are embedded: $\boldsymbol{t}_1$, $\boldsymbol{t}_2$ and $\boldsymbol{t}_3$. Their root nodes are $\boldsymbol{n}_1$, $\boldsymbol{n}_2$ and $\boldsymbol{n}_3$. Figure 2 shows the extraction of a unary pattern $\boldsymbol{n}_2\_\boldsymbol{r}_3\_\boldsymbol{i}$, while Figure 3 illustrates the further extraction and construction of a binary pattern $\boldsymbol{n}_1\_\boldsymbol{r}_1\_\boldsymbol{r}_2\_\boldsymbol{j}$ and a ternary pattern $\boldsymbol{n}_3\_\boldsymbol{r}_1\_\boldsymbol{r}_2\_\boldsymbol{r}_3\_\boldsymbol{k}$. In practice, not all branches in the subtrees will be kept. In the following, we give a general definition of our seed-driven bottom-up pattern extraction algorithm:

input: (i) relation = $<r_1, r_2, ..., r_n>$: the target relation tuple with n argument roles.
T: a set of linguistic analysis trees annotated with i seed relation arguments ($1 \le i \le n$)

output: P: a set of pattern instances which can extract i or a subset of i arguments.

Pattern extraction:
for each tree t $\in$ T

Step 1: (depicted in Figure 2)

1. replace all terminal nodes that are instantiated with the seed arguments by new nodes. Label these new nodes with the seed argument roles and possibly the corresponding entity classes;
2. identify the set of the lowest nonterminal nodes N_1 in t that dominate only one argument (possibly among other nodes).
3. substitute N_1 by nodes labelled with the seed argument roles and their entity classes
4. prune the subtrees dominated by N_1 from t and add these subtrees into P. These subtrees are assigned the argument role information and a unique id.

Step2: For i=2 to n: (depicted in Figure 3)

1. find the set of the lowest nodes N_1 in t that dominate in addition to other children only i seed arguments;
2. substitute N_1 by nodes labelled with the i seed argument role combination information (e.g., $r_i\_r_j$) and with a unique id.
3. prune the subtrees T_i dominated by N_i in t;
4. add T_i to P together with the argument role combination information and the unique id

With this approach, we can learn rules like (6) in a straightforward way.

4.2 Rule Validation: Ranking and Filtering

Our ranking strategy has incorporated the ideas proposed by Riloff (1996), Agichtein and Gravano (2000), Yangarber (2003) and Sudo et al. (2003). We take two properties of a pattern into account:

- *domain relevance*: its distribution in the relevant documents and irrelevant documents (documents in other domains);
- *trustworthiness of its origin*: the relevance score of the seeds from which it is extracted.

In Riloff (1996) and Sudo et al. (2003), the relevance of a pattern is mainly dependent on its occurrences in the relevant documents vs. the whole corpus. Relevant patterns with lower frequencies cannot float to the top. It is known that some complex patterns are relevant even if they have low occurrence rates. We propose a new method for calculating the domain relevance of a pattern. We assume that the domain relevance of a pattern is dependent on the relevance of the lexical terms (words or collocations) constructing the pattern, e.g., the domain relevance of (5) and (6) are dependent on the terms "prize" and "win" respectively. Given *n* different domains, the domain relevance score (*DR*) of a term *t* in a domain d_i is:

$$DR(t, d_i) = \begin{cases} 0, \text{ if } df(t, d_i) = 0; \\ \frac{df(t,d_i)}{N \times D} \times LOG(n \times \frac{df(t,d_i)}{\sum_{j=1}^{n} df(t,d_j)}), \text{ otherwise} \end{cases}$$

where

- *$df(t, d_i)$: is the document frequency of a term t in the domain d_i*
- *D: the number of the documents in d_i*
- *N: the total number of the terms in d_i*

Here the domain relevance of a term is dependent both on its document frequency and its document frequency distribution in other domains. Terms mentioned by more documents within the domain than outside are more relevant (Xu et al., 2002). In the case of *n=3* such different domains might be, e.g., *management succession*, *book review* or *biomedical texts*. Every domain corpus should ideally have the same number of documents and similar average document size. In the calculation of the trustworthiness of the origin, we follow Agichtein and Gravano (2000) and Yangarber (2003). Thus, the relevance of a pattern is dependent on the relevance of its terms and the score value of the most trustworthy seed from which it origins. Finally, the score of a pattern ***p*** is calculated as follows:

$$score(\mathbf{p}) = \sum_{i=0}^{|T|} DR(t_i) \times \max\{score(s) : s \in Seeds\}$$

where $|T| > 0$ and $t_i \in T$

- *T: is the set of the terms occur in p;*
- *Seeds: a set of seeds from which the pattern is extracted;*
- *score(s): is the score of the seed s;*

This relevance score is not dependent on the distribution frequency of a pattern in the domain corpus. Therefore, patterns with lower frequency, in particular, some complex patterns, can be ranked higher when they contain relevant domain terms or come from reliable seeds.

5 Top down Rule Application

After the acquisition of pattern rules, the ***DARE*** system applies these rules to the linguistically annotated corpus. The rule selection strategy moves from complex to simple. It first matches the most complex pattern to the analyzed sentence in order to extract the maximal number of relation arguments. According to the duality principle (Yangarber 2001), the score of the new extracted relation instance *S* is dependent on the patterns from which it origins. Our score method is a simplified version of that defined by Agichtein and Gravano (2000):

$$\text{score}(S)=1-\prod_{i=0}^{|P|}(1-score(P_i))$$

where $P=\{P_i\}$ is the set of patterns that extract S.

The extracted instances can be used as potential seeds for the further pattern extraction iteration, when their scores are validated. The initial seeds obtain 1 as their score.

6 Experiments and Evaluation

We apply our framework to two application domains: Nobel Prize awards and management succession events. Table 1 gives an overview of our test data sets.

Data Set Name	Doc Number	Data Amount
Nobel Prize A (1999-2005)	2296	12,6 MB
Nobel Prize B (1981-1998)	1032	5,8 MB
MUC-6	199	1 MB

Table1. Overview of Test Data Sets.

For the Nobel Prize award scenario, we use two test data sets with different sizes: Nobel Prize A and Nobel Prize B. They are Nobel Prize related articles from New York Times, online BBC and CNN news reports. The target relation for the experiment is a quaternary relation as mentioned in (3), repeated here again:

<recipient, prize, area, year>

Our test data is not annotated with target relation instances. However, the entire list of Nobel Prize award events is available for the evaluation from the Nobel Prize official website[3]. We use it as our reference relation database for building our Ideal table (Agichtein and Gravano, 2000).

For the management succession scenario, we use the test data from MUC-6 (MUC-6, 1995) and define a simpler relation structure than the MUC-6 scenario template with four arguments:

<Person_In, Person_Out, Position, Organisation>

In the following tables, we use PI for Person_In, PO for Person_Out, POS for Position and ORG for Organisation. In our experiments, we attempt to investigate the influence of the size of the seed and the size of the test data on the performance. All these documents are processed by named entity recognition (Drozdzynski et al., 2004) and dependency parser MINIPAR (Lin, 1998).

6.1 Nobel Prize Domain Evaluation

For this domain, three test runs have been evaluated, initialized by one randomly selected relation instance as seed each time. In the first run, we use the largest test data set Nobel Prize A. In the second and third runs, we have compared two random selected seed samples with 50% of the data each, namely Nobel Prize B. For data sets in this domain, we are faced with an evaluation challenge pointed out by DIPRE (Brin, 1998) and Snowball (Agichtein and Gravano, 2000), because there is no gold-standard evaluation corpus available. We have adapted the evaluation method suggested by Agichtein and Gravano, i.e., our system is successful if we capture one mentioning of a Nobel Prize winner event through one instance of the relation tuple or its projections. We constructed two tables (named Ideal) reflecting an approximation of the maximal detectable relation instances: one for Nobel Prize A and another for Nobel Prize B. The Ideal tables contain the Nobel Prize winners that co-occur with the word "Nobel" in the test corpus. Then precision is the correctness of the extracted relation instances, while recall is the coverage of the extracted tuples that match with the Ideal table. In Table 2 we show the precision and recall of the three runs and their random seed sample:

Data Set	Seed	Precision	Recall	
			total	time interval
Nobel Prize A	[Zewail, Ahmed H], nobel, chemistry,1999	**71,6%**	**50,7%**	**70,9%** (1999-2005)
Nobel Prize B	[Sen, Amartya], nobel, economics, 1998	**87,3%**	**31%**	**43%** (1981-1998)
Nobel Prize B	[Arias, Oscar], nobel, peace, 1987	**83,8%**	**32%**	**45%** (1981-1998)

Table 2. Precision, Recall against the Ideal Table

The first experiment with the full test data has achieved much higher recall than the two experiments with the set Nobel Prize B. The two experiments with the Nobel Prize B corpus show similar

3 http://nobelprize.org/

performance. All three experiments have better recalls when taking only the relation instances during the report years into account, because there are more mentionings during these years in the corpus. Figure (6) depicts the pattern learning and new seed extracting behavior during the iterations for the first experiment. Similar behaviours are observed in the other two experiments.

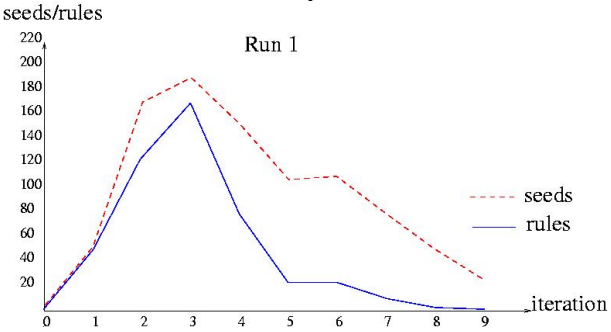

Figure 6. Experiment with Nobel Prize A

6.2 Management Succession Domain

The MUC-6 corpus is much smaller than the Nobel Prize corpus. Since the gold standard of the target relations is available, we use the standard IE precision and recall method. The total gold standard table contains 256 event instances, from which we randomly select seeds for our experiments. Table 3 gives an overview of performance of the experiments. Our tests vary between one seed, 20 seeds and 55 seeds.

Initial Seed Nr.		Precision	Recall
1	A	12.6%	7.0%
	B	15.1%	21.8%
20		48.4%	34.2%
55		62.0%	48.0%

Table 3. Results for various initial seed sets

The first two one-seed tests achieved poor performance. With 55 seeds, we can extract additional 67 instances to obtain the half size of the instances occurring in the corpus. Table 4 show evaluations of the single arguments. B works a little better because the randomly selected single seed appears a better sample for finding the pattern for extracting PI argument.

Arg	precision (A)	precision (B)	Recall (A)	Recall (B)
PI	10.9%	15.1%	8.6%	34.4%
PO	28.6%	–	2.3%	2.3%
ORG	25.6%	100%	2.6%	2.6%
POS	11.2%	11.2%	5.5%	5.5%

Table 4. Evaluation of one-seed tests (A and B)

Table 5 shows the performance with 20 and 55 seeds respectively. Both of them are better than the one-seed tests, while 55 seeds deliver the best performance in average, in particular, the recall value.

arg	precision (20)	precision (55)	recall (20)	recall (55)
PI	84%	62.8%	27.9%	56.1%
PO	41.2%	59%	34.2%	31.2%
ORG	82.4%	58.2%	7.4%	20.2%
POS	42%	64.8%	25.6%	30.6%

Table 5. Evaluation of 20 and 55 seeds tests

Our result with 20 seeds (precision of 48.4% and recall of 34.2%) is comparable with the best result reported by Greenwood and Stevenson (2006) with the linked chain model (precision of 0.434 and recall of 0.265). Since the latter model uses patterns as seeds, applying a similarity measure for pattern ranking, a fair comparison is not possible. Our result is not restricted to binary relations and our model also assigns the exact argument role to the Person role, i.e. Person_In or Person_Out.

We have also evaluated the top 100 event-independent binary relations such as Person-Organisation and Position-Organisation. The precision of these by-product relations of our IE system is above 98%.

7 Conclusion and Future Work

Several parameters are relevant for the success of a seed-based bootstrapping approach to relation extraction. One of these is the arity of the relation. Another one is the locality of the relation instance in an average mentioning. A third one is the types of the relation arguments: Are they named entities in the classical sense? Are they lexically marked? Are there several arguments of the same type? Both tasks we explored involved extracting quaternary relations. The Nobel Prize domain shows better lexical marking because of the prize name. The management succession domain has two slots of the same NE type, i.e., persons. These differences are relevant for any relation extraction approach.

The success of the bootstrapping approach crucially depends on the nature of the training data base. One of the most relevant properties of this data base is the ratio of documents to relation instances. Several independent reports of an instance usually yield a higher number of patterns.

The two tasks we used to investigate our method drastically differ in this respect. The Nobel Prize

domain we selected as a learning domain for general award events since it exhibits a high degree of redundancy in reporting. A Nobel Prize triggers more news reports than most other prizes. The achieved results met our expectations. With one randomly selected seed, we could finally extract most relevant events in some covered time interval.

However, it turns out that it is not just the average number of reports per events that matters but also the distribution of reportings to events. Since the Nobel prizes data exhibit a certain type of skewed distribution, the graph exhibits properties of scale-free graphs. The distances between events are shortened to a few steps. Therefore, we can reach most events in a few iterations. The situation is different for the management succession task where the reports came from a single newspaper. The ratio of events to reports is close to one. This lack of informational redundancy requires a higher number of seeds. When we started the bootstrapping with a single event, the results were rather poor. Going up to twenty seeds, we still did not get the performance we obtain in the Nobel Prize task but our results compare favorably to the performance of existing bootstrapping methods.

The conclusion, we draw from the observed difference between the two tasks is simple: We shall always try to find a highly redundant training data set. If at all possible, the training data should exhibit a skewed distribution of reports to events. Actually, such training data may be the only realistic chance for reaching a large number of rare patterns. In future work we will try to exploit the web as training resource for acquiring patterns while using the parsed domain data as the source for obtaining new seeds in bootstrapping the rules before applying these to any other nonredundant document base. This is possible because our seed tuples can be translated into simple IR queries and further linguistic processing is limited to the retrieved candidate documents.

A Multi-resolution Framework for Information Extraction from Free Text

Mstislav Maslennikov and Tat-Seng Chua
Department of Computer Science
National University of Singapore
{maslenni,chuats}@comp.nus.edu.sg

Abstract

Extraction of relations between entities is an important part of Information Extraction on free text. Previous methods are mostly based on statistical correlation and dependency relations between entities. This paper re-examines the problem at the multi-resolution layers of phrase, clause and sentence using dependency and discourse relations. Our multi-resolution framework ARE (Anchor and Relation) uses clausal relations in 2 ways: 1) to filter noisy dependency paths; and 2) to increase reliability of dependency path extraction. The resulting system outperforms the previous approaches by 3%, 7%, 4% on MUC4, MUC6 and ACE RDC domains respectively.

1 Introduction

Information Extraction (IE) is the task of identifying information in texts and converting it into a predefined format. The possible types of information include entities, relations or events. In this paper, we follow the IE tasks as defined by the conferences MUC4, MUC6 and ACE RDC: slot-based extraction, template filling and relation extraction, respectively.

Previous approaches to IE relied on co-occurrence (Xiao et al., 2004) and dependency (Zhang et al., 2006) relations between entities. These relations enable us to make reliable extraction of correct entities/relations at the level of a single clause. However, Maslennikov et al. (2006) reported that the increase of relation path length will lead to considerable decrease in performance. In most cases, this decrease in performance occurs because entities may belong to different clauses. Since clauses in a sentence are connected by clausal relations (Halliday and Hasan, 1976), it is thus important to perform discourse analysis of a sentence.

Discourse analysis may contribute to IE in several ways. First, Taboada and Mann (2005) reported that discourse analysis helps to decompose long sentences into clauses. Therefore, it helps to distinguish relevant clauses from non-relevant ones. Second, Miltsakaki (2003) stated that entities in subordinate clauses are less salient. Third, the knowledge of textual structure helps to interpret the meaning of entities in a text (Grosz and Sidner 1986). As an example, consider the sentences *"ABC Co. appointed a new chairman. Additionally, the current CEO was retired"*. The word 'additionally' connects the event in the second sentence to the entity 'ABC Co.' in the first sentence. Fourth, Moens and De Busser (2002) reported that discourse segments tend to be in a fixed order for structured texts such as court decisions or news. Hence, analysis of discourse order may reduce the variability of possible relations between entities.

To model these factors, we propose a multi-resolution framework ARE that integrates both discourse and dependency relations at 2 levels. ARE aims to filter noisy dependency relations from training and support their evaluation with discourse relations between entities. Additionally, we encode semantic roles of entities in order to utilize semantic relations. Evaluations on MUC4, MUC6 and ACE RDC 2003 corpora demonstrates that our approach outperforms the state-of-art systems mainly due to modeling of discourse relations.

The contribution of this paper is in applying discourse relations to supplement dependency relations in a multi-resolution framework for IE. The

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 592–599,
Prague, Czech Republic, June 2007.

framework enables us to connect entities in different clauses and thus improve the performance on long-distance dependency paths.

Section 2 describes related work, while Section 3 presents our proposed framework, including the extraction of anchor cues and various types of relations, integration of extracted relations, and complexity classification. Section 4 describes our experimental results, with the analysis of results in Section 5. Section 6 concludes the paper.

2 Related work

Recent work in IE focuses on relation-based, semantic parsing-based and discourse-based approaches. Several recent research efforts were based on modeling relations between entities. Culotta and Sorensen (2004) extracted relationships using dependency-based kernel trees in Support Vector Machines (SVM). They achieved an F_1-measure of 63% in relation detection. The authors reported that the primary source of mistakes comes from the heterogeneous nature of non-relation instances. One possible direction to tackle this problem is to carry out further relationship classification. Maslennikov et al. (2006) classified relation path between candidate entities into simple, average and hard cases. This classification is based on the length of connecting path in dependency parse tree. They reported that dependency relations are not reliable for the hard cases, which, in our opinion, need the extraction of discourse relations to supplement dependency relation paths.

Surdeanu et al. (2003) applied semantic parsing to capture the predicate-argument sentence structure. They suggested that semantic parsing is useful to capture verb arguments, which may be connected by long-distance dependency paths. However, current semantic parsers such as the ASSERT are not able to recognize support verb constructions such as *"X conducted an attack on Y"* under the verb frame "attack" (Pradhan et al. 2004). Hence, many useful predicate-argument structures will be missed. Moreover, semantic parsing belongs to the intra-clausal level of sentence analysis, which, as in the dependency case, will need the support of discourse analysis to bridge inter-clausal relations.

Webber et al. (2002) reported that discourse structure helps to extract anaphoric relations. However, their set of grammatical rules is heuristic. Our task needs construction of an automated approach to be portable across several domains. Cimiano et al. (2005) employed a discourse-based analysis for IE. However, their approach requires a predefined domain-dependent ontology in the format of extended logical description grammar as described by Cimiano and Reely (2003). Moreover, they used discourse relations between events, whereas in our approach, discourse relations connect entities.

3 Motivation for using discourse relations

Our method is based on Rhetorical Structure Theory (RST) by Taboada and Mann (2005). RST splits the texts into 2 parts: a) nuclei, the most important parts of texts; and b) satellites, the secondary parts. We can often remove satellites without losing the meaning of text. Both nuclei and satellites are connected with discourse relations in a hierarchical structure. In our work, we use 16 classes of discourse relations between clauses: *Attribution, Background, Cause, Comparison, Condition, Contrast, Elaboration, Enablement, Evaluation, Explanation, Joint, Manner-Means, Topic-Comment, Summary, Temporal, Topic-Change*. The additional 3 relations impose a tree structure: *textual-organization, span* and *same-unit*. All the discourse relation classes are potentially useful, since they encode some knowledge about textual structure. Therefore, we decide to include all of them in the learning process to learn patterns with best possible performance.

We consider two main rationales for utilizing discourse relations to IE. First, discourse relations help to narrow down the search space to the level of a single clause. For example, the sentence *"[<Soc-A1>**Trudeau**</>'s <Soc-A2>**son**</> told everyone], [their prime minister was his father], [who took him to a secret base in the arctic] [and let him peek through a window]."* contains 4 clauses and 7 anchor cues (key phrases) for the type Social, which leads to 21 possible variants. Splitting this sentence into clauses reduces the combinations to 4 possible variants. Additionally, this reduction eliminates the long and noisy dependency paths.

Second, discourse analysis enables us to connect entities in different clauses with clausal relations. As an example, we consider a sentence *"It's a dark comedy about a boy named <AT-A1>**Marshal**</> played by Amourie Kats who discovers all kinds of*

*on and scary things going on in <AT-A2>**a seemingly quiet little town**</>"*. In this example, we need to extract the relation "At" between the entities "Marshal" and "a seemingly quiet little town". The discourse structure of this sentence is given in Figure 1.

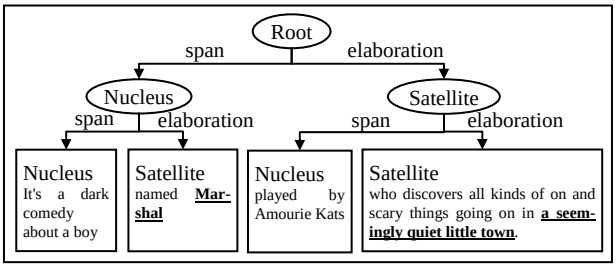

Figure 1. Example of discourse parsing

The discourse path *"Marshal <-elaboration- _ <-span- _ -elaboration-> _ -elaboration-> town"* is relatively short and captures the necessary relations. At the same time, prediction based on dependency path *"Marshal <–obj- _ <-i- _ <-fc- _ <-pnmod- _ <-pred- _ <-i- _ <-null- _ -null-> _ -rel-> _ -i-> _ -mod-> _ -pcomp-n-> town"* is unreliable, since the relation path is long. Thus, it is important to rely on discourse analysis in this example. In addition, we need to evaluate both the score and reliability of prediction by relation path of each type.

4 Anchors and Relations

In this section, we define the key components that we use in ARE: anchors, relation types and general architecture of our system. Some of these components are also presented in detail in our previous work (Maslennikov et al., 2006).

4.1 Anchors

The first task in IE is to identify candidate phrases (which we call anchor or anchor cue) of a predefined type (anchor type) to fill a desired slot in an IE template. The example anchor for the phrase "Marshal" is shown in Figure 2. Given a training set of sentences, we extract the anchor cues $A_{Cj} = [A_1, \ldots, A_{Nanch}]$ of type C_j using the procedures described in Maslennikov et al. (2006). The linguistic features of these anchors for the anchor types of Perpetrator, Action, Victim and Target for the MUC4 domain are given in Table 1.

Figure 2. Example of anchor

Anchor types / Feature	Perpetrator_Cue (A)	Action_Cue (D)	Victim_Cue (A)	Target_Cue (A)
Lexical (Head noun)	terrorists, individuals, Soldiers	attacked, murder, Massacre	Mayor, general, priests	bridge, house, Ministry
Part-of-Speech	Noun	Verb	Noun	Noun
Named Entities	Soldiers (PERSON)	-	Jesuit priests (PERSON)	WTC (OBJECT)
Synonyms	Synset 130, 166	Synset 22	Synset 68	Synset 71
Concept Class	ID 2, 3	ID 9	ID 22, 43	ID 61, 48
Co-referenced entity	He -> terrorist, soldier	-	They -> peasants	-
Clausal type	Nucleus Satellite	Nucleus, Satellite	Nucleus, Satellite	Nucleus, Satellite
Argument type	Arg_0, Arg_1	Target, -, ArgM-MNR	Arg_0, Arg_1	Arg_1, ArgM-MNR

Table 1. Linguistic features for anchor extraction

Given an input phrase P from a test sentence, we need to classify if the phrase belongs to anchor cue type C_j. We calculate the entity score as:

$$Entity\_Score(P) = \sum \delta_i * Feature\_Score_i(P,C_j) \quad (1)$$

where $Feature\_Score(P,C_j)$ is a score function for a particular linguistic feature representation of type C_j, and δ_i is the corresponding weight for that representation in the overall entity score. The weights are learned automatically using Expectation Maximization (Dempster et al., 1977). The $Feature\_Score_i(P,C_j)$ is estimated from the training set as the number of slots containing the correct feature representation type versus all the slots:

$$Feature\_Score_i(P,C_j) = \#(positive\ slots) / \#(all\ slots) \quad (2)$$

We classify the phrase P as belonging to an anchor type C_j when its $Entity\_score(P)$ is above an empirically determined threshold ω. We refer to this anchor as A_j. We allow a phrase to belong to multiple anchor types and hence the anchors alone are not enough for filling templates.

4.2 Relations

To resolve the correct filling of phrase P of type C_i in a desired slot in the template, we need to consider the relations between multiple candidate phrases of related slots. To do so, we consider several types of relations between anchors: discourse, dependency and semantic relations. These relations capture the interactions between anchors and are therefore useful for tackling the paraphrasing and alignment problems (Maslennikov et al., 2006). Given 2 anchors A_i and A_j of anchor types C_i and C_j, we consider a relation $Path_l = [A_i, Rel_1, \ldots, Rel_n, A_j]$ between them, such that there are no anchors between A_i and A_j. Additionally, we assume that the relations between anchors are represented in the form of a tree T_l, where $l = \{s, c, d\}$ refers to

discourse, dependency and semantic relation types respectively. We describe the nodes and edges of T_l separately for each type, because their representations are different:

1) The nodes of discourse tree T_c consist of clauses $[Clause_1, ..., Clause_{Ncl}]$; and their relation edges are obtained from the Spade system described in Soricut and Marcu (2003). This system performs RST-based parsing at the sentence level. The reported accuracy of Spade is 49% on the RST-DT corpus. To obtain a clausal path, we map each anchor A_i to its clause in Spade. If anchors A_i and A_j belong to the same clause, we assign them the relation *same-clause*.
2) The nodes of dependency tree T_d consist of words in sentences; and their relation edges are obtained from Minipar by Lin (1997). Lin (1997) reported a parsing performance of Precision = 88.5% and Recall = 78.6% on the SUSANNE corpus.
3) The nodes of semantic tree T_s consist of arguments $[Arg_0, ..., Arg_{Narg}]$ and targets $[Target_1, ..., Target_{Ntarg}]$. Both arguments and targets are obtained from the ASSERT parser developed by Pradhan (2004). The reported performance of ASSERT is F_1=83.8% on the identification and classification task for all arguments, evaluated using PropBank and AQUAINT as the training and testing corpora, respectively. Since the relation edges have a form $Target_k$ -> Arg_l, the relation path in semantic frame contains only a single relation. Therefore, we encode semantic relations as part of the anchor features.

In later parts of this paper, we consider only discourse and dependency relation paths $Path_l$, where $l=\{c, d\}$.

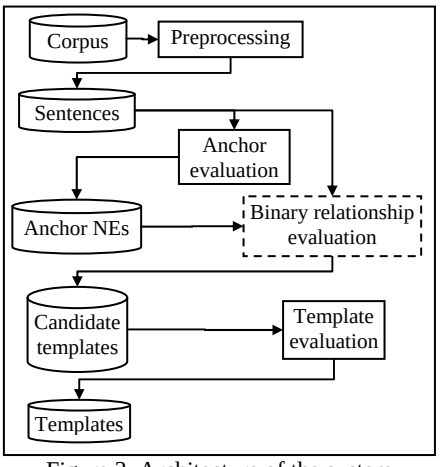

Figure 3. Architecture of the system

4.3 Architecture of ARE system

In order to perform IE, it is important to extract candidate entities (anchors) of appropriate anchor types, evaluate the relationships between them, further evaluate all possible candidate templates, and output the final template. For the case of relation extraction task, the final templates are the same as an extracted binary relation. The overall architecture of ARE is given in Figure 3.

The focus of this paper is in applying discourse relations for binary relationship evaluation.

5 Overall approach

In this section, we describe our relation-based approach to IE. We start with the evaluation of relation paths (single relation ranking, relation path ranking) to assess the suitability of their anchors as entities to template slots. Here we want to evaluate given a single relation or relation path, whether the two anchors are correct in filling the appropriate slots in a template. This is followed by the integration of relation paths and evaluation of templates.

5.1 Evaluation of relation path

In the first stage, we evaluate from training data the relevance of relation path $Path_l = [A_i, Rel_1, ..., Rel_n, A_j]$ between candidate anchors A_i and A_j of types C_i and C_j. We divide this task into 2 steps. The first step ranks each single relation $Rel_k \in Path_l$; while the second step combines the evaluations of Rel_k to rank the whole relation path $Path_l$.

Single relation ranking

Let Set_i and Set_j be the set of linguistic features of anchors A_i and A_j respectively. To evaluate Rel_k, we consider 2 characteristics: (1) the direction of relation Rel_k as encoded in the tree structure; and (2) the linguistic features, Set_i and Set_j, of anchors A_i and A_j. We need to construct multiple single relation classifiers, one for each anchor pair of types C_i and C_j, to evaluate the relevance of Rel_k with respect to these 2 anchor types.

(a) Construction of classifiers. The training data to each classifier consists of anchor pairs of types C_i and C_j extracted from the training corpus. We use these anchor pairs to construct each classifier in four stages. First, we compose the set of possible patterns in the form $P^+ = \{ P_m = <S_i –Rel-> S_j> \mid S_i \in Set_i , S_j \in Set_j \}$. The construction of P_m

conforms to the 2 characteristics given above. Figure 4 illustrates several discourse and dependency patterns of P^+ constructed from a sample sentence.

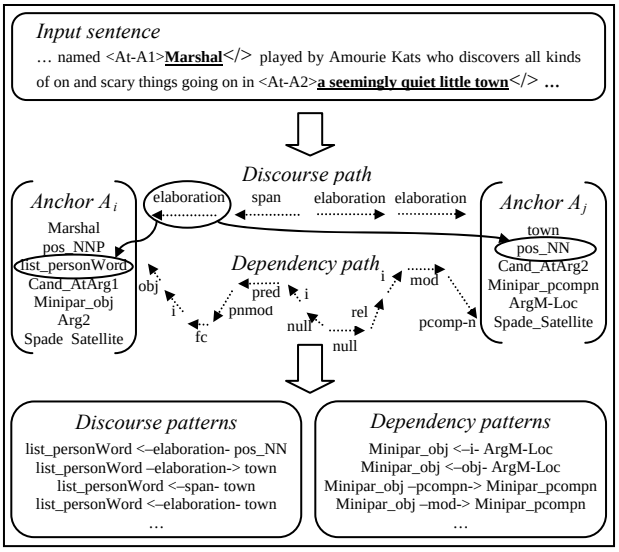

Figure 4. Examples of discourse and dependency patterns

Second, we identify the candidate anchor A, whose type matches slot C in a template. Third, we find the correct patterns for the following 2 cases: 1) A_i, A_j are of correct anchor types; and 2) A_i is an action anchor, while A_j is a correct anchor. Any other patterns are considered as incorrect. We note that the discourse and dependency paths between anchors A_i and A_j are either correct or wrong simultaneously.

Fourth, we evaluate the relevance of each pattern $P_m \in P^+$. Given the training set, let $PairSet_m$ be the set of anchor pairs extracted by P_m; and $PairSet^+(C_i, C_j)$ be the set of correct anchor pairs of types C_i, C_j. We evaluate both precision and recall of P_m as

$$Precision(P_m) = \frac{\| PairSet_m \text{ I } PairsSet^+(C_i, C_j) \|}{\| PairSet_m \|} \quad (3)$$

$$Recall(P_m) = \frac{\| PairSet_m \text{ I } PairsSet^+(C_i, C_j) \|}{\| PairsSet^+(C_i, C_j) \|} \quad (4)$$

These values are stored and used in the training model for use during testing.

(b) Evaluation of relation. Here we want to evaluate whether relation *InputRel* belongs to a path between anchors $InputA_i$ and $InputA_j$. We employ the constructed classifier for the anchor types $InputC_i$ and $InputC_j$ in 2 stages. First, we find a subset $P^{(0)} = \{ P_m = <S_i \text{ –}InputRel\text{->} S_j> \in P^+ \mid S_i \in InputSet_i, S_j \in InputSet_j \}$ of applicable patterns. Second, we utilize $P^{(0)}$ to find the pattern $P_m^{(0)}$ with maximal precision:

$$Precision(P_m^{(0)}) = argmax_{Pm \in P(0)} Precision(P_m) \quad (5)$$

A problem arises if $P_m^{(0)}$ is evaluated only on a small amount of training instances. For example, we noticed that patterns that cover 1 or 2 instances may lead to $Precision=1$, whereas on the testing corpus their accuracy becomes less than 50%. Therefore, it is important to additionally consider the recall parameter of $P_m^{(0)}$.

Relation path ranking

In this section, we want to evaluate relation path connecting template slots C_i and C_j. We do this independently for each relation of type discourse and dependency. Let $Recall_k$ and $Precision_k$ be the recall and precision values of Rel_k in $Path = [A_i, Rel_1, \ldots, Rel_n, A_j]$, both obtained from the previous step. First, we calculate the average recall of the involved relations:

$$W = (1/Length_{Path}) * \Sigma_{Relk \in Path} Recall_k \quad (6)$$

W gives the average recall of the involved relations and can be used as a measure of reliability of the relation *Path*. Next, we compute a combined score of average $Precision_k$ weighted by $Recall_k$:

$$Score = 1/(W*Length_{Path}) * \Sigma_{Relk \in Path} Recall_k * Precision_k \quad (7)$$

We use all $Precision_k$ values in the path here, because omitting a single relation may turn a correct path into the wrong one, or vice versa. The combined score value is used as a ranking of the relation path. Experiments show that we need to give priority to scores with higher reliability W. Hence we use $(W, Score)$ to evaluate each *Path*.

5.2 Integration of different relation path types

The purpose of this stage is to integrate the evaluations for different types of relation paths. The input to this stage consists of evaluated relation paths $Path_C$ and $Path_D$ for discourse and dependency relations respectively. Let $(W_l, Score_l)$ be an evaluation for $Path_l$, $l \in [c, d]$. We first define an integral path $Path_I$ between A_i and A_j as: 1) $Path_I$ is enabled if at least one of $Path_l$, $l \in [c, d]$, is enabled; and 2) $Path_I$ is correct if at least one of $Path_l$ is correct. To evaluate $Path_I$, we consider the average recall W_l of each $Path_l$, because W_l esti-

mates the reliability of $Score_I$. We define a weighted average for $Path_I$ as:

$$W_I = W_C + W_D \quad (8)$$

$$Score_I = 1/W_I * \sum_l W_l * Score_l \quad (9)$$

Next, we want to determine the threshold score $Score_I^O$ above which $Score_I$ is acceptable. This score may be found by analyzing the integral paths on the training corpus. Let $S_I = \{ Path_I \}$ be the set of integral paths between anchors A_i and A_j on the training set. Among the paths in S_I, we need to define a set function $S_I(X) = \{ Path_I \mid Score_I(Path_I) \geq X \}$ and find the optimal threshold for X. We find the optimal threshold based on F_1-measure, because precision and recall are equally important in IE. Let $S_I(X)^+ \subset S_I(X)$ and $S(X)^+ \subset S(X)$ be sets of correct path extractions. Let $F_I(X)$ be F_1-measure of $S_I(X)$:

$$P_I(X) = \frac{\| S_I(X)^+ \|}{\| S_I(X) \|} \quad (10) \qquad R_I(X) = \frac{\| S_I(X)^+ \|}{\| S(X)^+ \|} \quad (11)$$

$$F_I(X) = \frac{2 * P_I(X) * R_I(X)}{P_I(X) + R_I(X)} \quad (12)$$

Based on the computed values $F_I(X)$ for each X on the training data, we determine the optimal threshold as $Score_I^O = argmax_X\ F_I(X)$, which corresponds to the maximal expected F_1-measure of anchor pair A_i and A_j.

5.3 Evaluation of templates

At this stage, we have a set of accepted integral relation paths between any anchor pair A_i and A_j. The next task is to merge appropriate set of anchors into candidate templates. Here we follow the methodology of Maslennikov et al. (2006). For each sentence, we compose a set of candidate templates T using the extracted relation paths between each A_i and A_j. To evaluate each template $T_i \in T$, we combine the integral scores from relation paths between its anchors A_i and A_j into the overall $Relation\_Score_T$:

$$Relation\_Score_T(T_i) = \frac{\sum_{1 \leq i,j \leq K} Score_I(A_i, A_j)}{M} \quad (13)$$

where K is the number of extracted slots, M is the number of extracted relation paths between anchors A_i and A_j, and $Score_I(A_i, A_j)$ is obtained from Equation (9).

Next, we calculate the extracted entity score based on the scores of all the anchors in T_i:

$$Entity\_Score_T(T_i) = \sum_{1 \leq k \leq K} Entity\_Score(A_k) / K \quad (14)$$

where $Entity\_Score(A_i)$ is taken from Equation (1).

Finally, we obtain the combined evaluation for a template:

$$Score_T(T_i) = (1 - \lambda) * Entity\_Score_T(T_i) + \lambda * Relation\_Score_T(T_i) \quad (15)$$

where λ is a predefined constant.

In order to decide whether the template T_i should be accepted or rejected, we need to determine a threshold $Score_T^O$ from the training data. If anchors of a candidate template match slots in a correct template, we consider the candidate template as correct. Let $TrainT = \{ T_i \}$ be the set of candidate templates extracted from the training data, $TrainT^+ \subset TrainT$ be the subset of correct candidate templates, and $TotalT^+$ be the total set of correct templates in the training data. Also, let $TrainT(X) = \{ T_i \mid Score_T(T_i) \geq X, T_i \in TrainT \}$ be the set of candidate templates with score above X and $TrainT^+(X) \subset TrainT(X)$ be the subset of correct candidate templates. We define the measures of precision, recall and F_1 as follows:

$$P_T(X) = \frac{\| TrainT^+(X) \|}{\| TrainT(X) \|} \quad (16) \qquad R_T(X) = \frac{\| TrainT^+(X) \|}{\| TotalT^+ \|} \quad (17)$$

$$F_T(X) = \frac{2 * P_T(X) R_T(X)}{P_T(X) + R_T(X)} \quad (18)$$

Since the performance in IE is measured in F_1-measure, an appropriate threshold to be used for the most prominent candidate templates is:

$$Score_T^O = argmax_X\ F_T(X) \quad (19)$$

The value $Score_T^O$ is used as a training model. During testing, we accept a candidate template $InputT_i$ if $Score_T(InputT_i) > Score_T^O$.

As an additional remark, we note that domains MUC4, MUC6 and ACE RDC 2003 are significantly different in the evaluation methodology for the candidate templates. While the performance of the MUC4 domain is measured for each slot individually; the MUC6 task measures the performance on the extracted templates; and the ACE RDC 2003 task evaluates performance on the matching relations. To overcome these differences, we construct candidate templates for all the domains and measure the required type of performance for each domain. Our candidate templates for the ACE RDC 2003 task consist of only 2 slots, which correspond to entities of the correct relations.

6 Experimental results

We carry out our experiments on 3 domains: MUC4 (Terrorism), MUC6 (Management Succession), and ACE-Relation Detection and Characterization (2003). The MUC4 corpus contains 1,300 documents as training set and 200 documents (TST3 and TST4) as official testing set. We used a modified version of the MUC6 corpus described by Soderland (1999). This version includes 599 documents as training set and 100 documents as testing set. Following the methodology of Zhang et al. (2006), we use only the English portion of ACE RDC 2003 training data. We used 97 documents for testing and the remaining 155 documents for training. Our task is to extract 5 major relation types and 24 subtypes.

Case (%)	P	R	F_1
GRID	52%	62%	57%
Riloff'05	46%	51%	48%
ARE (2006)	58%	61%	60%
ARE	65%	61%	63%

Table 2. Results on MUC4

To compare the results on the terrorism domain in MUC4, we choose the recent state-of-art systems GRID by Xiao et al. (2004), Riloff et al. (2005) and ARE (2006) by Maslennikov et al. (2006) which does not utilize discourse and semantic relations. The comparative results are given in Table 2. It shows that our enhanced ARE results in 3% improvement in F_1 measure over ARE (2006) that does not use clausal relations. The improvement was due to the use of discourse relations on long paths, such as "X *distributed leaflets claiming responsibility for* murder *of* Y". At the same time, for many instances, it would be useful to store the extracted anchors for another round of learning. For example, the extracted features of discourse pattern "murder –same_clause-> HUM_PERSON" may boost the score for patterns that correspond to relation path "X <-span- _ -Elaboration-> murder". In this way, high-precision patterns will support the refinement of patterns with average recall and low precision. This observation is similar to that described in Ciravegna's work on $(LP)^2$ (Ciravegna 2001).

Case (%)	P	R	F_1
Chieu et al.'02	75%	49%	59%
ARE (2006)	73%	58%	65%
ARE	73%	70%	72%

Table 3. Results on MUC6

Next, we present the performance of our system on MUC6 corpus (Management Succession) as shown in Table 3. The improvement of 7% in F_1 is mainly due to the filtering of irrelevant dependency relations. Additionally, we noticed that 22% of testing sentences contain 2 answer templates, and entities in many of such templates are intertwined. One example is the sentence *"Mr. Bronczek who is 39 years old succeeds Kenneth Newell 55 who was named to the new post of senior vice president"*, which refers to 2 positions. We therefore we need to extract 2 templates *"PersonIn: Bronczek, PersonOut: Newell"* and *"PersonIn: Newell, Post: senior vice president"*. The discourse analysis is useful to extract the second template, while rejecting another long-distance template *"PersonIn: Bronczek, PersonOut: Newell, Post: seniour vice president"*. Another remark is that it is important to assign 2 anchors of 'Cand_PersonIn' and 'Cand_PersonOut' for the phrase "Kenneth Newell".

The characteristic of the ACE corpus is that it contains a large amount of variations, while only 2% of possible dependency paths are correct. Since many of the relations occur only at the level of single clause (for example, most instances of relation *At*), the discourse analysis is used to eliminate long-distance dependency paths. It allows us to significantly decrease the dimensionality of the problem. We noticed that 38% of relation paths in ACE contain a single relation, 28% contain 2 relations and 34% contain ≥ 3 relations. For the case of ≥ 3 relations, the analysis of dependency paths alone is not sufficient to eliminate the unreliable paths. Our results for general types and specific subtypes are presented in Tables 6 and 7, respectively.

Case (%)	P	R	F_1
Zhang et al.'06	77%	65%	70%
ARE	79%	66%	73%

Table 4. Results on ACE RDC'03, general types

Based on our results in Table 4, discourse and dependency relations support each other in different situations. We also notice that multiple instances require modeling of entities in the path. Thus, in our future work we need to enrich the search space for relation patterns. This observation corresponds to that reported in Zhang et al. (2006).

Discourse parsing is very important to reduce the amount of variations for specific types on ACE

RDC'03, as there are 48 possible anchor types.

Case (%)	P	R	F_1
Zhang et al.'06	64%	51%	57%
ARE	67%	54%	61%

Table 5. Results on ACE RDC'03, specific types

The relatively small improvement of results in Table 5 may be attributed to the following reasons: 1) it is important to model the commonality relations, as was done by Zhou et al. (2006); and 2) our relation paths do not encode entities. This is different from Zhang et al. (2006), who were using entities in their subtrees.

Overall, the results indicate that the use of discourse relations leads to improvement over the state-of-art systems.

7 Conclusion

We presented a framework that permits the integration of discourse relations with dependency relations. Different from previous works, we tried to use the information about sentence structure based on discourse analysis. Consequently, our system improves the performance in comparison with the state-of-art IE systems. Another advantage of our approach is in using domain-independent parsers and features. Therefore, ARE may be easily portable into new domains.

Currently, we explored only 2 types of relation paths: dependency and discourse. For future research, we plan to integrate more relations in our multi-resolution framework.

Abstract

Many errors produced by unsupervised and semi-supervised relation extraction (RE) systems occur because of wrong recognition of entities that participate in the relations. This is especially true for systems that do not use separate named-entity recognition components, instead relying on general-purpose shallow parsing. Such systems have greater applicability, because they are able to extract relations that contain attributes of unknown types. However, this generality comes with the cost in accuracy. In this paper we show how to use corpus statistics to validate and correct the arguments of extracted relation instances, improving the overall RE performance. We test the methods on SRES – a self-supervised Web relation extraction system. We also compare the performance of corpus-based methods to the performance of validation and correction methods based on supervised NER components.

1 Introduction

Information Extraction (IE) is the task of extracting factual assertions from text. Most IE systems rely on knowledge engineering or on machine learning to generate the "task model" that is subsequently used for extracting instances of entities and relations from new text. In the knowledge engineering approach the model (usually in the form of extraction rules) is created manually, and in the machine learning approach the model is learned automatically from a manually labeled training set of documents. Both approaches require substantial human effort, particularly when applied to the broad range of documents, entities, and relations on the Web. In order to minimize the manual effort necessary to build Web IE systems, semi-supervised and completely unsupervised systems are being developed by many researchers.

The task of extracting facts from the Web has significantly different aims than the regular information extraction. The goal of regular IE is to identify and label all mentions of all instances of the given relation type inside a document or inside a collection of documents. Whereas, in the Web Extraction (WE) tasks we are only interested in extracting relation instances and not interested in particular mentions.

This difference in goals leads to a difference in the methods of performance evaluation. The usual measures of performance of regular IE systems are precision, recall, and their combinations – the breakeven point and F-measure. Unfortunately, the true recall usually cannot be known for WE tasks. Consequently, for evaluating the performance of WE systems, the recall is substituted by the number of extracted instances.

WE systems usually order the extracted instances by the system's confidence in their correctness. The precision of top-confidence extractions is usually very high, but it gets progressively lower when lower-confidence candidates are considered. The curve that plots the number of extractions against precision level is the best indicator of system's quality. Naturally, for a comparision be-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 600–607,
Prague, Czech Republic, June 2007.

tween different systems to be meaningful, the evaluations must be performed on the same corpus.

In this paper we are concerned with Web RE systems that extract binary relations between named entities. Most of such systems utilize separate named entity recognition (NER) components, which are usualy trained in a supervised way on a separate set of manually labeled documents. The NER components recognize and extract the values of relation attributes (also called *arguments*, or *slots*), while the RE systems are concerned with patterns of contexts in which the slots appear. However, good NER components only exist for common and very general entity types, such as *Person*, *Organization*, and *Location*. For some relations, the types of attributes are less common, and no ready NER components (or ready labeled training sets) exist for them. Also, some Web RE systems (e.g., KnowItAll (Etzioni, Cafarella et al. 2005)) do not use separate NER components even for known entity types, because such components are usually domain-specific and may perform poorly on cross-domain text collections extracted from the Web.

In such cases, the values for relation attributes must be extracted by generic methods – shallow parsing (extracting noun phrases), or even simple substring extraction. Such methods are naturally much less precise and produce many entity-recognition errors (Feldman and Rosenfeld 2006).

In this paper we propose several methods of using corpus statistics to improve Web RE precision by validating and correcting the entities extracted by generic methods. The task of Web Extraction is particularly suited for the corpus statistics-based methods because of very large size of the corpora involved, and because the system is not required to identify individual mentions of the relations.

Our methods of entity validation and correction are based on the following two observations:

First, the entities that appear in target relations will often also appear in many other contexts, some of which may strongly discriminate in favor of entities of specific type. For example, assume the system encounters a sentence "*Oracle bought PeopleSoft.*" If the system works without a NER component, it only knows that "*Oracle*" and "*PeopleSoft*" are proper noun phrases, and its confidence in correctness of a candidate relation instance *Acquisition*(*Oracle*, *PeopleSoft*) cannot be very high. However, both entities occur many times elsewhere in the corpus, sometimes in strongly discriminating contexts, such as "*Oracle is a company that…*" or "*PeopleSoft Inc.*" If the system somehow learned that such contexts indicate entities of the correct type for the *Acquisition* relation (i.e., companies), then the system would be able to boost its confidence in both entities ("*Oracle*" and "*PeopleSoft*") being of correct types and, consequently, in (*Oracle*, *PeopleSoft*) being a correct instance of the *Acquisition* relation.

Another observation that we can use is the fact that the entities, in which we are interested, usually have sufficient frequency in the corpus for statistical term extraction methods to perform reasonably well. These methods may often correct a wrongly placed entity boundary, which is a common mistake of general-purpose shallow parsers.

In this paper we show how to use these observations to supplement a Web RE system with an entity validation and correction component, which is able to significantly improve the system's accuracy. We evaluate the methods using SRES (Feldman and Rosenfeld 2006) – a Web RE system, designed to extend and improve KnowItAll (Etzioni, Cafarella et al. 2005). The contributions of this paper are as follows:

- We show how to automatically generate the validating patterns for the target relation arguments, and how to integrate the results produced by the validating patterns into the whole relation extraction system.
- We show how to use corpus statistics and term extraction methods to correct the boundaries of relation arguments.
- We experimentally compare the improvement produced by the corpus-based entity validation and correction methods with the improvements produced by two alternative validators – a CRF-based NER system trained on a separate labeled corpus, and a small manually-built rule-based NER component.

The rest of the paper is organized as follows: Section 2 describes previous work. Section 3 outlines the general design principles of SRES and briefly describes its components. Section 4 describes in detail the different entity validation and correction methods, and Section 5 presents their

experimental evaluation. Section 6 contains conclusions and directions for future work.

2 Related Work

We are not aware of any work that deals specifically with validation and/or correction of entity recognition for the purposes of improving relation extraction accuracy. However, the background techniques of our methods are relatively simple and known. The validation is based on the same ideas that underlie semi-supervised entity extraction (Etzioni, Cafarella et al. 2005), and uses a simplified SRES code. The boundary correction process utilizes well-known term extraction methods, e.g., (Su, Wu et al. 1994).

We also recently became aware of the work by Downey, Broadhead and Etzioni (2007) that deals with locating entities of arbitrary types in large corpora using corpus statistics.

The IE systems most similar to SRES are based on bootstrap learning: Mutual Bootstrapping (Riloff and Jones 1999), the DIPRE system (Brin 1998), and the Snowball system (Agichtein and Gravano 2000). Ravichandran and Hovy (Ravichandran and Hovy 2002) also use bootstrapping, and learn simple surface patterns for extracting binary relations from the Web.

Unlike these systems, SRES surface patterns allow gaps that can be matched by any sequences of tokens. This makes SRES patterns more general, and allows to recognize instances in sentences inaccessible to the simple surface patterns of systems such as (Brin 1998; Riloff and Jones 1999; Ravichandran and Hovy 2002).

Another direction for unsupervised relation learning was taken in (Hasegawa, Sekine et al. 2004; Chen, Ji et al. 2005). These systems use a NER system to identify frequent pairs of entities and then cluster the pairs based on the types of the entities and the words appearing between the entities. The main benefit of this approach is that all relations between two entity types can be discovered simultaneously and there is no need for the user to supply the relations definitions.

3 Description of SRES

The goal of SRES is extracting instances of specified relations from the Web without human supervision. Accordingly, the supervised input to the system is limited to the specifications of the target relations. A specification for a given relation consists of the *relation schema* and a small set of *seeds* – known true instances of the relation. In the full-scale SRES, the seeds are also generated automatically, by using a set of generic patterns instantiated with the relation schema. However, the seed generation is not relevant to this paper.

A relation schema specifies the name of the relation, the names and types of its arguments, and the arguments ordering. For example, the schema of the *Acquisition* relation

Acquisition(Buyer=ProperNP,
Acquired=ProperNP) ordered

specifies that *Acquisition* has two slots, named *Buyer* and *Acquired*, which must be filled with entities of type *ProperNP*. The order of the slots is important (as signified by the word "*ordered*", and as opposed to relations like *Merger*, which are "*unordered*" or, in binary case, "*symmetric*").

The baseline SRES does not utilize a named entity recognizer, instead using a shallow parser for exracting the relation slots. Thus, the only allowed entity types are *ProperNP*, *CommonNP*, and *AnyNP*, which mean the heads of, respectively, proper, common, and arbitrary noun phrases. In the experimental section we compare the baseline SRES to its extensions containing additional NER components. When using those components we allow further subtypes of *ProperNP*, and the relation schema above becomes

... (Buyer=Company, Acquired=Company) ...

The main components of SRES are the Pattern Learner, the Instance Extractor, and the Classifier. The Pattern Learner uses the seeds to learn likely patterns of relation occurrences. Then, the Instance Extractor uses the patterns to extract the candidate instances from the sentences. Finally, the Classifier assigns the confidence score to each extraction. We shall now briefly describe these components.

3.1 Pattern Learner

The *Pattern Learner* receives a relation schema and a set of seeds. Then it finds the occurences of seeds inside a large (unlabeled) text corpus, analyzes their contexts, and extracts common patterns among these contexts. The details of the patterns language and the process of pattern learning are not significant for this paper, and are described fully in (Feldman and Rosenfeld 2006).

3.2 Instance Extractor

The Instance Extractor applies the patterns generated by the Pattern Learner to the text corpus. In order to be able to match the slots of the patterns, the Instance Extractor utilizes an external shallow parser from the OpenNLP package (http://opennlp.sourceforge.net/), which is able to find all proper and common noun phrases in a sentence. These phrases are matched to the slots of the patterns. In other respects, the pattern matching and extraction process is straightforward.

3.3 Classifier

The goal of the final classification stage is to filter the list of all extracted instances, keeping the correct extractions, and removing mistakes that would always occur regardless of the quality of the patterns. It is of course impossible to know which extractions are correct, but there exist properties of patterns and pattern matches that increase or decrease the confidence in the extractions that they produce.

These properties are turned into a set of binary features, which are processed by a linear feature-rich classifier. The classifier receives a feature vector for a candidate, and produces a confidence score between 0 and 1.

The set of features is small and is not specific to any particular relation. This allows to train a model using a small amount of labeled data for one relation, and then use the model for scoring the candidates of all other relations. Since the supervised training stage needs to be run only once, it is a part of the system development, and the complete system remains unsupervised, as demonstrated in (Feldman and Rosenfeld 2006).

4 Entity Validation and Correction

In this paper we describe three different methods of validation and correction of relation arguments in the extracted instances. Two of them are "classical" and are based, respectively, on the knowledge-engineering, and on the statistical supervised approaches to the named entity recognition problems. The third is our novel approach, based on redundancy and corpus statistics.

The methods are implemented as components for SRES, called Entity Validators, inserted between the Instance Extractor and the Classifier. The result of applying Entity Validator to a candidate instance is an (optionally) fixed instance, with validity values attached to all slots. There are three validity values: *valid*, *invalid*, and *uncertain*.

The Classifier uses the validity values by converting them into two additional binary features, which are then able to influence the confidence of extractions.

We shall now describe the three different validators in details.

4.1 Small Rule-based NER validator

This validator is a small Perl script that checks whether a character string conforms to a set of simple regular expression patterns, and whether it appears inside lists of known named entities. There are two sets of regular expression patterns – for *Person* and for *Company* entity types, and three large lists – for known personal names, known companies, and "other known named entities", currently including locations, universities, and government agencies.

The manually written regular expression represent simple regularities in the internal structure of the entity types. For example, the patterns for *Person* include:

```
Person = KnownFirstName  [Initial]  LastName
Person = Honorific [FirstName] [Initial] LastName
Honorific = ("Mr" | "Ms" | "Dr" |…) ["."]
Initial = CapitalLetter ["."]
KnownFirstName = member of
                        KnownPersonalNamesList
FirstName = CapitalizedWord
LastName = CapitalizedWord
LastName = CapitalizedWord ["–"CapitalizedWord]
LastName = ("o" | "de" | …) "`"CapitalizedWord
        …
```

while the patterns for *Company* include:

```
Company = KnownCompanyName
Company = CompanyName CompanyDesignator
Company = CompanyName FrequentCompanySfx
KnownCompanyName = member of
                              KnownCompaniesList
CompanyName = CapitalizedWord +
CompanyDesignator = "inc" | "corp" | "co" | …
FrequentCompanySfx = "systems" | "software" | …
        …
```

The validator works in the following way: it receives a sentence with a labeled candidate entity of a specified entity type (which can be either *Person* or *Company*). It then applies all of the regular expression patterns to the labeled text and to its en-

closing context. It also checks for membership in the lists of known entities. If a boundary is incorrectly placed according to the patterns or to the lists, it is fixed. Then, the following result is returned:

Valid, if some pattern/list of the right entity type matched the candidate entity, while there were no matches for patterns/lists of other entity types.

Invalid, if no pattern/list of the right entity type matched the candidate entity, while there were matches for patterns/lists of other entity types.

Uncertain, otherwise, that is either if there were no matches at all, or if both correct and incorrect entity types matched.

The number of patterns is relatively small, and the whole component consists of about 300 lines in Perl and costs several person-days of knowledge engineering work. Despite its simplicity, we will show in the experimental section that it is quite effective, and even often outperforms the CRF-based NER component, described below.

4.2 CRF-based NER validator

This validator is built using a feature-rich CRF-based sequence classifier, trained upon an English dataset of the CoNLL 2003 shared task (Rosenfeld, Fresko et al. 2005). For the gazetteer lists it uses the same large lists as the rule-based component described above.

The validator receives a sentence with a labeled candidate entity of a specified entity type (which can be either *Person* or *Company*). It then sends the sentence to the CRF-based classifier, which labels all named entities it knows – *Dates*, *Times*, *Percents*, *Persons*, *Organizations*, and *Locations*. If the CRF classifier places the entity boundaries differently, they are fixed. Then, the following result is returned:

Valid, if CRF classification of the entity accords with the expected argument type.

Invalid, if CRF classification of the entity is different from the expected argument type.

Uncertain, otherwise, that is if the CRF classifier didn't recognize the entity at all.

4.3 Corpus-based NER validator

The goal of building the corpus-based NER validator is to provide the same level of performance as the supervised NER components, while requiring neither additional human supervision nor additional labeled corpora or other resources. There are several important facts that help achieve this goal.

First, the relation instances that are used as seeds for the pattern learning are known to contain correct instances of the right entity type. These instances can be used as seeds in their own right, for learning the patterns of occurrence of the corresponding entity types. Second, the entities in which we are interested usually appear in the corpus with a sufficient frequency. The validation is based on the first observation, while the boundary fixing on the second.

Corpus-based entity validation

There is a preparation stage, during which the information required for validation is extracted from the corpus. This information is the lists of all entities of every type that appears in the target relations. In order to extract these lists we use a simplified SRES. The entities are considered to be unary relations, and the seeds for them are taken from the slots of the target binary relations seeds. We don't use the Classifier on the extracted entity instances. Instead, for every extracted instance we record the number of different sentences the entity was extracted from.

During the validation process, the validator's task is to evaluate a given candidate entity instance. The validator compares the number of times the instance was extracted (during the preparation stage) by the patterns for the correct entity type, and by the patterns for all other entity types. The validator then returns

Valid, if the number of times the entity was extracted for the specified entity type is at least 5, and at least two times bigger than the number of times it was extracted for all other entity types.

Invalid, if the number of times the instance was extracted for the specified entity type is less than 5, and at least 2 times smaller than the number of times it was extracted for all other entity types.

Uncertain, otherwise, that is if it was never extracted at all, or extracted with similar frequency for both correct and wrong entity types.

Corpus-based correction of entity boundaries

Our entity boundaries correction mechanism is similar to the known statistical term extraction techniques (Su, Wu et al. 1994). It is based on the assumption that the component words of a term (an entity in our case) are more tightly bound to each other than to the context. In the statistical sense, this fact is expressed by a high mutual information between the adjacent words belonging to the same term.

There are two possible boundary fixes: removing words from the candidate entity, or adding words from the context to the entity. There is a significant practical difference between the two cases.

Assume that an entity boundary was placed too broadly, and included extra words. If this was a chance occurrence (and only such cases can be found by statistical methods), then the resulting sequence of tokens will be very infrequent, while its parts will have relatively high frequency. For example, consider a sequence "*Formerly Microsoft Corp*.", which is produced by mistakenly labeling "*Formerly*" as a proper noun by the PoS tagger. While it is easy to know from the frequencies that a boundary mistake was made, it is unclear (to the system) which part is the correct entity. But since the entity (one of the parts of the candidate) has a high frequency, there is a chance that the relation instance, in which the entity appears, will be repeated elsewhere in the corpus and will be extracted correctly there. Therefore, in such case, the simplest recourse is to simply label the entity as *Invalid*, and not to try fixing the boundaries.

On the other hand, if a word was missed from an entity (e.g., "*Beverly O*", instead of "*Beverly O ' Neill*"), the resulting sequence will be frequent. Moreover, it is quite probable that the same boundary mistake is made in many places, because the same sequence of tokens is being analyzed in all those places. Therefore, it makes sense to try to fix the bounary in this case, especially since it can be done simply and reliably: a word (or several words) is attached to the entity string if both their frequencies and their mutual information are above a threshold.

5 Experimental Evaluation

The experiments described in this paper aim to confirm the effectiveness of the proposed corpus-based relation argument validation and correction method, and to compare its performance with the classical knowledge-engineering-based and supervised-training-based methods. The experiments were performed with five relations:

Acquisition(BuyerCompany, AcquiredCompany),
Merger(Company1, Company2),
CEO_Of(Company, Person),
MayorOf(City, Person),
InventorOf(Person, Invention).

The data for the experiments were collected by the KnowItAll crawler. The data for the Acquisition and Merger consist of about 900,000 sentences for each of the two relations. The data for the bound relations consist of sentences, such that each contains one of a hundred values of the first (bound) attribute. Half of the hundred are frequent entities (>100,000 search engine hits), and another half are rare (<10,000 hits).

For evaluating the validators we randomly selected a set of 10000 sentences from the corpora for each of the relations, and manually evaluated the SRES results generated from these sentences. Four sets of results were evaluated: the baseline results produced without any NER validator, and three sets of results produced using three different NER validators. For the *InventorOf* relation, only the corpus-based validator results can be produced, since the other two NER components cannot be adapted to validate/correct entities of type *Invention*.

The results for the five relations are shown in the Figure 1. Several conclusions can be drawn from the graphs. First, all of the NER validators improve over the baseline SRES, sometimes as much as doubling the recall at the same level of precision. In most cases the three validators show roughly similar levels of performance. A notable difference is the *CEO_Of* relation, where the simple rule-based component performs much better than CRF, which performs yet better than the corpus-based component. The *CEO_Of* relation is tested as bound, which means that only the second relation argument, of type *Person*, is validated. The *Person* entities have much more rigid internal structure than the other entities – *Companies* and *Inventions*. Consequently, the best performing of

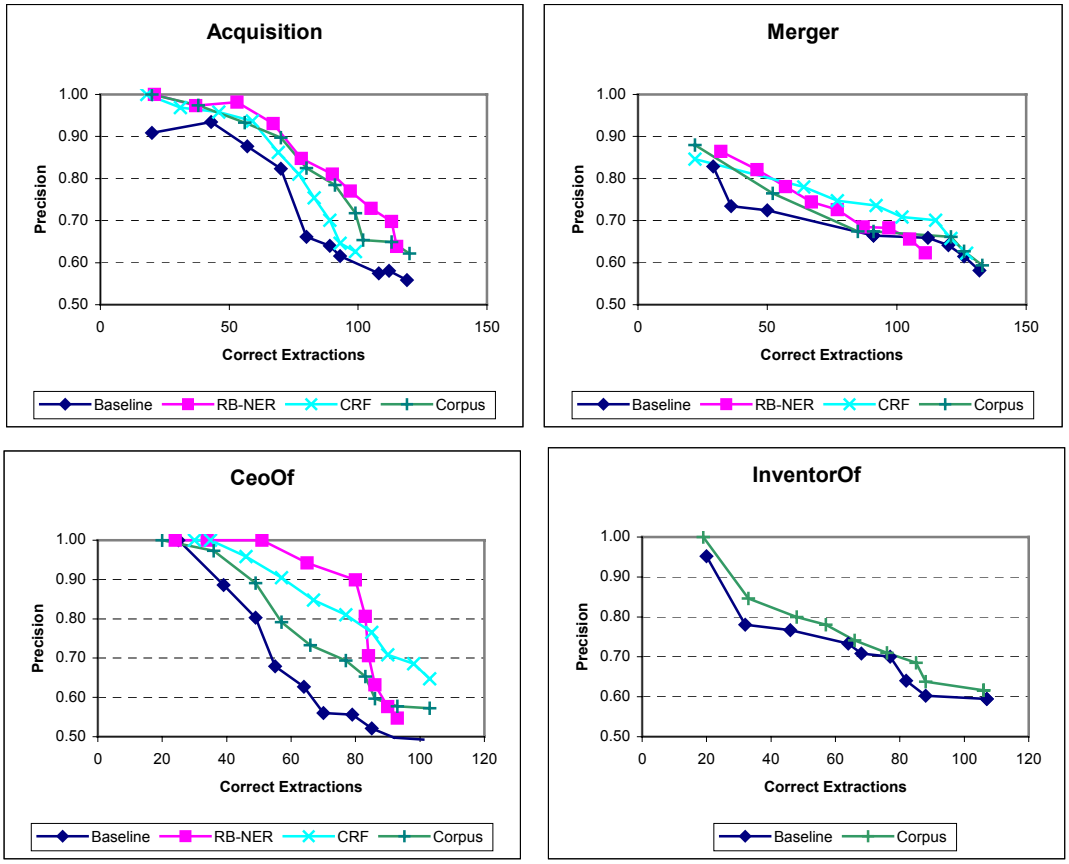

Figure 1. Comparison between Baseline-SRES and its extensions with three different NER validators: a simple Rule-Based one, a CRF-based statistical one, and a Corpus-based one.

the three validators is the rule-based, which directly tests this internal structure. The CRF-based validator is also able to take advantage of the structure, although in a weaker manner. The Corpus-based validator, however, works purely on the basis of context, entirely disregarding the internal structure of entities, and thus performs worst of all in this case. On the other hand, the Corpus-based validator is able to improve the results for the *Inventor* relation, which the other two validators are completely unable to do.

It is also of interest to compare the performance of CRF-based and the rule-based NER components in other cases. As can be seen, in most cases the rule-based component, despite its simplicity, outperforms the CRF-based one. The possible reason for this is that relation extraction setting is significantly different from the classical named entity recognition setting. A classical NER system is set to maximize the F_1 measure of all mentions of all entities in the corpus. A relation argument extractor, on the other hand, should maximize its performance on relation arguments, and apparently their statistical properties are often significantly different.

6 Conclusions

We have presented a novel method for validation and correction of relation arguments for the state-of-the-art unsupervised Web relation extraction system SRES. The method is based on corpus statistics and requires no human supervision and no additional corpus resources beyond the corpus that is used for relation extraction.

We showed experimentally the effectiveness of our method, which performed comparably to both simple rule-based NER and a statistical CRF-based NER in the task of validating *Companies*, and somewhat worse in the task of validating *Persons*,

due to its complete disregard of internal structure of entities. The ways to learn and use this structure in an unsupervised way are left for future research.

Our method also successfully validated the *Invention* entities, which are inaccessible to the other methods due to the lack of training data.

In our experiments we made use of a unique feature of SRES system – a feature-rich classifier that assigns confidence score to the candidate instances, basing its decisions on various features of the patterns and of the contexts from which the candidates were extracted. This architecture allows easy integration of the entity validation components as additional feature generators. We believe, however, that our results have greater applicability, and that the corpus statistics-based components can be added to RE systems with other architectures as well.

Beyond Projectivity: Multilingual Evaluation of Constraints and Measures on Non-Projective Structures

Jiří Havelka
Institute of Formal and Applied Linguistics
Charles University in Prague
Czech Republic
havelka@ufal.mff.cuni.cz

Abstract

Dependency analysis of natural language has gained importance for its applicability to NLP tasks. Non-projective structures are common in dependency analysis, therefore we need fine-grained means of describing them, especially for the purposes of machine-learning oriented approaches like parsing. We present an evaluation on twelve languages which explores several constraints and measures on non-projective structures. We pursue an edge-based approach concentrating on properties of individual edges as opposed to properties of whole trees. In our evaluation, we include previously unreported measures taking into account levels of nodes in dependency trees. Our empirical results corroborate theoretical results and show that an edge-based approach using levels of nodes provides an accurate and at the same time expressive means for capturing non-projective structures in natural language.

1 Introduction

Dependency analysis of natural language has been gaining an ever increasing interest thanks to its applicability in many tasks of NLP—a recent example is the dependency parsing work of McDonald et al. (2005), which introduces an approach based on the search for maximum spanning trees, capable of handling non-projective structures naturally.

The study of dependency structures occurring in natural language can be approached from two sides: by trying to delimit permissible dependency structures through formal constraints (for a recent review paper, see Kuhlmann and Nivre (2006)), or by providing their linguistic description (see e.g. Veselá et al. (2004) and Hajičová et al. (2004) for a linguistic analysis of non-projective constructions in Czech.[1])

We think that it is worth bearing in mind that neither syntactic structures in dependency treebanks, nor structures arising in machine-learning approaches, such as MST dependency parsing, need a priori fall into any formal subclass of dependency trees. We should therefore aim at formal means capable of describing all non-projective structures that are both expressive and fine-grained enough to be useful in statistical approaches, and at the same time suitable for an adequate linguistic description.[2]

Holan et al. (1998) first defined an infinite hierarchy of classes of dependency trees, going from projective to unrestricted dependency trees, based on the notion of gap degree for subtrees (cf. Section 3). Holan et al. (2000) present linguistic considerations concerning Czech and English with respect to this hierarchy (cf. also Section 6).

In this paper, we consider all constraints and measures evaluated by Kuhlmann and Nivre (2006)—with some minor variations, cf. Section 4.2. Ad-

[1] These two papers contain an error concerning an alternative condition of projectivity, which is rectified in Havelka (2005).

[2] The importance of such means becomes more evident from the asymptotically negligible proportion of projective trees to all dependency trees; there are super-exponentially many unrestricted trees compared to exponentially many projective trees on n nodes. Unrestricted dependency trees (i.e. labelled rooted trees) and projective dependency trees are counted by sequences A000169 and A006013 (offset 1), respectively, in the On-Line Encyclopedia of Sequences (Sloane, 2007).

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 608–615,
Prague, Czech Republic, June 2007.

ditionally, we introduce several measures not considered in their work. We also extend the empirical basis from Czech and Danish to twelve languages, which were made available in the CoNLL-X shared task on dependency parsing.

In our evaluation, we do not address the issue of what possible effects the annotations and/or conversions used when creating the data might have on non-projective structures in the different languages.

The newly considered measures have the first or both of the following desiderata: they are based on properties of individual non-projective edges (cf. Definition 3); and they take into account levels of nodes in dependency trees explicitly. None of the constraints and measures in Kuhlmann and Nivre (2006) take into account levels of nodes explicitly.

Level types of non-projective edges, introduced by Havelka (2005), have both desiderata. They provide an edge-based means of characterizing all non-projective structures; they also have some further interesting formal properties.

We propose a novel, more detailed measure, *level signatures* of non-projective edges, combining levels of nodes with the partitioning of gaps of non-projective edges into components. We derive a formal property of these signatures that links them to the constraint of well-nestedness, which is an extension of the result for level types (see also Havelka (2007b)).

The paper is organized as follows: Section 2 contains formal preliminaries; in Section 3 we review the constraint of projectivity and define related notions necessary in Section 4, where we define and discuss all evaluated constraints and measures; Section 5 describes our data and experimental setup; empirical results are presented in Section 6.

2 Formal preliminaries

Here we provide basic definitions and notation used in subsequent sections.

Definition 1 A *dependency tree* is a triple $(V, \rightarrow, \preceq)$, where V is a finite set of nodes, $\rightarrow$ a *dependency* relation on V, and $\preceq$ a total order on V.[3]

Relation $\rightarrow$ models linguistic dependency, and so represents a directed, rooted tree on V. There are many ways of characterizing rooted trees, we give here a characterization via the properties of $\rightarrow$: there is a *root* $r \in V$ such that $r \rightarrow^* v$ for all $v \in V$ and there is a unique *edge* $p \rightarrow v$ for all $v \in V$, $v \neq r$, and no edge into r. Relation $\rightarrow^*$ is the reflexive transitive closure of $\rightarrow$ and is usually called *subordination*.

For each node i we define its *level* as the length of the path $r \rightarrow^* i$; we denote it level_i. The symmetrization $\leftrightarrow = \rightarrow \cup \rightarrow^{-1}$ makes it possible to talk about edges (pairs of nodes i, j such that $i \rightarrow j$) without explicitly specifying the *parent* (*head*; i here) and the *child* (*dependent*; j here); so $\rightarrow$ represents directed edges and $\leftrightarrow$ undirected edges. To retain the ability to talk about the direction of edges, we define $\mathsf{Parent}_{i \leftrightarrow j} = \begin{cases} i & \text{if } i \rightarrow j \\ j & \text{if } j \rightarrow i \end{cases}$ and $\mathsf{Child}_{i \leftrightarrow j} = \begin{cases} j & \text{if } i \rightarrow j \\ i & \text{if } j \rightarrow i \end{cases}$. To make the exposition clearer by avoiding overuse of the symbol $\rightarrow$, we introduce notation for rooted *subtrees* not only for nodes, but also for edges: $\mathsf{Subtree}_i = \{v \in V \mid i \rightarrow^* v\}$, $\mathsf{Subtree}_{i \leftrightarrow j} = \{v \in V \mid \mathsf{Parent}_{i \leftrightarrow j} \rightarrow^* v\}$ (note that the subtree of an edge is defined relative to its parent node). To be able to talk concisely about the total order on nodes $\preceq$, we define *open intervals* whose endpoints need not be in a prescribed order $(i, j) = \{v \in V \mid \min_{\preceq}\{i, j\} \prec v \prec \max_{\preceq}\{i, j\}\}$.

3 Condition of projectivity

Projectivity of a dependency tree can be characterized both through the properties of its subtrees and through the properties of its edges.[4]

Definition 2 A dependency tree $T = (V, \rightarrow, \preceq)$ is *projective* if it satisfies the following equivalent conditions:

(Harper & Hays)
$i \rightarrow j \;\&\; v \in (i, j) \Longrightarrow v \in \mathsf{Subtree}_i$,

(Lecerf & Ihm)
$j \in \mathsf{Subtree}_i \;\&\; v \in (i, j) \Longrightarrow v \in \mathsf{Subtree}_i$,

(Fitialov)
$j_1, j_2 \in \mathsf{Subtree}_i \;\&\; v \in (j_1, j_2) \Longrightarrow v \in \mathsf{Subtree}_i$.

Otherwise T is *non-projective*.

[3] We adopt the following convention: nodes are drawn top-down according to their increasing level, with nodes on the same level being the same distance from the root; nodes are drawn from left to right according to the total order on nodes; edges are drawn as solid lines, paths as dotted curves.

[4] There are many other equivalent characterizations of projectivity, we give only three historically prominent ones.

It was Marcus (1965) who proved the equivalence of the conditions in Definition 2, proposed in the early 1960's (we denote them by the names of those to whom Marcus attributes their authorship).

We see that the antecedents of the projectivity conditions move from edge-focused to subtree-focused (i.e. from talking about dependency to talking about subordination).

It is the condition of Fitialov that has been mostly explored when studying so-called relaxations of projectivity. (The condition is usually worded as follows: A dependency tree is projective if the nodes of all its subtrees constitute contiguous intervals in the total order on nodes.)

However, we find the condition of Harper & Hays to be the most appealing from the linguistic point of view because it gives prominence to the primary notion of dependency edges over the derived notion of subordination. We therefore use an edge-based approach whenever we find it suitable.

To that end, we need the notion of a non-projective edge and its gap.

Definition 3 For any edge $i \leftrightarrow j$ in a dependency tree T we define its *gap* as follows

$$\mathsf{Gap}_{i \leftrightarrow j} = \{v \in V \mid v \in (i,j) \ \&\ v \notin \mathsf{Subtree}_{i \leftrightarrow j}\} \ .$$

An edge with an empty gap is *projective*, an edge whose gap is non-empty is *non-projective*.[5]

We see that non-projective are those edges $i \leftrightarrow j$ for which there is a node v such that together they violate the condition of Harper & Hays; we group all such nodes v into $\mathsf{Gap}_{i \leftrightarrow j}$, the gap of the non-projective edge $i \leftrightarrow j$.

The notion of gap is defined differently for subtrees of a dependency tree (Holan et al., 1998; Bodirsky et al., 2005). There it is defined through the nodes of the whole dependency tree not in the considered subtree that intervene between its nodes in the total order on nodes $\preceq$.

4 Relaxations of projectivity: evaluated constraints and measures

In this section we present all constraints and measures on dependency trees that we evaluate empirically in Section 6. First we give definitions of global constraints on dependency trees, then we present measures of non-projectivity based on properties of individual non-projective edges (some of the edge-based measures have corresponding tree-based counterparts, however we do not discuss them in detail).

4.1 Tree constraints

We consider the following three global constraints on dependency trees: projectivity, planarity, and well-nestedness. All three constraints can be applied to more general structures, e.g. dependency forests or even general directed graphs. Here we adhere to their primary application to dependency trees.

Definition 4 A dependency tree T is *non-planar* if there are two edges $i_1 \leftrightarrow j_1$, $i_2 \leftrightarrow j_2$ in T such that

$$i_1 \in (i_2, j_2) \ \ \&\ \ i_2 \in (i_1, j_1) \ .$$

Otherwise T is *planar*.

Planarity is a relaxation of projectivity that corresponds to the "no crossing edges" constraint. Although it might get confused with projectivity, it is in fact a strictly weaker constraint. Planarity is equivalent to projectivity for dependency trees with their root node at either the left or right fringe of the tree.

Planarity is a recent name for a constraint studied under different names already in the 1960's—we are aware of independent work in the USSR (*weakly non-projective trees*; see the survey paper by Dikovsky and Modina (2000) for references) and in Czechoslovakia (*smooth trees*; Nebeský (1979) presents a survey of his results).

Definition 5 A dependency tree T is *ill-nested* if there are two non-projective edges $i_1 \leftrightarrow j_1$, $i_2 \leftrightarrow j_2$ in T such that

$$i_1 \in \mathsf{Gap}_{i_2 \leftrightarrow j_2} \ \ \&\ \ i_2 \in \mathsf{Gap}_{i_1 \leftrightarrow j_1} \ .$$

Otherwise T is *well-nested*.

Well-nestedness was proposed by Bodirsky et al. (2005). The original formulation forbids interleaving of disjoint subtrees in the total order on nodes; we present an equivalent formulation in terms of non-projective edges, derived in (Havelka, 2007b).

Figure 1 illustrates the subset hierarchy between classes of dependency trees satisfying the particular constraints:

projective $\subsetneq$ planar $\subsetneq$ well-nested $\subsetneq$ unrestricted

[5] In figures with sample configurations we adopt this convention: for a non-projective edge, we draw all nodes in its gap explicitly and assume that no node on any path crossing the span of the edge lies in the interval delimited by its endpoints.

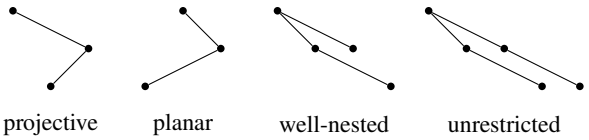

Figure 1: Sample dependency trees (trees satisfy corresponding constraints and violate all preceding ones)

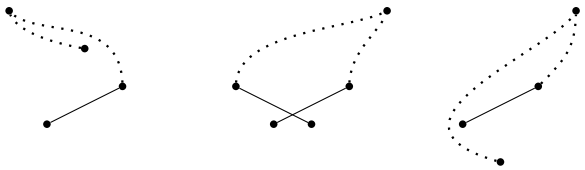

Figure 2: Sample configurations with non-projective edges of different level types

4.2 Edge measures

The first two measures are based on two ways of partitioning the gap of a non-projective edge—into intervals and into components. The third measure, level type, is based on levels of nodes. We also propose a novel measure combining levels of nodes and the partitioning of gaps into components.

Definition 6 For any edge $i \leftrightarrow j$ in a dependency tree T we define its *interval degree* as follows

$$\mathsf{ideg}_{i\leftrightarrow j} = \text{number of intervals in } \mathsf{Gap}_{i\leftrightarrow j} \ .$$

By an interval we mean a contiguous interval in $\preceq$, i.e. a maximal set of nodes comprising all nodes between its endpoints in the total order on nodes $\preceq$.

This measure corresponds to the tree-based *gap degree* measure in (Kuhlmann and Nivre, 2006), which was first introduced in (Holan et al., 1998)—there it is defined as the maximum over gap degrees of all subtrees of a dependency tree (the gap degree of a subtree is the number of contiguous intervals in the gap of the subtree). The interval degree of an edge is bounded from above by the gap degree of the subtree rooted in its parent node.

Definition 7 For any edge $i \leftrightarrow j$ in a dependency tree T we define its *component degree* as follows

$$\mathsf{cdeg}_{i\leftrightarrow j} = \text{number of components in } \mathsf{Gap}_{i\leftrightarrow j} \ .$$

By a component we mean a connected component in the relation $\leftrightarrow$, in other words a weak component in the relation $\rightarrow$ (we consider relations induced on the set $\mathsf{Gap}_{i\leftrightarrow j}$ by relations on T).

This measure was introduced by Nivre (2006); Kuhlmann and Nivre (2006) call it *edge degree*. Again, they define it as the maximum over all edges.

Each component of a gap can be represented by a single node, its *root* in the dependency relation induced on the nodes of the gap (i.e. a node of the component closest to the root of the whole tree). Note that a component need not constitute a full subtree of the dependency tree (there may be nodes in the subtree of the component root that lie outside the span of the particular non-projective edge).

Definition 8 The *level type* (or just *type*) of a non-projective edge $i \leftrightarrow j$ in a dependency tree T is defined as follows

$$\mathsf{Type}_{i\leftrightarrow j} = \mathsf{level}_{\mathsf{Child}_{i\leftrightarrow j}} - \min_{n\in\mathsf{Gap}_{i\leftrightarrow j}} \mathsf{level}_n \ .$$

The level type of an edge is the relative distance in levels of its child node and a node in its gap closest to the root; there may be more than one node witnessing an edge's type. For sample configurations see Figure 2. Properties of level types are presented in Havelka (2005; 2007b).[6]

We propose a new measure combining level types and component degrees. (We do not use interval degrees, i.e. the partitioning of gaps into intervals, because we cannot specify a unique representative of an interval with respect to the tree structure.)

Definition 9 The *level signature* (or just *signature*) of an edge $i \leftrightarrow j$ in a dependency tree T is a mapping $\mathsf{Signature}_{i\leftrightarrow j} : \mathcal{P}(V) \rightarrow {}^{\mathbb{Z}}\mathbb{N}_0$ defined as follows

$$\mathsf{Signature}_{i\leftrightarrow j} = \{\mathsf{level}_{\mathsf{Child}_{i\leftrightarrow j}} - \mathsf{level}_r \mid r \text{ is component root in } \mathsf{Gap}_{i\leftrightarrow j}\} \ .$$

(The right-hand side is considered as a multiset, i.e. elements may repeat.) We call the elements of a signature *component levels*.

The signature of an edge is a multiset consisting of the relative distances in levels of all component roots in its gap from its child node.

Further, we disregard any possible orderings on signatures and concentrate only on the relative distances in levels. We present signatures as non-

[6] For example, presence of non-projective edges of nonnegative level type in equivalent to non-projectivity of a dependency tree; moreover, all such edges can be found in linear time.

decreasing sequences and write them in angle brackets $\langle\ \rangle$, component levels separated by commas (by doing so, we avoid combinatorial explosion).

Notice that level signatures subsume level types: the level type of a non-projective edge is the component level of any of possibly several component roots closest to the root of the whole tree. In other words, the level type of an edge is equal to the largest component level occurring in its level signature.

Level signatures share interesting formal properties with level types of non-projective edges. The following result is a direct extension of the results presented in Havelka (2005; 2007b).

Theorem 10 *Let $i \leftrightarrow j$ be a non-projective edge in a dependency tree T. For any component c in $\mathsf{Gap}_{i\leftrightarrow j}$ represented by root r_c with component level $l_c \leq 0$ (< 0) there is a non-projective edge $v \rightarrow r_c$ in T with $\mathsf{Type}_{v\leftrightarrow r_c} \geq 0$ (> 0) such that either $i \in \mathsf{Gap}_{v\leftrightarrow r_c}$, or $j \in \mathsf{Gap}_{v\leftrightarrow r_c}$.*

PROOF. From the assumptions $l_c \leq 0$ and $r_c \in \mathsf{Gap}_{i\leftrightarrow j}$ the parent v of node r_c lies outside the span of the edge $i \leftrightarrow j$, hence $v \notin \mathsf{Gap}_{i\leftrightarrow j}$. Thus either $i \in (v, r_c)$, or $j \in (v, r_c)$. Since $\mathsf{level}_v \geq \mathsf{level}_{\mathsf{Parent}_{i\leftrightarrow j}}$, we have that $\mathsf{Parent}_{i\leftrightarrow j} \notin \mathsf{Subtree}_v$, and so either $i \in \mathsf{Gap}_{v\leftrightarrow r_c}$, or $j \in \mathsf{Gap}_{v\leftrightarrow r_c}$. Finally from $l_c = \mathsf{level}_{\mathsf{Child}_{i\leftrightarrow j}} - \mathsf{level}_{r_c} \leq 0$ (< 0) we get $\mathsf{level}_{r_c} - \mathsf{level}_{\mathsf{Child}_{i\leftrightarrow j}} \geq 0$ (> 0), hence $\mathsf{Type}_{v\leftrightarrow r_c} \geq 0$ (> 0). ∎

This result links level signatures to well-nestedness: it tells us that whenever an edge's signature contains a nonpositive component level, the whole dependency tree is ill-nested (because then there are two edges satisfying Definition 5).

All discussed edge measures take integer values: interval and component degrees take only nonnegative values, level types and level signatures take integer values (in all cases, their absolute values are bounded by the size of the whole dependency tree). Both interval and component degrees are defined also for projective edges (for which they take value 0), level type is undefined for projective edges, however the level signature of projective edges is defined—it is the empty multiset/sequence.

5 Data and experimental setup

We evaluate all constraints and measures described in the previous section on 12 languages, whose treebanks were made available in the CoNLL-X shared task on dependency parsing (Buchholz and Marsi, 2006). In alphabetical order they are: Arabic, Bulgarian, Czech, Danish, Dutch, German, Japanese, Portuguese, Slovene, Spanish, Swedish, and Turkish (Hajič et al., 2004; Simov et al., 2005; Böhmová et al., 2003; Kromann, 2003; van der Beek et al., 2002; Brants et al., 2002; Kawata and Bartels, 2000; Afonso et al., 2002; Džeroski et al., 2006; Civit Torruella and Martí Antonín, 2002; Nilsson et al., 2005; Oflazer et al., 2003).[7] We do not include Chinese, which is also available in this data format, because all trees in this data set are projective.

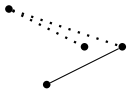

Figure 3: Sample non-projective tree considered planar in empirical evaluation

We take the data "as is", although we are aware that structures occurring in different languages depend on the annotations and/or conversions used (some languages were not originally annotated with dependency syntax, but only converted to a unified dependency format from other representations).

The CoNLL data format is a simple tabular format for capturing dependency analyses of natural language sentences. For each sentence, it uses a technical root node to which dependency analyses of parts of the sentence (possibly several) are attached. Equivalently, the representation of a sentence can be viewed as a forest consisting of dependency trees.

By conjoining partial dependency analyses under one technical root node, we let all their edges interact. Since the technical root comes before the sentence itself, no new non-projective edges are introduced. However, edges from technical roots may introduce non-planarity. Therefore, in our empirical evaluation we disregard all such edges when counting trees conforming to the planarity constraint; we also exclude them from the total numbers of edges. Figure 3 exemplifies how this may affect counts of non-planar trees;[8] cf. also the remark after Definition 4. Counts of well-nested trees are not affected.

[7] All data sets are the train parts of the CoNLL-X shared task.

[8] The sample tree is non-planar according to Definition 4, however we do not consider it as such, because all pairs of "crossing edges" involve an edge from the technical root (edges from the technical root are depicted as dotted lines).

6 Empirical results

Our complete results for global constraints on dependency trees are given in Table 1. They confirm the findings of Kuhlmann and Nivre (2006): planarity seems to be almost as restrictive as projectivity; well-nestedness, on the other hand, covers large proportions of trees in all languages.

In contrast to global constraints, properties of individual non-projective edges allow us to pinpoint the causes of non-projectivity. Therefore they provide a means for a much more fine-grained classification of non-projective structures occurring in natural language. Table 2 presents highlights of our analysis of edge measures.

Both interval and component degrees take generally low values. On the other hand, Holan et al. (1998; 2000) show that at least for Czech neither of these two measures can in principle be bounded.

Taking levels of nodes into account seems to bring both better accuracy and expressivity. Since level signatures subsume level types as their last components, we only provide counts of edges of positive, nonpositive, and negative level types. For lack of space, we do not present full distributions of level types nor of level signatures.

Positive level types give an even better fit with real linguistic data than the global constraint of well-nestedness (an ill-nested tree need not contain a non-projective edge of nonpositive level type; cf. Theorem 10). For example, in German less than one tenth of ill-nested trees contain an edge of nonpositive level type. Minimum negative level types for Czech, Slovene, Swedish, and Turkish are respectively -1, -5, -2, and -4.

Level signatures combine level types and component degrees, and so give an even more detailed picture of the gaps of non-projective edges. In some languages the actually occurring signatures are quite limited, in others there is a large variation.

Because we consider it linguistically relevant, we also count how many non-projective edges contain in their gaps a component rooted in an ancestor of the edge (an *ancestor* of an edge is any node on the path from the root of the whole tree to the parent node of the edge). The proportions of such non-projective edges vary widely among languages and for some this property seems highly important.

Empirical evidence shows that edge measures of non-projectivity taking into account levels of nodes fit very well with linguistic data. This supports our theoretical results and confirms that properties of non-projective edges provide a more accurate as well as expressive means for describing non-projective structures in natural language than the constraints and measures considered by Kuhlmann and Nivre (2006).

7 Conclusion

In this paper, we evaluate several constraints and measures on non-projective dependency structures. We pursue an edge-based approach giving prominence to properties of individual edges. At the same time, we consider levels of nodes in dependency trees. We find an edge-based approach also more appealing linguistically than traditional approaches based on properties of whole dependency trees or their subtrees. Furthermore, edge-based properties allow machine-learning techniques to model global phenomena locally, resulting in less sparse models.

We propose a new edge measure of non-projectivity, level signatures of non-projective edges. We prove that, analogously to level types, they relate to the constraint of well-nestedness.

Our empirical results on twelve languages can be summarized as follows: Among the global constraints, well-nestedness fits best with linguistic data. Among edge measures, the previously unreported measures taking into account levels of nodes stand out. They provide both the best fit with linguistic data of all constraints and measures we have considered, as well as a substantially more detailed capability of describing non-projective structures.

The interested reader can find a more in-depth and broader-coverage discussion of properties of dependency trees and their application to natural language syntax in (Havelka, 2007a).

As future work, we plan to investigate more languages and carry out linguistic analyses of non-projective structures in some of them. We will also apply our results to statistical approaches to NLP tasks, such as dependency parsing.

Abstract

Creating large amounts of annotated data to train statistical PCFG parsers is expensive, and the performance of such parsers declines when training and test data are taken from different domains. In this paper we use self-training in order to improve the quality of a parser and to adapt it to a different domain, using only small amounts of manually annotated seed data. We report significant improvement both when the seed and test data are in the same domain and in the out-of-domain adaptation scenario. In particular, we achieve 50% reduction in annotation cost for the in-domain case, yielding an improvement of 66% over previous work, and a 20-33% reduction for the domain adaptation case. This is the first time that self-training with small labeled datasets is applied successfully to these tasks. We were also able to formulate a characterization of when self-training is valuable.

1 Introduction

State of the art statistical parsers (Collins, 1999; Charniak, 2000; Koo and Collins, 2005; Charniak and Johnson, 2005) are trained on manually annotated treebanks that are highly expensive to create. Furthermore, the performance of these parsers decreases as the distance between the genres of their training and test data increases. Therefore, enhancing the performance of parsers when trained on *small* manually annotated datasets is of great importance, both when the seed and test data are taken from the same domain (the *in-domain* scenario) and when they are taken from different domains (the *out-of-domain* or *parser adaptation* scenario). Since the problem is the expense in manual annotation, we define 'small' to be 100-2,000 sentences, which are the sizes of sentence sets that can be manually annotated by constituent structure in a few hours[1].

Self-training is a method for using unannotated data when training supervised models. The model is first trained using manually annotated ('seed') data, then the model is used to automatically annotate a pool of unannotated ('self-training') data, and then the manually and automatically annotated datasets are combined to create the training data for the final model. Self-training of parsers trained on small datasets is of enormous potential practical importance, due to the huge amounts of unannotated data that are becoming available today and to the high cost of manual annotation.

In this paper we use self-training to enhance the performance of a generative statistical PCFG parser (Collins, 1999) for both the in-domain and the parser adaptation scenarios, using only small amounts of manually annotated data. We perform four experiments, examining all combinations of in-domain and out-of-domain seed and self-training data.

Our results show that self-training is of substantial benefit for the problem. In particular, we present:

- 50% reduction in annotation cost when the seed and test data are taken from the same domain, which is 66% higher than any previous result with small manually annotated datasets.

[1] We note in passing that quantitative research on the cost of annotation using various annotation schemes is clearly lacking.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 616–623,
Prague, Czech Republic, June 2007.

- The first time that self-training improves a generative parser when the seed and test data are from the same domain.

- 20-33% reduction in annotation cost when the seed and test data are from different domains.

- The first time that self-training succeeds in adapting a generative parser between domains using a small manually annotated dataset.

- The first formulation (related to the number of unknown words in a sentence) of when self-training is valuable.

Section 2 discusses previous work, and Section 3 compares in-depth our protocol to a previous one. Sections 4 and 5 present the experimental setup and our results, and Section 6 analyzes the results in an attempt to shed light on the phenomenon of self-training.

2 Related Work

Self-training might seem a strange idea: why should a parser trained on its own output learn anything new? Indeed, (Clark et al., 2003) applied self-training to POS-tagging with poor results, and (Charniak, 1997) applied it to a generative statistical PCFG parser trained on a large seed set (40K sentences), without any gain in performance.

Recently, (McClosky et al., 2006a; McClosky et al., 2006b) have successfully applied self-training to various parser adaptation scenarios using the reranking parser of (Charniak and Johnson, 2005). A reranking parser (see also (Koo and Collins, 2005)) is a layered model: the base layer is a generative statistical PCFG parser that creates a ranked list of k parses (say, 50), and the second layer is a reranker that reorders these parses using more detailed features. McClosky et al (2006a) use sections 2-21 of the WSJ PennTreebank as seed data and between 50K to 2,500K unlabeled NANC corpus sentences as self-training data. They train the PCFG parser and the reranker with the manually annotated WSJ data, and parse the NANC data with the 50-best PCFG parser. Then they proceed in two directions. In the first, they reorder the 50-best parse list with the reranker to create a new 1-best list. In the second, they leave the 1-best list produced by the generative PCFG parser untouched. Then they combine the 1-best list (each direction has its own list) with the WSJ training set, to retrain the PCFG parser. The final PCFG model and the reranker (trained only on annotated WSJ material) are then used to parse the test section (23) of WSJ.

There are two major differences between these papers and the current one, stemming from their usage of a reranker and of large seed data. First, when their 1-best list of the base PCFG parser was used as self training data for the PCFG parser (the second direction), the performance of the base parser did not improve. It had improved only when the 1-best list of the *reranker* was used. In this paper we show how the 1-best list of a base (generative) PCFG parser can be used as a self-training material for the base parser itself and enhance its performance, without using any reranker. This reveals a noteworthy characteristic of generative PCFG models and offers a potential direction for parser improvement, since the quality of a parser-reranker combination critically depends on that of the base parser.

Second, these papers did not explore self-training when the seed is small, a scenario whose importance has been discussed above. In general, PCFG models trained on small datasets are less likely to parse the self-training data correctly. For example, the f-score of WSJ data parsed by the base PCFG parser of (Charniak and Johnson, 2005) when trained on the training sections of WSJ is between 89% to 90%, while the f-score of WSJ data parsed with the Collins' model that we use, and a small seed, is between 40% and 80%. As a result, the good results of (McClosky et al, 2006a; 2006b) with large seed sets do not immediately imply success with small seed sets. Demonstration of such success is a contribution of the present paper.

Bacchiani et al (2006) explored the scenario of out-of-domain seed data (the Brown training set containing about 20K sentences) and in-domain self-training data (between 4K to 200K sentences from the WSJ) and showed an improvement over the baseline of training the parser with the seed data only. However, they did not explore the case of small seed datasets (the effort in manually annotating 20K is substantial) and their work addresses only one of our scenarios (OI, see below).

A work closely related to ours is (Steedman et al., 2003a), which applied co-training (Blum and Mitchell, 1998) and self-training to Collins' parsing model using a small seed dataset (500 sentences for both methods and 1,000 sentences for co-training only). The seed, self-training and test datasets they used are similar to those we use in our II experiment (see below), but the self-training protocols are different. They first train the parser with the seed sentences sampled from WSJ sections 2-21. Then, iteratively, 30 sentences are sampled from these sections, parsed by the parser, and the 20 best sentences (in terms of parser confidence defined as probability of top parse) are selected and combined with the previously annotated data to retrain the parser. The co-training protocol is similar except that each parser is trained with the 20 best sentences of the other parser. Self-training did not improve parser performance on the WSJ test section (23). Steedman et al (2003b) followed a similar co-training protocol except that the selection function (three functions were explored) considered the differences between the confidence scores of the two parsers. In this paper we show a self-training protocol that achieves better results than all of these methods (Table 2). The next section discusses possible explanations for the difference in results. Steedman et al (2003b) and Hwa et al, (2003) also used several versions of corrected co-training which are not comparable to ours and other suggested methods because their evaluation requires different measures (e.g. reviewed and corrected constituents are separately counted).

As far as we know, (Becker and Osborne, 2005) is the only additional work that tries to improve a generative PCFG parsers using small seed data. The techniques used are based on active learning (Cohn et al., 1994). The authors test two novel methods, along with the tree entropy (TE) method of (Hwa, 2004). The seed, the unannotated and the test sets, as well as the parser used in that work, are similar to those we use in our II experiment. Our results are superior, as shown in Table 3.

3 Self-Training Protocols

There are many possible ways to do self-training. A main goal of this paper is to identify a self-training protocol most suitable for enhancement and domain adaptation of statistical parsers trained on small datasets. No previous work has succeeded in identifying such a protocol for this task. In this section we try to understand why.

In the protocol we apply, the self-training set contains several thousand sentences A parser trained with a small seed set parses the self-training set, and then the *whole* automatically annotated self-training set is combined with the manually annotated seed set to retrain the parser. This protocol and that of Steedman et al (2003a) were applied to the problem, with the same seed, self-training and test sets. As we show below (see Section 4 and Section 5), while Steedman's protocol does not improve over the baseline of using only the seed data, our protocol does.

There are four differences between the protocols. First, Steedman et al's seed set consists of *consecutive* WSJ sentences, while we select them randomly. In the next section we show that this difference is immaterial. Second, Steedman et al's protocol looks for sentences of high quality parse, while our protocol prefers to use many sentences without checking their parse quality. Third, their protocol is iterative while ours uses a single step. Fourth, our self-training set is orders of magnitude larger than theirs. To examine the parse quality issue, we performed their experiment using their setting but selecting the high quality parse sentences using their f-score relative to the gold standard annotation from secs 2-21 rather than a quality estimate. No improvement over the baseline was achieved even with this oracle. Thus the problem with their protocol does not lie with the parse quality assessment function; no other function would produce results better than the oracle. To examine the iteration issue, we performed their experiment in a single step, selecting at once the oracle-best 2,000 among 3,000 sentences[2], which produced only a mediocre improvement. We thus conclude that the size of the self-training set is a major factor responsible for the difference between the protocols.

4 Experimental Setup

We used a reimplementation of Collins' parsing model 2 (Bikel, 2004). We performed four experiments, II, IO, OI, and OO, two with in-domain seed

[2]Corresponding to a 100 iterations of 30 sentences each.

(II, IO) and two with out-of-domain seed (OI, OO), examining in-domain self-training (II, OI) and out-of-domain self-training (IO, OO). Note that being 'in' or 'out' of domain is determined by the *test* data. Each experiment contained 19 runs. In each run a different seed size was used, from 100 sentences onwards, in steps of 100. For statistical significance, we repeated each experiment five times, in each repetition randomly sampling different manually annotated sentences to form the seed dataset[3].

The seed data were taken from WSJ sections 2-21. For II and IO, the test data is WSJ section 23 (2416 sentences) and the self-training data are either WSJ sections 2-21 (in II, excluding the seed sentences) or the Brown training section (in IO). For OI and OO, the test data is the Brown test section (2424 sentences), and the self-training data is either the Brown training section (in OI) or WSJ sections 2-21 (in OO). We removed the manual annotations from the self-training sections before using them.

For the Brown corpus, we based our division on (Bacchiani et al., 2006; McClosky et al., 2006b). The test and training sections consist of sentences from all of the genres that form the corpus. The training division consists of 90% (9 of each 10 consecutive sentences) of the data, and the test section are the remaining 10% (We did not use any held out data). Parsing performance is measured by f-score, $f = \frac{2 \times P \times R}{P+R}$, where P, R are labeled precision and recall.

To further demonstrate our results for parser adaptation, we also performed the OI experiment where seed data is taken from WSJ sections 2-21 and both self-training and test data are taken from the Switchboard corpus. The distance between the domains of these corpora is much greater than the distance between the domains of WSJ and Brown. The Brown and Switchboard corpora were divided to sections in the same way.

We have also performed all four experiments with the seed data taken from the Brown training section. The results were very similar and will not be detailed here due to space constraints.

[3] (Steedman et al., 2003a) used the *first* 500 sentences of WSJ training section as seed data. For direct comparison, we performed our protocol in the II scenario using the first 500 or 1000 sentences of WSJ training section as seed data and got similar results to those reported below for our protocol with *random* selection. We also applied the protocol of Steedman et al to scenario II with 500 randomly selected sentences, getting no improvement over the random baseline.

5 Results

5.1 In-domain seed data

In these two experiments we show that when the seed and test data are taken from the same domain, a very significant enhancement of parser performance can be achieved, whether the self-training material is in-domain (II) or out-of-domain (IO). Figure 1 shows the improvement in parser f-score when self-training data is used, compared to when it is not used. Table 1 shows the reduction in manually annotated seed data needed to achieve certain f-score levels. The enhancement in performance is very impressive in the in-domain self-training data scenario – a reduction of 50% in the number of manually annotated sentences needed for achieving 75 and 80 f-score values. A significant improvement is achieved in the out-of-domain self-training scenario as well.

Table 2 compares our results with self-training and co-training results reported by (Steedman et al, 20003a; 2003b). As stated earlier, the experimental setup of these works is similar to ours, but the self-training protocols are different. For self-training, our II improves an absolute 3.74% over their 74.3% result, which constitutes a 14.5% reduction in error (from 25.7%).

The table shows that for both seed sizes our self training protocol outperforms both the self-training and co-training protocols of (Steedman et al, 20003a; 2003b). Results are not included in the table only if they are not reported in the relevant paper. The self-training protocol of (Steedman et al., 2003a) does not actually improve over the baseline of using only the seed data. Section 3 discussed a possible explanation to the difference in results.

In Table 3 we compare our results to the results of the methods tested in (Becker and Osborne, 2005) (including TE)[4]. To do that, we compare the reduction in manually annotated data needed to achieve an f-score value of 80 on WSJ section 23 achieved by each method. We chose this measure since it is

[4] The measure is constituents and not sentences because this is how results are reported in (Becker and Osborne, 2005). However, the same reduction is obtained when sentences are counted, because the number of constituents is averaged when taking many sentences.

f-score	75	80
Seed data only	600(0%)	1400(0%)
II	**300**(**50**%)	**700**(**50**%)
IO	500(17%)	1200(14.5%)

Table 1: Number of in-domain seed sentences needed for achieving certain f-scores. Reductions compared to no self-training (line 1) are given in parentheses.

Seed size	our II	our IO	Steedman ST	Steedman CT 2003a	Steedman CT 2003b
500 sent.	**78.04**	75.81	74.3	76.9	—-
1,000 sent.	**81.43**	79.49	—-	79	81.2

Table 2: F-scores of our in-domain-seed self-training vs. self-training (ST) and co-training (CT) of (Steedman et al, 20003a; 2003b).

the only explicitly reported number in that work. As the table shows, our method is superior: our reduction of 50% constitutes an improvement of 66% over their best reduction of 30.6%.

When applying self-training to a parser trained with a small dataset we expect the coverage of the parser to increase, since the combined training set should contain items that the seed dataset does not. On the other hand, since the accuracy of annotation of such a parser is poor (see the no self-training curve in Figure 1) the combined training set surely includes inaccurate labels that might harm parser performance. Figure 2 (left) shows the increase in coverage achieved for in-domain and out-of-domain self-training data. The improvements induced by both methods are similar. This is quite surprising given that the Brown sections we used as self-training data contain science, fiction, humor, romance, mystery and adventure texts while the test section in these experiments, WSJ section 23, contains only news articles.

Figure 2 also compares recall (middle) and precision (right) for the different methods. For II there is a significant improvement in both precision and recall even though many more sentences are parsed. For IO, there is a large gain in recall and a much smaller loss in precision, yielding a substantial improvement in f-score (Figure 1).

F - score	This work - II	Becker unparsed	Becker entropy/unparsed	Hwa TE
80	**50%**	29.4%	30.6%	-5.7%

Table 3: Reduction of the number of manually annotated constituents needed for achieving f score value of 80 on section 23 of the WSJ. In all cases the seed and additional sentences selected to train the parser are taken from sections 02-21 of WSJ.

5.2 Out-of-domain seed data

In these two experiments we show that self-training is valuable for adapting parsers from one domain to another. Figure 3 compares out-of-domain seed data used with in-domain (OI) or out-of-domain (OO) self-training data against the baseline of training only with the out-of-domain seed data.

The left graph shows a significant improvement in f-score. In the middle and right graphs we examine the quality of the parses produced by the model by plotting recall and precision vs. seed size. Regarding precision, the difference between the three conditions is small relative to the f-score difference shown in the left graph. The improvement in the recall measure is much greater than the precision differences, and this is reflected in the f-score result. The gain in coverage achieved by both methods, which is not shown in the figure, is similar to that reported for the in-domain seed experiments. The left graph along with the increase in coverage show the power of self-training in parser adaptation when small seed datasets are used: not only do OO and OI parse many more sentences than the baseline, but their f-score values are consistently better.

To see how much manually annotated data can be saved by using out-of-domain seed, we train the parsing model with manually annotated data from the Brown training section, as described in Section 4. We assume that given a fixed number of training sentences the best performance of the parser without self-training will occur when these sentences are selected from the domain of the test section, the Brown corpus. We compare the amounts of manually annotated data needed to achieve certain f-score levels in this condition with the corresponding amounts of data needed by OI and OO. The results are summarized in Table 4. We compare to two baselines using in- and out-of-domain seed data without

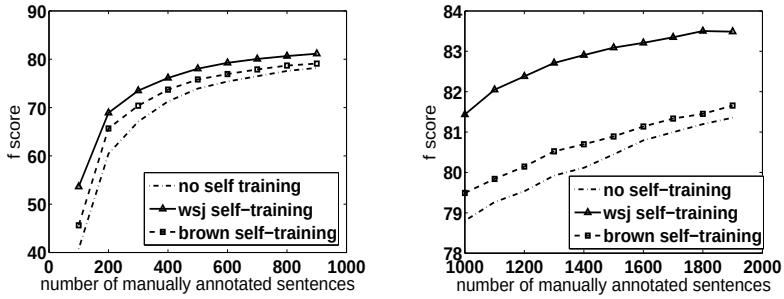

Figure 1: Number of seed sentences vs. f-score, for the two in-domain seed experiments: II (triangles) and IO (squares), and for the no self-training baseline. Self-training provides a substantial improvement.

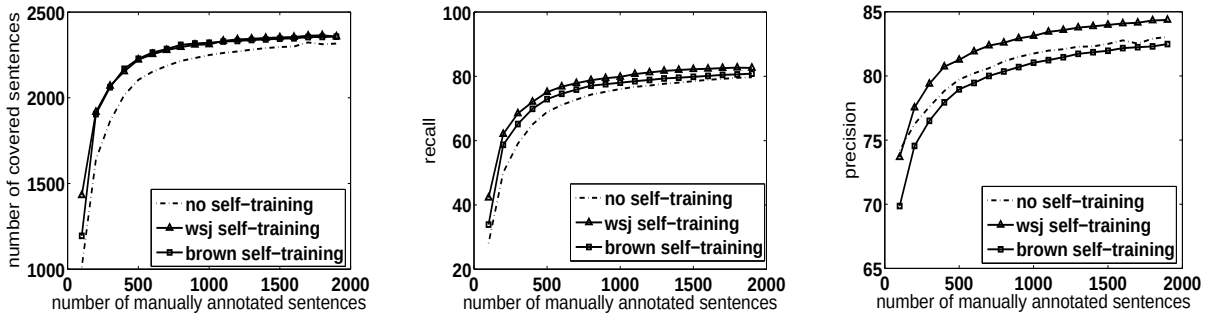

Figure 2: Number of seed sentences vs. coverage (left), recall (middle) and precision (right) for the two in-domain seed experiments: II (triangles) and IO (squares), and for the no self-training baseline.

any self-training. The second line (ID) serves as a reference to compute how much manual annotation of the test domain was saved, and the first line (OD) serves as a reference to show by how much self-training improves the out-of-domain baseline. The table stops at an f-score of 74 because that is the best that the baselines can do.

A significant reduction in annotation cost over the ID baseline is achieved where the seed size is between 100 and 1200. Improvement over the OD baseline is for the whole range of seed sizes. Both OO and OI achieve 20-33% reduction in manual annotation compared to the ID baseline and enhance the performance of the parser by as much as 42.9%.

The only previous work that adapts a parser trained on a small dataset between domains is that of (Steedman et al., 2003a), which used co-training (no self-training results were reported there or elsewhere). In order to compare with that work, we performed OI with seed taken from the Brown corpus and self-training and test taken from WSJ, which is the setup they use, obtaining a similar improvement to that reported there. However, co-training is a more complex method that requires an additional parser (LTAG in their case).

To further substantiate our results for the parser adaptation scenario, we used an additional corpus, Switchboard. Figure 4 shows the results of an OI experiment with WSJ seed and Switchboard self-training and test data. Although the domains of these two corpora are very different (more so than WSJ and Brown), self-training provides a substantial improvement.

We have also performed all four experiments with Brown and WSJ trading places. The results obtained were very similar to those reported here, and will not be detailed due to lack of space.

6 Analysis

In this section we try to better understand the benefit in using self-training with small seed datasets. We formulate the following criterion: the number of words in a test sentence that do not appear in the seed data ('unknown words') is a strong indicator

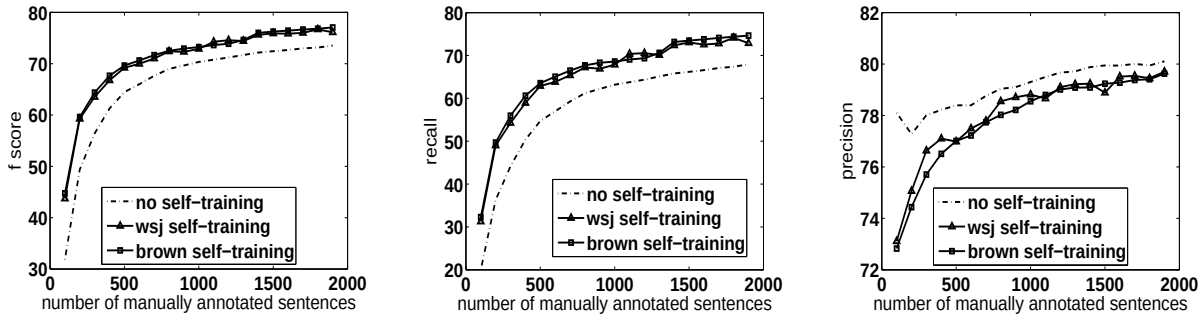

Figure 3: Number of seed sentences vs. f-score (left), recall (middle) and precision (right), for the two out-of-domain seed data experiments: OO (triangles) and OI (squares), and for the no self-training baseline.

f-sc.	66	68	70	72	74
OD	600	800	1,000	1,400	–
ID	600	700	800	1,000	1,200
OO	**400**	**500**	**600**	**800**	**1100**
	33, 33	28.6, 37.5	33, 40	20, 42.9	8, –
OI	**400**	**500**	**600**	**800**	1,300
	33, 33	28.6, 37.5	33, 40	20, 42.9	−8, –

Table 4: Number of manually annotated seed sentences needed for achieving certain f-score values. The first two lines show the out-of-domain and in-domain seed baselines. The reductions compared to the baselines is given as ID, OD.

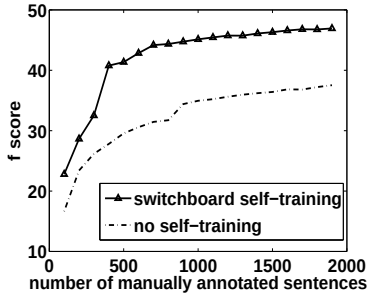

Figure 4: Number of seed sentences vs. f-score, for the OI experiment using WSJ seed data and SwitchBoard self-training and test data. In spite of the strong dissimilarity between the domains, self-training provides a substantial improvement.

to whether it is worthwhile to use small seed self-training. Figure 5 shows the number of unknown words in a sentence vs. the probability that the self-training model will parse a sentence no worse (upper curve) or better (lower curve) than the baseline model.

The upper curve shows that regardless of the

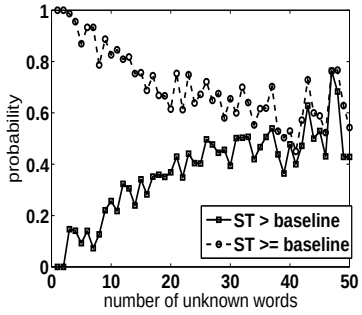

Figure 5: For sentences having the same number of unknown words, we show the probability that the self-training model parses a sentence from the set no worse (upper curve) or better (lower curve) than the baseline model.

number of unknown words in the sentence, there is more than 50% chance that the self-training model will not harm the result. This probability decreases from almost 1 for a very small number of unknown words to about 0.55 for 50 unknown words. The lower curve shows that when the number of unknown words increases, the probability that the self-training model will do better than the baseline model increases from almost 0 (for a very small number of unknown words) to about 0.55. Hence, the number of unknown words is an indication for the potential benefit (value on the lower curve) and risk (1 minus the value on the upper curve) in using the self-training model compared to using the baseline model. Unknown words were not identified in (McClosky et al., 2006a) as a useful predictor for the benefit of self-training.

We also identified a length effect similar to that studied by (McClosky et al., 2006a) for self-training (using a reranker and large seed, as detailed in Section 2). Due to space limitations we do not discuss it here.

7 Discussion

Self-training is usually not considered to be a valuable technique in improving the performance of generative statistical parsers, especially when the manually annotated seed sentence dataset is small. Indeed, in the II scenario, (Steedman et al., 2003a; McClosky et al., 2006a; Charniak, 1997) reported no improvement of the base parser for small (500 sentences, in the first paper) and large (40K sentences, in the last two papers) seed datasets respectively. In the II, OO, and OI scenarios, (McClosky et al, 2006a; 2006b) succeeded in improving the parser performance only when a reranker was used to reorder the 50-best list of the generative parser, with a seed size of 40K sentences. Bacchiani et al (2006) improved the parser performance in the OI scenario but their seed size was large (about 20K sentences).

In this paper we have shown that self-training can enhance the performance of generative parsers, without a reranker, in four in- and out-of-domain scenarios using a small seed dataset. For the II, IO and OO scenarios, we are the first to show improvement by self-training for generative parsers. We achieved a 50% (20-33%) reduction in annotation cost for the in-domain (out-of-domain) seed data scenarios. Previous work with small seed datasets considered only the II and OI scenarios. Our results for the former are better than any previous method, and our results for the latter (which are the first reported self-training results) are similar to previous results for co-training, a more complex method. We demonstrated our results using three corpora of varying degrees of domain difference.

A direction for future research is combining self-training data from various domains to enhance parser adaptation.

Abstract

We present a novel framework that combines strengths from surface syntactic parsing and deep syntactic parsing to increase deep parsing accuracy, specifically by combining dependency and HPSG parsing. We show that by using surface dependencies to constrain the application of wide-coverage HPSG rules, we can benefit from a number of parsing techniques designed for high-accuracy dependency parsing, while actually performing deep syntactic analysis. Our framework results in a 1.4% absolute improvement over a state-of-the-art approach for wide coverage HPSG parsing.

1 Introduction

Several efficient, accurate and robust approaches to data-driven dependency parsing have been proposed recently (Nivre and Scholz, 2004; McDonald et al., 2005; Buchholz and Marsi, 2006) for syntactic analysis of natural language using bilexical dependency relations (Eisner, 1996). Much of the appeal of these approaches is tied to the use of a simple formalism, which allows for the use of efficient parsing algorithms, as well as straightforward ways to train discriminative models to perform disambiguation. At the same time, there is growing interest in parsing with more sophisticated lexicalized grammar formalisms, such as Lexical Functional Grammar (LFG) (Bresnan, 1982), Lexicalized Tree Adjoining Grammar (LTAG) (Schabes et al., 1988), Head-driven Phrase Structure Grammar (HPSG) (Pollard and Sag, 1994) and Combinatory Categorial Grammar (CCG) (Steedman, 2000), which represent deep syntactic structures that cannot be expressed in a shallower formalism designed to represent only aspects of surface syntax, such as the dependency formalism used in current mainstream dependency parsing.

We present a novel framework that combines strengths from surface syntactic parsing and deep syntactic parsing, specifically by combining dependency and HPSG parsing. We show that, by using surface dependencies to constrain the application of wide-coverage HPSG rules, we can benefit from a number of parsing techniques designed for high-accuracy dependency parsing, while actually performing deep syntactic analysis. From the point of view of HPSG parsing, accuracy can be improved significantly through the use of highly accurate discriminative dependency models, without the difficulties involved in adapting these models to a more complex and linguistically sophisticated formalism. In addition, improvements in dependency parsing accuracy are converted directly into improvements in HPSG parsing accuracy. From the point of view of dependency parsing, the application of HPSG rules to structures generated by a surface dependency model provides a principled and linguistically motivated way to identify deep syntactic phenomena, such as long-distance dependencies, raising and control.

We begin by describing our dependency and HPSG parsing approaches in section 2. In section 3, we present our framework for HPSG parsing with shallow dependency constraints, and in section 4 we

evaluate this framework empirically. Sections 5 and 6 discuss related work and conclusions.

2 Fast dependency parsing and wide-coverage HPSG parsing

2.1 Data-driven dependency parsing

Because we use dependency parsing as a step in deep parsing, it is important that we choose a parsing approach that is not only accurate, but also efficient. The deterministic shift/reduce classifier-based dependency parsing approach (Nivre and Scholz, 2004) has been shown to offer state-of-the-art accuracy (Nivre et al., 2006) with high efficiency due to a greedy search strategy. Our approach is based on Nivre and Scholz's approach, using support vector machines for classification of shift/reduce actions.

2.2 Wide-coverage HPSG parsing

HPSG (Pollard and Sag, 1994) is a syntactic theory based on lexicalized grammar formalism. In HPSG, a small number of *schemas* explain general construction rules, and a large number of *lexical entries* express word-specific syntactic/semantic constraints. Figure 1 shows an example of the process of HPSG parsing. First, lexical entries are assigned to each word in a sentence. In Figure 1, lexical entries express subcategorization frames and predicate argument structures. Parsing proceeds by applying schemas to lexical entries. In this example, the Head-Complement Schema is applied to the lexical entries of "*tried*" and "*running*". We then obtain a phrasal structure for "*tried running*". By repeatedly applying schemas to lexical/phrasal structures,

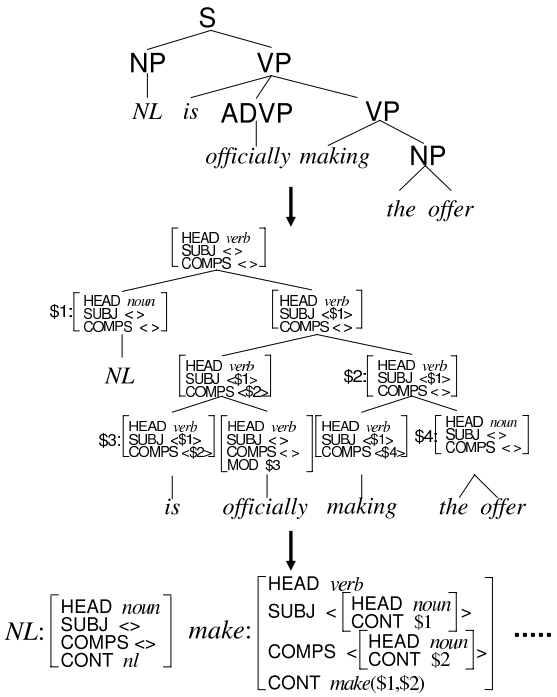

Figure 2: Extracting HPSG lexical entries from the Penn Treebank

we finally obtain an HPSG parse tree that covers the entire sentence.

In this paper, we use an HPSG parser developed by Miyao and Tsujii (2005). This parser has a wide-coverage HPSG lexicon which is extracted from the Penn Treebank. Figure 2 illustrates their method for extraction of HPSG lexical entries. First, given a parse tree from the Penn Treebank (top), HPSG-style constraints are added and an HPSG-style parse tree is obtained (middle). Lexical entries are then extracted from the terminal nodes of the HPSG parse tree (bottom). This way, in addition to a wide-coverage lexicon, we also obtain an HPSG treebank, which can be used as training data for disambiguation models.

The disambiguation model of this parser is based on a maximum entropy model (Berger et al., 1996). The probability $p(T|W)$ of an HPSG parse tree T for the sentence $W = \langle w_1, \ldots, w_n \rangle$ is given as:

$$\begin{aligned} p(T|W) &= p(T|L,W)p(L|W) \\ &= \frac{1}{Z}\exp\left(\sum_i \lambda_i f_i(T)\right)\prod_j p(l_j|W), \end{aligned}$$

where $L = \langle l_1, \ldots, l_n \rangle$ are lexical entries and

$p(l_i|W)$ is the *supertagging probability*, i.e., the probability of assignining the lexical entry l_i to w_i (Ninomiya et al., 2006). The probability $p(T|L, W)$ is a maximum entropy model on HPSG parse trees, where Z is a normalization factor, and feature functions $f_i(T)$ represent syntactic characteristics, such as head words, lengths of phrases, and applied schemas. Given the HPSG treebank as training data, the model parameters λ_i are estimated so as to maximize the log-likelihood of the training data (Malouf, 2002).

3 HPSG parsing with dependency constraints

While a number of fairly straightforward models can be applied successfully to dependency parsing, designing and training HPSG parsing models has been regarded as a significantly more complex task. Although it seems intuitive that a more sophisticated linguistic formalism should be more difficult to parameterize properly, we argue that the difference in complexity between HPSG and dependency structures can be seen as incremental, and that the use of accurate and efficient techniques to determine the surface dependency structure of a sentence provides valuable information that aids HPSG disambiguation. This is largely because HPSG is based on a lexicalized grammar formalism, and as such its syntactic structures have an underlying dependency backbone. However, HPSG syntactic structures includes long-distance dependencies, and the underlying dependency structure described by and HPSG structure is a directed acyclic graph, not a dependency tree (as used by mainstream approaches to data-driven dependency parsing). This difference manifests itself in words that have multiple heads. For example, in the sentence *I tried to run*, the pronoun *I* is a dependent of *tried* and of *run*. This makes it possible to represent that *I* is the subject of both verbs, precisely the kind of information that cannot be represented in dependency parsing. If we ignore long-distance dependencies, however, HPSG structures can be seen as lexicalized trees that can be easily converted into dependency trees.

Given that for an HPSG representation of the syntactic structure of a sentence we can determine a dependency tree by removing long-distance dependencies, we can use dependency parsing techniques (such as the deterministic dependency parsing approach mentioned in section 2.1) to determine the underlying dependency trees in HPSG structures. This is the basis for the parsing framework presented here. In this approach, deep dependency analysis is done in two stages. First, a dependency parser determines the shallow dependency tree for the input sentence. This shallow dependency tree corresponds to the underlying dependency graph of the HPSG structure for the input sentence, without dependencies that roughly correspond to deep syntax. The second step is to perform HPSG parsing, as described in section 2.2, but using the shallow dependency tree to constrain the application of HPSG rules. We now discuss these two steps in more detail.

3.1 Determining shallow dependencies in HPSG structures using dependency parsing

In order to apply a data-driven dependency approach to the task of identifying the shallow dependency tree in HPSG structures, we first need a corpus of such dependency trees to serve as training data. We created a dependency training corpus based on the Penn Treebank (Marcus et al., 1993), or more specifically on the HPSG Treebank generated from the Penn Treebank (see section 2.2). For each HPSG structure in the HPSG Treebank, a dependency tree is extracted in two steps. First, the HPSG tree is converted into a CFG-style tree, simply by removing long-distance dependency links between nodes. A dependency tree is then extracted from the resulting lexicalized CFG-style tree, as is commonly done for converting constituent trees into dependency trees after the application of a head-percolation table (Collins, 1999).

Once a dependency training corpus is available, it is used to train a dependency parser as described in section 2.1. This is done by training a classifier to determine parser actions based on local features that represent the current state of the parser (Nivre and Scholz, 2004; Sagae and Lavie, 2005). Training data for the classifier is obtained by applying the parsing algorithm over the training sentences (for which the correct dependency structures are known) and recording the appropriate parser actions that result in the formation of the correct dependency trees, coupled with the features that represent the state of

the parser mentioned in section 2.1. An evaluation of the resulting dependency parser and its efficacy in aiding HPSG parsing is presented in section 4.

3.2 Parsing with dependency constraints

Given a set of dependencies, the bottom-up process of HPSG parsing can be constrained so that it does not violate the given dependencies. This can be achieved by a simple extension of the parsing algorithm, as follows. During parsing, we store the lexical head of each partial parse tree. In each schema application, we can determine which child is the head; for example, the left child is the head when we apply the Head-Complement Schema. Given this information and lexical heads, the parser can identify the dependency produced by this schema application, and can therefore judge whether the schema application violates the dependency constraints.

This method forces the HPSG parser to produce parse trees that strictly conform to the output of the dependency parser. However, this means that the HPSG parser outputs no successful parse results when it cannot find the parse tree that is completely consistent with the given dependencies. This situation may occur when the dependency parser produces structures that are not covered in the HPSG grammar. This is especially likely with a fully data-driven dependency parser that uses local classification, since its output may not be globally consistent grammatically. In addition, the HPSG grammar is extracted from the HPSG Treebank using a corpus-based procedure, and it does not necessarily cover all possible grammatical phenomena in unseen text (Miyao and Tsujii, 2005).

We therefore propose an extension of this approach that uses predetermined dependencies as *soft* constraints. Violations of schema applications are detected in the same way as before, but instead of strictly prohibiting schema applications, we penalize the log-likelihood of partial parse trees created by schema applications that violate the dependencies constraints. Given a negative value α, we add α to the log-probability of a partial parse tree when the schema application violates the dependency constraints. That is, when a parse tree violates n dependencies, the log-probability of the parse tree is lowered by $n\alpha$. The meta parameter α is determined so as to maximize the accuracy on the development set.

Soft dependency constraints can be implemented as explained above as a straightforward extension of the parsing algorithm. In addition, it is easily integrated with beam thresholding methods of parsing. Because beam thresholding discards partial parse trees that have low log-probabilities, we can expect that the parser would discard partial parse trees based on violation of the dependency constraints.

4 Experiments

We evaluate the accuracy of HPSG parsing with dependency constraints on the HPSG Treebank (Miyao et al., 2003), which is extracted from the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1993)[1]. Sections 02-21 were used for training (for HPSG and dependency parsers), section 22 was used as development data, and final testing was performed on section 23. Following previous work on wide-coverage parsing with lexicalized grammars using the Penn Treebank, we evaluate the parser by measuring the accuracy of predicate-argument relations in the parser's output. A predicate-argument relation is defined as a tuple $\langle \sigma, w_h, a, w_a \rangle$, where σ is the predicate type (e.g. adjective, intransitive verb), w_h is the head word of the predicate, a is the argument label (MODARG, ARG1, ... , ARG4), and w_a is the head word of the argument. Labeled precision (LP)/labeled recall (LR) is the ratio of tuples correctly identified by the parser. These predicate-argument relations cover the full range of syntactic dependencies produced by the HPSG parser (including, long-distance dependencies, raising and control, in addition to surface dependencies).

In the experiments presented in this section, input sentences were automatically tagged with parts-of-speech with about 97% accuracy, using a maximum entropy POS tagger. We also report results on parsing text with gold standard POS tags, where explicitly noted. This provides an upper-bound on what can be expected if a more sophisticated multi-tagging scheme (James R. Curran and Vadas, 2006) is used, instead of hard assignment of single tags in a preprocessing step as done here.

[1] The extraction software can be obtained from http://www-tsujii.is.s.u-tokyo.ac.jp/enju.

4.1 Baseline

HPSG parsing results using the same HPSG grammar and treebank have recently been reported by Miyao and Tsujii (2005) and Ninomia et al. (2006). By running the HPSG parser described in section 2.2 on the development data *without* dependency constraints, we obtain similar values of LP (86.8%) and LR (85.6%) as those reported by Miyao and Tsujii (Miyao and Tsujii, 2005). Using the extremely lexicalized framework of (Ninomiya et al., 2006) by performing supertagging before parsing, we obtain similar accuracy as Ninomiya et al. (87.1% LP and 85.9% LR).

4.2 Dependency constraints and the penalty parameter

Parsing the development data with *hard dependency constraints* confirmed the intuition that these constraints often describe dependency structures that do not conform to HPSG schema used in parsing, resulting in parse failures. To determine the upper-bound on HPSG parsing with hard dependency constraints, we set the HPSG parser to disallow the application of any rules that result in the creation of dependencies that violate *gold standard dependencies*. This results in high precision (96.7%), but recall is low (82.3%) due to parse failures caused by lack of grammatical coverage [2]. Using dependencies produced by the shift-reduce SVM parser, we obtain 91.5% LP and 65.7% LR. This represents a large gain in precision over the baseline, but an even greater loss in recall, which limits the usefulness of the parser, and severely hurts the appeal of hard constraints.

We focus the rest of our experiments on parsing with *soft dependency constraints*. As explained in section 3, this involves setting the penalty parameter α. During parsing, we subtract α from the log-probability of applying any schema that violates the dependency constraints given to the HPSG parser. Figure 3 illustrates the effect of α when gold standard dependencies (and gold standard POS tags) are used. We note that setting $\alpha = 0$ causes the parser to ignore dependency constraints, providing baseline performance. Conversely, setting a high enough value ($\alpha = 30$ is sufficient, in practice) causes any substructures that violate the dependency constraints to be used only when they are absolutely necessary to produce a valid parse for the input sentence. In figure 3, this corresponds to an upper-bound on the accuracy of parsing with soft dependency constraints (94.7% f-score), since gold standard dependencies are used.

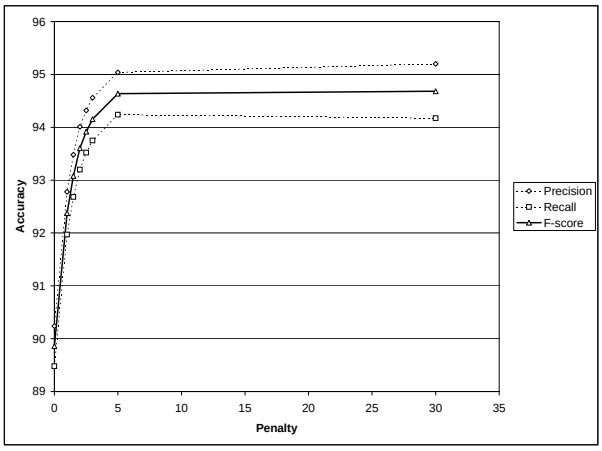

Figure 3: The effect of α on HPSG parsing constrained by gold standard dependencies.

We set α empirically with simple hill climbing on the development set. Because it is expected that the optimal value of α depends on the accuracy of the surface dependency parser, we set separate values for parsing with a POS tagger or with gold standard POS tags. Figure 4 shows the accuracy of HPSG predicate-argument relations obtained with dependency constraints determined by dependency parsing with gold standard POS tags. With both automatically assigned and gold standard POS tags, we observe an improvement of about 0.6% in precision, recall and f-score, when the optimal α value is used in each case. While this corresponds to a relative error reduction of over 6% (or 12%, if we consider the upper-bound dictated by imperfect grammatical coverage), a more interesting aspect of this framework is that it allows techniques designed for improving dependency accuracy to improve HPSG parsing accuracy directly, as we illustrate next.

[2] Although the HPSG grammar does not have perfect coverage of unseen text, it supports complete and *mostly* correct analyses for all sentences in the development set. However, when we require *completely* correct analyses by using hard constraints, lack of coverage may cause parse failures.

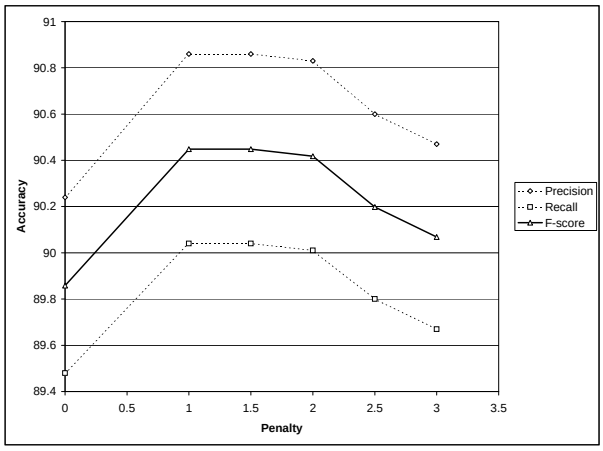

Figure 4: The effect of α on HPSG parsing constrained by the output of a dependency parser using gold standard POS tags.

4.3 Determining constraints with dependency parser combination

Parser combination has been shown to be a powerful way to obtain very high accuracy in dependency parsing (Sagae and Lavie, 2006). Using dependency constraints allows us to improve HPSG parsing accuracy simply by using an existing parser combination approach. As a first step, we train two additional parsers with the dependencies extracted from the HPSG Treebank. The first uses the same shift-reduce framework described in section 2.1, but it process the input from right to left (RL). This has been found to work well in previous work on dependency parser combination (Zeman and Žabokrtský, 2005; Sagae and Lavie, 2006). The second parser is MSTParser, the large-margin maximum spanning tree parser described in (McDonald et al., 2005)[3].

We examine the use of two combination schemes: one using two parsers, and one using three parsers. The first combination approach is to keep only dependencies for which there is agreement between the two parsers. In other words, dependencies that are proposed by one parser but not the other are simply discarded. Using the left-to-right shift-reduce parser and MSTParser, we find that this results in very high precision of surface dependencies on the development data. In the second approach, combination of the three dependency parsers is done according to the maximum spanning tree combination scheme of Sagae and Lavie (2006), which results in high accuracy of surface dependencies. For each of the combination approaches, we use the resulting dependencies as constraints for HPSG parsing, determining the optimal value of α on the development set in the same way as done for a single parser. Table 1 summarizes our experiments on development data using parser combinations to produce dependency constraints [4]. The two combination approaches are denoted as C1 and C2.

Parser	Dep	α	HPSG	Diff
none (baseline)	–	–	86.5	–
LR shift-reduce	91.2	1.5	87.1	0.6
RL shift-reduce	90.1	–	–	
MSTParser	91.0	–	–	
C1 (agreement)	96.8*	2.5	87.4	0.9
C2 (MST)	92.4	2.5	87.4	0.9

Table 1: Summary of results on development data. * The shallow accuracy of combination C1 corresponds to the dependency precision (no dependencies were reported for 8% of all words in the development set).

4.4 Results

Having determined α values on development data for the shift-reduce dependency parser, the two-parser agreement combination, and the three-parser maximum spanning tree combination, we parse the test data (section 23) using these three different sources of dependency constraints for HPSG parsing. Our final results are shown in table 2, where we also include the results published in (Ninomiya et al., 2006) for comparison purposes, and the result of using dependency constraints obtained with gold standard POS tags.

By using two unlabeled dependency parsers to provide soft dependency constraints, we obtain a 1% absolute improvement in precision and recall of predicate-argument identification in HPSG parsing over a strong baseline. Our baseline approach outperformed previously published results on this test

[3]Downloaded from http://sourceforge.net/projects/mstparser

[4]The accuracy figures for the dependency parsers is expressed as unlabeled accuracy of the surface dependencies only, and are not comparable to the HPSG parsing accuracy figures

Parser	LP	LR	F-score
HPSG Baseline	87.4	87.0	87.2
Shift-Reduce + HPSG	88.2	87.7	87.9
C1 + HPSG	**88.5**	**88.0**	**88.2**
C2 + HPSG	88.4	87.9	88.1
Baseline(gold)	89.8	89.4	89.6
Shift-Reduce(gold)	90.62	90.23	90.42
C1+HPSG(gold)	**90.9**	**90.4**	**90.6**
C2+HPSG(gold)	90.8	90.4	90.6
Miyao and Tsujii, 2005	85.0	84.3	84.6
Ninomiya et al., 2006	87.4	86.3	86.8

Table 2: Final results on test set. The first set of results show our HPSG baseline and HPSG with soft dependency constraints using three different sources of dependency constraints. The second set of results show the accuracy of the same parsers when gold part-of-speech tags are used. The third set of results is from existing published models on the same data.

set, and our best performing combination scheme obtains an absolute improvement of 1.4% over the best previously published results using the HPSG Treebank. It is interesting to note that the results obtained with dependency parser combinations C1 and C2 were very similar, even though in C1 only two parsers were used, and constraints were provided for about 92% of shallow dependencies (with accuracy higher than 96%). Clearly, precision is crucial in dependency constraints.

Finally, although it is necessary to perform dependency parsing to pre-compute dependency constraints, the total time required to perform the entire process of HPSG parsing with dependency constraints is close to that of the baseline HPSG approach. This is due to two reasons: (1) the dependency parsing approaches used to pre-compute constraints are several times faster than the baseline HPSG approach, and (2) the HPSG portion of the process is significantly faster when dependency constraints are used, since the constraints help sharpen the search space, making search more efficient. Using the baseline HPSG approach, it takes approximately 25 minutes to parse the test set. The total time required to parse the test set using HPSG with dependency constraints generated by the shift-reduce parser is 27 minutes. With combination C1, parsing time increases to 30 minutes, since two dependency parsers are used sequentially.

5 Related work

There are other approaches that combine shallow processing with deep parsing (Crysmann et al., 2002; Frank et al., 2003; Daum et al., 2003) to improve parsing *efficiency*. Typically, shallow parsing is used to create robust minimal recursion semantics, which are used as constraints to limit ambiguity during parsing. Our approach, in contrast, uses syntactic dependencies to achieve a significant improvement in the *accuracy* of wide-coverage HPSG parsing. Additionally, our approach is in many ways similar to supertagging (Bangalore and Joshi, 1999), which uses sequence labeling techniques as an efficient way to pre-compute parsing constraints (specifically, the assignment of lexical entries to input words).

6 Conclusion

We have presented a novel framework for taking advantage of the strengths of a shallow parsing approach and a deep parsing approach. We have shown that by constraining the application of rules in HPSG parsing according to results from a dependency parser, we can significantly improve the accuracy of deep parsing by using shallow syntactic analyses.

To illustrate how this framework allows for improvements in the accuracy of dependency parsing to be used directly to improve the accuracy of HPSG parsing, we showed that by combining the results of different dependency parsers using the search-based parsing ensemble approach of (Sagae and Lavie, 2006), we obtain improved HPSG parsing accuracy as a result of the improved dependency accuracy.

Although we have focused on the use of HPSG and dependency parsing, the general framework presented here can be applied to other lexicalized grammar formalisms, such as LTAG, CCG and LFG.

Abstract

We introduce a framework for syntactic parsing with latent variables based on a form of dynamic Sigmoid Belief Networks called Incremental Sigmoid Belief Networks. We demonstrate that a previous feed-forward neural network parsing model can be viewed as a coarse approximation to inference with this class of graphical model. By constructing a more accurate but still tractable approximation, we significantly improve parsing accuracy, suggesting that ISBNs provide a good idealization for parsing. This generative model of parsing achieves state-of-the-art results on WSJ text and 8% error reduction over the baseline neural network parser.

1 Introduction

Latent variable models have recently been of increasing interest in Natural Language Processing, and in parsing in particular (e.g. (Koo and Collins, 2005; Matsuzaki et al., 2005; Riezler et al., 2002)). Latent variables provide a principled way to include features in a probability model without needing to have data labeled with those features in advance. Instead, a labeling with these features can be induced as part of the training process. The difficulty with latent variable models is that even small numbers of latent variables can lead to computationally intractable inference (a.k.a. decoding, parsing). In this paper we propose a solution to this problem based on dynamic Sigmoid Belief Networks (SBNs) (Neal, 1992). The dynamic SBNs which we peopose, called Incremental Sigmoid Belief Networks (ISBNs) have large numbers of latent variables, which makes exact inference intractable. However, they can be approximated sufficiently well to build fast and accurate statistical parsers which induce features during training.

We use SBNs in a generative history-based model of constituent structure parsing. The probability of an unbounded structure is decomposed into a sequence of probabilities for individual derivation decisions, each decision conditioned on the unbounded history of previous decisions. The most common approach to handling the unbounded nature of the histories is to choose a pre-defined set of features which can be unambiguously derived from the history (e.g. (Charniak, 2000; Collins, 1999)). Decision probabilities are then assumed to be independent of all information not represented by this finite set of features. Another previous approach is to use neural networks to compute a compressed representation of the history and condition decisions on this representation (Henderson, 2003; Henderson, 2004). It is possible that an unbounded amount of information is encoded in the compressed representation via its continuous values, but it is not clear whether this is actually happening due to the lack of any principled interpretation for these continuous values.

Like the former approach, we assume that there are a finite set of features which encode the relevant information about the parse history. But unlike that approach, we allow feature values to be ambiguous, and represent each feature as a distribution over (binary) values. In other words, these history features are treated as latent variables. Unfortunately, inter-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 632–639,
Prague, Czech Republic, June 2007.

preting the history representations as distributions over discrete values of latent variables makes the exact computation of decision probabilities intractable. Exact computation requires marginalizing out the latent variables, which involves summing over all possible vectors of discrete values, which is exponential in the length of the vector.

We propose two forms of approximation for dynamic SBNs, a neural network approximation and a form of mean field approximation (Saul and Jordan, 1999). We first show that the previous neural network model of (Henderson, 2003) can be viewed as a coarse approximation to inference with ISBNs. We then propose an incremental mean field method, which results in an improved approximation over the neural network but remains tractable. The resulting parser achieves significantly higher accuracy than the neural network parser (90.0% F-measure vs 89.1%). We argue that this correlation between better approximation and better accuracy suggests that dynamic SBNs are a good abstract model for natural language parsing.

2 Sigmoid Belief Networks

A belief network, or a Bayesian network, is a directed acyclic graph which encodes statistical dependencies between variables. Each variable S_i in the graph has an associated conditional probability distributions $P(S_i|Par(S_i))$ over its values given the values of its parents $Par(S_i)$ in the graph. A Sigmoid Belief Network (Neal, 1992) is a particular type of belief networks with binary variables and conditional probability distributions in the form of the logistic sigmoid function:

$$P(S_i{=}1|Par(S_i)) = \frac{1}{1{+}\exp(-\sum_{S_j \in Par(S_i)} J_{ij} S_j)},$$

where J_{ij} is the weight for the edge from variable S_j to variable S_i. In this paper we consider a generalized version of SBNs where we allow variables with any range of discrete values. We thus generalize the logistic sigmoid function to the normalized exponential (a.k.a. softmax) function to define the conditional probabilities for non-binary variables.

Exact inference with all but very small SBNs is not tractable. Initially sampling methods were used (Neal, 1992), but this is also not feasible for large networks, especially for the dynamic models of the type described in section 2.2. Variational methods have also been proposed for approximating SBNs (Saul and Jordan, 1999). The main idea of variational methods (Jordan et al., 1999) is, roughly, to construct a tractable approximate model with a number of free parameters. The free parameters are set so that the resulting approximate model is as close as possible to the original graphical model for a given inference problem.

2.1 Mean Field Approximation Methods

The simplest example of a variation method is the mean field method, originally introduced in statistical mechanics and later applied to unsupervised neural networks in (Hinton et al., 1995). Let us denote the set of visible variables in the model (i.e. the inputs and outputs) by V and hidden variables by $H = h_1, \ldots, h_l$. The mean field method uses a fully factorized distribution Q as the approximate model:

$$Q(H|V) = \prod_i Q_i(h_i|V).$$

where each Q_i is the distribution of an individual latent variable. The independence between the variables h_i in this approximate distribution Q does not imply independence of the free parameters which define the Q_i. These parameters are set to minimize the Kullback-Leibler divergence (Cover and Thomas, 1991) between the approximate distribution $Q(H|V)$ and the true distribution $P(H|V)$:

$$KL(Q\|P) = \sum_H Q(H|V) \ln \frac{Q(H|V)}{P(H|V)}, \qquad (1)$$

or, equivalently, to maximize the expression:

$$L_V = \sum_H Q(H|V) \ln \frac{P(H,V)}{Q(H|V)}. \qquad (2)$$

The expression L_V is a lower bound on the log-likelihood $\ln P(V)$. It is used in the mean field theory (Saul and Jordan, 1999) to approximate the likelihood. However, in our case of dynamic graphical models, we have to use a different approach which allows us to construct an incremental parsing method without needing to introduce the additional parameters proposed in (Saul and Jordan, 1999). We will describe our modification of the mean field method in section 3.3.

2.2 Dynamics

Dynamic Bayesian networks are Bayesian networks applied to arbitrarily long sequences. A new set of variables is instantiated for each position in the sequence, but the edges and weights for these variables are the same as in other positions. The edges which connect variables instantiated for different positions must be directed forward in the sequence, thereby allowing a temporal interpretation of the sequence. Typically a dynamic Bayesian Network will only involve edges between adjacent positions in the sequence (i.e. they are Markovian), but in our parsing models the pattern of interconnection is determined by structural locality, rather than sequence locality, as in the neural networks of (Henderson, 2003).

Using structural locality to define the graph in a dynamic SBN means that the subgraph of edges with destinations at a given position cannot be determined until all the parser decisions for previous positions have been chosen. We therefore call these models *Incremental* SBNs, because, at any given position in the parse, we only know the graph of edges for that position and previous positions in the parse. For example in figure 1, discussed below, it would not be possible to draw the portion of the graph after t, because we do not yet know the decision d_k^t.

The incremental specification of model structure means that we cannot use an undirected graphical model, such as Conditional Random Fields. With a directed dynamic model, all edges connecting the known portion of the graph to the unknown portion of the graph are directed toward the unknown portion. Also there are no variables in the unknown portion of the graph whose values are known (i.e. no visible variables), because at each step in a history-based model the decision probability is conditioned only on the parsing history. Only visible variables can result in information being reflected backward through a directed edge, so it is impossible for anything in the unknown portion of the graph to affect the probabilities in the known portion of the graph. Therefore inference can be performed by simply ignoring the unknown portion of the graph, and there is no need to sum over all possible structures for the unknown portion of the graph, as would be necessary for an undirected graphical model.

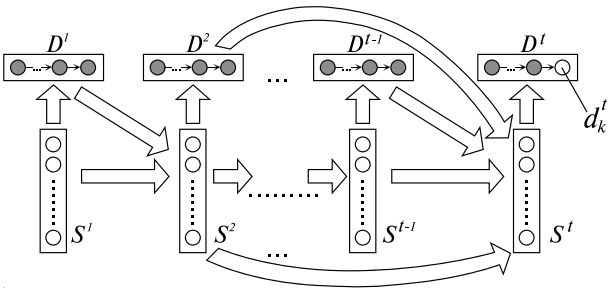

Figure 1: Illustration of an ISBN.

3 The Probabilistic Model of Parsing

In this section we present our framework for syntactic parsing with dynamic Sigmoid Belief Networks. We first specify the form of SBN we propose, namely ISBNs, and then two methods for approximating the inference problems required for parsing. We only consider generative models of parsing, since generative probability models are simpler and we are focused on probability estimation, not decision making. Although the most accurate parsing models (Charniak and Johnson, 2005; Henderson, 2004; Collins, 2000) are discriminative, all the most accurate discriminative models make use of a generative model. More accurate generative models should make the discriminative models which use them more accurate as well. Also, there are some applications, such as language modeling, which require generative models.

3.1 The Graphical Model

In ISBNs, we use a history-based model, which decomposes the probability of the parse as:

$$P(T) = P(D^1, ..., D^m) = \prod_t P(D^t | D^1, \ldots, D^{t-1}),$$

where T is the parse tree and $D^1, \ldots, D^m$ is its equivalent sequence of parser decisions. Instead of treating each D^t as atomic decisions, it is convenient to further split them into a sequence of elementary decisions $D^t = d_1^t, \ldots, d_n^t$:

$$P(D^t | D^1, \ldots, D^{t-1}) = \prod_k P(d_k^t | h(t,k)),$$

where $h(t,k)$ denotes the parsing history $D^1, \ldots, D^{t-1}, d_1^t, \ldots, d_{k-1}^t$. For example, a

decision to create a new constituent can be divided in two elementary decisions: deciding to create a constituent and deciding which label to assign to it. We use a graphical model to define our proposed class of probability models. An example graphical model for the computation of $P(d_k^t|h(t,k))$ is illustrated in figure 1.

The graphical model is organized into vectors of variables: latent state variable vectors $S^{t'} = s_1^{t'}, \ldots, s_n^{t'}$, representing an intermediate state of the parser at derivation step t', and decision variable vectors $D^{t'} = d_1^{t'}, \ldots, d_l^{t'}$, representing a parser decision at derivation step t', where $t' \leq t$. Variables whose value are given at the current decision (t,k) are shaded in figure 1, latent and output variables are left unshaded.

As illustrated by the arrows in figure 1, the probability of each state variable $s_i^{t'}$ depends on all the variables in a finite set of relevant previous state and decision vectors, but there are no *direct* dependencies between the different variables in a single state vector. Which previous state and decision vectors are connected to the current state vector is determined by a set of structural relations specified by the parser designer. For example, we could select the most recent state where the same constituent was on the top of the stack, and a decision variable representing the constituent's label. Each such selected relation has its own distinct weight matrix for the resulting edges in the graph, but the same weight matrix is used at each derivation position where the relation is relevant.

As indicated in figure 1, the probability of each elementary decision $d_k^{t'}$ depends both on the current state vector $S^{t'}$ and on the previously chosen elementary action $d_{k-1}^{t'}$ from $D^{t'}$. This probability distribution has the form of a normalized exponential:

$$P(d_k^{t'} = d|S^{t'}, d_{k-1}^{t'}) = \frac{\Phi_{h(t',k)}(d)\, e^{\sum_j W_{dj} s_j^{t'}}}{\sum_{d'} \Phi_{h(t',k)}(d')\, e^{\sum_j W_{d'j} s_j^{t'}}}, \quad (3)$$

where $\Phi_{h(t',k)}$ is the indicator function of a set of elementary decisions that may possibly follow the parsing history $h(t',k)$, and the W_{dj} are the weights.

For our experiments, we replicated the same pattern of interconnection between state variables as described in (Henderson, 2003).[1] We also used the same left-corner parsing strategy, and the same set of decisions, features, and states. We refer the reader to (Henderson, 2003) for details.

Exact computation with this model is not tractable. Sampling of parse trees from the model is not feasible, because a generative model defines a joint model of both a sentence and a tree, thereby requiring sampling over the space of sentences. Gibbs sampling (Geman and Geman, 1984) is also impossible, because of the huge space of variables and need to resample after making each new decision in the sequence. Thus, we know of no reasonable alternatives to the use of variational methods.

3.2 A Feed-Forward Approximation

The first model we consider is a strictly incremental computation of a variational approximation, which we will call the feed-forward approximation. It can be viewed as the simplest form of mean field approximation. As in any mean field approximation, each of the latent variables is independently distributed. But unlike the general case of mean field approximation, in the feed-forward approximation we only allow the parameters of the distributions Q_i to depend on the distributions of their parents. This additional constraint increases the potential for a large Kullback-Leibler divergence with the true model, defined in expression (1), but it significantly simplifies the computations.

The set of hidden variables H in our graphical model consists of all the state vectors $S^{t'}$, $t' \leq t$, and the last decision d_k^t. All the previously observed decisions $h(t,k)$ comprise the set of visible variables V. The approximate fully factorisable distribution $Q(H|V)$ can be written as:

$$Q(H|V) = q_k^t(d_k^t) \prod_{t',i} \left(\mu_i^{t'}\right)^{s_i^{t'}} \left(1 - \mu_i^{t'}\right)^{1 - s_i^{t'}}.$$

where $\mu_i^{t'}$ is the free parameter which determines the distribution of state variable i at position t', namely its mean, and $q_k^t(d_k^t)$ is the free parameter which determines the distribution over decisions d_k^t.

Because we are only allowed to use information about the distributions of the parent variables to

[1] In the neural network of (Henderson, 2003), our variables map to their "units", and our dependencies/edges map to their "links".

compute the free parameters $\mu_i^{t'}$, the optimal assignment of values to the $\mu_i^{t'}$ is:

$$\mu_i^{t'} = \sigma\left(\eta_i^{t'}\right),$$

where σ denotes the logistic sigmoid function and $\eta_i^{t'}$ is a weighted sum of the parent variables' means:

$$\eta_i^{t'} = \sum_{t'' \in RS(t')} \sum_j J_{ij}^{\tau(t',t'')} \mu_j^{t''} + \sum_{t'' \in RD(t')} \sum_k B_{id_k^{t''}}^{\tau(t',t'')}, \quad (4)$$

where $RS(t')$ is the set of previous positions with edges from their state vectors to the state vector at t', $RD(t')$ is the set of previous positions with edges from their decision vectors to the state vector at t', $\tau(t', t'')$ is the relevant relation between the position t'' and the position t', and J_{ij}^{τ} and B_{id}^{τ} are weight matrices.

In order to maximize (2), the approximate distribution of the next decisions $q_k^t(d)$ should be set to

$$q_k^t(d) = \frac{\Phi_{h(t,k)}(d)\, e^{\sum_j W_{dj}\mu_j^t}}{\sum_{d'} \Phi_{h(t,k)}(d')\, e^{\sum_j W_{d'j}\mu_j^t}}, \quad (5)$$

as follows from expression (3). The resulting estimate of the tree probability is given by:

$$P(T) \approx \prod_{t,k} q_k^t(d_k^t).$$

This approximation method replicates exactly the computation of the feed-forward neural network in (Henderson, 2003), where the above means $\mu_i^{t'}$ are equivalent to the neural network hidden unit activations. Thus, that neural network probability model can be regarded as a simple approximation to the graphical model introduced in section 3.1.

In addition to the drawbacks shared by any mean field approximation method, this feed-forward approximation cannot capture backward reasoning. By backward (a.k.a. top-down) reasoning we mean the need to update the state vector means $\mu_i^{t'}$ after observing a decision d_k^t, for $t' \leq t$. The next section discusses how backward reasoning can be incorporated in the approximate model.

3.3 A Mean Field Approximation

This section proposes a more accurate way to approximate ISBNs with mean field methods, which we will call the mean field approximation. Again, we are interested in finding the distribution Q which maximizes the quantity L_V in expression (2). The decision distribution $q_k^t(d_k^t)$ maximizes L_V when it has the same dependence on the state vector means μ_k^t as in the feed-forward approximation, namely expression (5). However, as we mentioned above, the feed-forward computation does not allow us to compute the optimal values of state means $\mu_i^{t'}$.

Optimally, after each new decision d_k^t, we should recompute all the means $\mu_i^{t'}$ for all the state vectors $S^{t'}$, $t' \leq t$. However, this would make the method intractable, due to the length of derivations in constituent parsing and the interdependence between these means. Instead, after making each decision d_k^t and adding it to the set of visible variables V, we recompute only means of the current state vector S^t.

The denominator of the normalized exponential function in (3) does not allow us to compute L_V exactly. Instead, we use a simple first order approximation:

$$\begin{aligned} &E_Q[\ln \sum_d \Phi_{h(t,k)}(d) \exp(\sum_j W_{dj} s_j^t)] \\ &\quad \approx \ln \sum_d \Phi_{h(t,k)}(d) \exp(\sum_j W_{dj}\mu_j^t), \end{aligned} \quad (6)$$

where the expectation $E_Q[\ldots]$ is taken over the state vector S^t distributed according to the approximate distribution Q.

Unfortunately, even with this assumption there is no analytic way to maximize L_V with respect to the means μ_k^t, so we need to use numerical methods. Assuming (6), we can rewrite the expression (2) as follows, substituting the true $P(H, V)$ defined by the graphical model and the approximate distribution $Q(H|V)$, omitting parts independent of μ_k^t:

$$\begin{aligned} L_V^{t,k} = &\sum_i -\mu_i^t \ln \mu_i^t - (1-\mu_i^t) \ln\left(1-\mu_i^t\right) \\ &+\mu_i^t \eta_i^t + \sum_{k'<k} \Phi_{h(t,k')}(d_{k'}^t) \sum_j W_{d_{k'}^t j} \mu_j^t \\ &- \sum_{k'<k} \ln\left(\sum_d \Phi_{h(t,k')}(d) \exp(\sum_j W_{dj}\mu_j^t)\right), \end{aligned} \quad (7)$$

here, η_i^t is computed from the previous relevant state means and decisions as in (4). This expression is

concave with respect to the parameters μ_i^t, so the global maximum can be found. We use coordinate-wise ascent, where each μ_i^t is selected by an efficient line search (Press et al., 1996), while keeping other $\mu_{i'}^t$ fixed.

3.4 Parameter Estimation

We train these models to maximize the fit of the *approximate* model to the data. We use gradient descent and a maximum likelihood objective function. This requires computation of the gradient of the approximate log-likelihood with respect to the model parameters. In order to compute these derivatives, the error should be propagated all the way back through the structure of the graphical model. For the feed-forward approximation, computation of the derivatives is straightforward, as in neural networks. But for the mean field approximation, it requires computation of the derivatives of the means μ_i^t with respect to the other parameters in expression (7). The use of a numerical search in the mean field approximation makes the analytical computation of these derivatives impossible, so a different method needs to be used to compute their values. If maximization of $L_V^{t,k}$ is done until convergence, then the derivatives of $L_V^{t,k}$ with respect to μ_i^t are close to zero:

$$F_i^{t,k} = \frac{\partial L_V^{t,k}}{\partial \mu_i^t} \approx 0 \text{ for all } i.$$

This system of equations allows us to use implicit differentiation to compute the needed derivatives.

4 Experimental Evaluation

In this section we evaluate the two approximations to dynamic SBNs discussed in the previous section, the feed-forward method equivalent to the neural network of (Henderson, 2003) (NN method) and the mean field method (MF method). The hypothesis we wish to test is that the more accurate approximation of dynamic SBNs will result in a more accurate model of constituent structure parsing. If this is true, then it suggests that dynamic SBNs of the form proposed here are a good abstract model of the nature of natural language parsing.

We used the Penn Treebank WSJ corpus (Marcus et al., 1993) to perform the empirical evaluation of the considered approaches. It is expensive to train the MF approximation on the whole WSJ corpus, so instead we use only sentences of length at most 15, as in (Taskar et al., 2004) and (Turian and Melamed, 2006). The standard split of the corpus into training (sections 2–22, 9,753 sentences), validation (section 24, 321 sentences), and testing (section 23, 603 sentences) was performed.[2]

Turian and Melamed, 2006	89.3	89.6	89.4
MF method	**89.3**	**90.7**	**90.0**
Charniak, 2000	90.0	90.2	90.1

Table 1: Percentage labeled constituent recall (R), precision (P), combination of both (F_1) on the testing set.

As in (Henderson, 2003; Turian and Melamed, 2006) we used a publicly available tagger (Ratnaparkhi, 1996) to provide the part-of-speech tag for each word in the sentence. For each tag, there is an unknown-word vocabulary item which is used for all those words which are not sufficiently frequent with that tag to be included individually in the vocabulary. We only included a specific tag-word pair in the vocabulary if it occurred at least 20 time in the training set, which (with tag-unknown-word pairs) led to the very small vocabulary of 567 tag-word pairs.

During parsing with both the NN method and the MF method, we used beam search with a post-word beam of 10. Increasing the beam size beyond this value did not significantly effect parsing accuracy. For both of the models, the state vector size of 40 was used. All the parameters for both the NN and MF models were tuned on the validation set. A single best model of each type was then applied to the final testing set.

Table 1 lists the results of the NN approximation and the MF approximation, along with results of dif-

[2] Training of our MF method on this subset of WSJ took less than 6 days on a standard desktop PC. We would expect that a model for the entire WSJ corpus can be trained in about 3 months time. The training time is about linear with the number of words, but a larger state vector is needed to accommodate all the information. The long training times on the entire WSJ would not allow us to tune the model parameters properly, which would have increased the randomness of the empirical comparison, although it would be feasible for building a system.

ferent generative and discriminative parsing methods (Bikel, 2004; Taskar et al., 2004; Turian and Melamed, 2006; Charniak, 2000) evaluated in the same experimental setup. The MF model improves over the baseline NN approximation, with an error reduction in F-measure exceeding 8%. This improvement is statically significant.[3] The MF model achieves results which do not appear to be significantly different from the results of the best model in the list (Charniak, 2000). It should also be noted that the model (Charniak, 2000) is the most accurate generative model on the standard WSJ parsing benchmark, which confirms the viability of our generative model.

These experimental results suggest that Incremental Sigmoid Belief Networks are an appropriate model for natural language parsing. Even approximations such as those tested here, with a very strong factorisability assumption, allow us to build quite accurate parsing models. The main drawback of our proposed mean field approach is the relative computational complexity of the numerical procedure used to maximize $L_V^{t,k}$. But this approximation has succeeded in showing that a more accurate approximation of ISBNs results in a more accurate parser. We believe this provides strong justification for more accurate approximations of ISBNs for parsing.

5 Related Work

There has not been much previous work on graphical models for full parsing, although recently several latent variable models for parsing have been proposed (Koo and Collins, 2005; Matsuzaki et al., 2005; Riezler et al., 2002). In (Koo and Collins, 2005), an undirected graphical model is used for parse reranking. Dependency parsing with dynamic Bayesian networks was considered in (Peshkin and Savova, 2005), with limited success. Their model is very different from ours. Roughly, it considered the whole sentence at a time, with the graphical model being used to decide which words correspond to leaves of the tree. The chosen words are then removed from the sentence and the model is recursively applied to the reduced sentence.

Undirected graphical models, in particular Conditional Random Fields, are the standard tools for shallow parsing (Sha and Pereira, 2003). However, shallow parsing is effectively a sequence labeling problem and therefore differs significantly from full parsing. As discussed in section 2.2, undirected graphical models do not seem to be suitable for history-based full parsing models.

Sigmoid Belief Networks were used originally for character recognition tasks, but later a dynamic modification of this model was applied to the reinforcement learning task (Sallans, 2002). However, their graphical model, approximation method, and learning method differ significantly from those of this paper.

6 Conclusions

This paper proposes a new generative framework for constituent parsing based on dynamic Sigmoid Belief Networks with vectors of latent variables. Exact inference with the proposed graphical model (called Incremental Sigmoid Belief Networks) is not tractable, but two approximations are considered. First, it is shown that the neural network parser of (Henderson, 2003) can be considered as a simple feed-forward approximation to the graphical model. Second, a more accurate but still tractable approximation based on mean field theory is proposed. Both methods are empirically compared, and the mean field approach achieves significantly better results, which are non-significantly different from the results of the most accurate generative parsing model (Charniak, 2000) on our testing set. The fact that a more accurate approximation leads to a more accurate parser suggests that ISBNs are a good abstract model for constituent structure parsing. This empirical result motivates research into more accurate approximations of dynamic SBNs.

We focused in this paper on generative models of parsing. The results of such a generative model can be easily improved by a discriminative reranking model, even without any additional feature engineering. For example, the discriminative training techniques successfully applied in (Henderson, 2004) to the feed-forward neural network model can be directly applied to the mean field model proposed in this paper. The same is true for reranking with data-defined kernels, with which we would

[3] We measured signifi cance of all the experiments in this paper with the randomized signifi cance test (Yeh, 2000).

expect similar improvements as were achieved with the neural network parser (Henderson and Titov, 2005). Such improvements should situate the resulting model among the best current parsing models.

Corpus Effects on the Evaluation of Automated Transliteration Systems

Sarvnaz Karimi **Andrew Turpin** **Falk Scholer**

Abstract

Most current machine transliteration systems employ a corpus of known source-target word pairs to train their system, and typically evaluate their systems on a similar corpus. In this paper we explore the performance of transliteration systems on corpora that are varied in a controlled way. In particular, we control the number, and prior language knowledge of human transliterators used to construct the corpora, and the origin of the source words that make up the corpora. We find that the word accuracy of automated transliteration systems can vary by up to 30% (in absolute terms) depending on the corpus on which they are run. We conclude that at least four human transliterators should be used to construct corpora for evaluating automated transliteration systems; and that although absolute word accuracy metrics may not translate across corpora, the relative rankings of system performance remains stable across differing corpora.

1 Introduction

Machine transliteration is the process of transforming a word written in a source language into a word in a target language without the aid of a bilingual dictionary. Word pronunciation is preserved, as far as possible, but the script used to render the target word is different from that of the source language. Transliteration is applied to proper nouns and out-of-vocabulary terms as part of machine translation and cross-lingual information retrieval (CLIR) (AbdulJaleel and Larkey, 2003; Pirkola et al., 2006). Several transliteration methods are reported in the literature for a variety of languages, with their performance being evaluated on multilingual corpora. Source-target pairs are either extracted from bilingual documents or dictionaries (AbdulJaleel and Larkey, 2003; Bilac and Tanaka, 2005; Oh and Choi, 2006; Zelenko and Aone, 2006), or gathered explicitly from human transliterators (Al-Onaizan and Knight, 2002; Zelenko and Aone, 2006). Some evaluations of transliteration methods depend on a single unique transliteration for each source word, while others take multiple target words for a single source word into account. In their work on transliterating English to Persian, Karimi et al. (2006) observed that the content of the corpus used for evaluating systems could have dramatic affects on the reported accuracy of methods.

The effects of corpus composition on the evaluation of transliteration systems has not been specifically studied, with only implicit experiments or claims made in the literature such as introducing the effects of different transliteration models (AbdulJaleel and Larkey, 2003), language families (Lindén, 2005) or application based (CLIR) evaluation (Pirkola et al., 2006). In this paper, we report our experiments designed to explicitly examine the effect that varying the underlying corpus used in both training and testing systems has on transliteration accuracy. Specifically, we vary the number of human transliterators that are used to construct the corpus; and the origin of the English words used in the corpus.

Our experiments show that the word accuracy of automated transliteration systems can vary by up to 30% (in absolute terms), depending on the corpus used. Despite the wide range of absolute values

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 640–647,
Prague, Czech Republic, June 2007.

in performance, the ranking of our two transliteration systems was preserved on all corpora. We also find that a human's confidence in the language from which they are transliterating can affect the corpus in such a way that word accuracy rates are altered.

2 Background

Machine transliteration methods are divided into grapheme-based (AbdulJaleel and Larkey, 2003; Lindén, 2005), phoneme-based (Jung et al., 2000; Virga and Khudanpur, 2003) and combined techniques (Bilac and Tanaka, 2005; Oh and Choi, 2006). Grapheme-based methods derive transformation rules for character combinations in the source text from a training data set, while phoneme-based methods use an intermediate phonetic transformation. In this paper, we use two grapheme-based methods for English to Persian transliteration. During a training phase, both methods derive rules for transforming character combinations (*segments*) in the source language into character combinations in the target language with some probability.

During transliteration, the source word s_i is segmented and rules are chosen and applied to each segment according to heuristics. The probability of a resulting word is the product of the probabilities of the applied rules. The result is a list of target words sorted by their associated probabilities, L^i.

The first system we use (SYS-1) is an n-gram approach that uses the last character of the previous source segment to condition the choice of the rule for the current source segment. This system has been shown to outperform other n-gram based methods for English to Persian transliteration (Karimi et al., 2006).

The second system we employ (SYS-2) makes use of some explicit knowledge of our chosen language pair, English and Persian, and is also on the collapsed-vowel scheme presented by Karimi et al. (2006). In particular, it exploits the tendency for runs of English vowels to be collapsed into a single Persian character, or perhaps omitted from the Persian altogether. As such, segments are chosen based on surrounding consonants and vowels. The full details of this system are not important for this paper; here we focus on the performance evaluation of systems, not the systems themselves.

2.1 System Evaluation

In order to evaluate the list L^i of target words produced by a transliteration system for source word s_i, a test corpus is constructed. The test corpus consists of a source word, s_i, and a list of possible target words $\{t_{ij}\}$, where $1 \leq j \leq d_i$, the number of distinct target words for source word s_i. Associated with each t_{ij} is a count n_{ij} which is the number of human transliterators who transliterated s_i into t_{ij}.

Often the test corpus is a proportion of a larger corpus, the remainder of which has been used for training the system's rule base. In this work we adopt the standard ten-fold cross validation technique for all of our results, where 90% of a corpus is used for training and 10% for testing. The process is repeated ten times, and the mean result taken. Forthwith, we use the term corpus to refer to the single corpus from which both training and test sets are drawn in this fashion.

Once the corpus is decided upon, a metric to measure the system's accuracy is required. The appropriate metric depends on the scenario in which the transliteration system is to be used. For example, in a machine translation application where only one target word can be inserted in the text to represent a source word, it is important that the word at the top of the system generated list of target words (by definition the most probable) is one of the words generated by a human in the corpus. More formally, the first word generated for source word s_i, L^i_1, must be one of $t_{ij}, 1 \leq j \leq d_i$. It may even be desirable that this is the target word most commonly used for this source word; that is, $L^i_1 = t_{ij}$ such that $n_{ij} \geq n_{ik}$, for all $1 \leq k \leq d_i$. Alternately, in a CLIR application, all variants of a source word might be required. For example, if a user searches for an English term "Tom" in Persian documents, the search engine should try and locate documents that contain both "تام" (3 letters:ت-ا-م) and "تم"(2 letters: ت-م), two possible transliterations of "Tom" that would be generated by human transliterators. In this case, a metric that counts the number of t_{ij} that appear in the top d_i elements of the system generated list, L^i, might be appropriate.

In this paper we focus on the "Top-1" case, where it is important for the most probable target word generated by the system, L^i_1 to be either the most pop-

ular t_{ij} (labeled the *Majority*, with ties broken arbitrarily), or just one of the t_{ij}'s (labeled *Uniform* because all possible transliterations are equally rewarded). A third scheme (labeled *Weighted*) is also possible where the reward for t_{ij} appearing as L_1^i is $n_{ij}/\sum_{j=1}^{d_i} n_{ij}$; here, each target word is given a weight proportional to how often a human transliterator chose that target word. Due to space considerations, we focus on the first two variants only.

In general, there are two commonly used metrics for transliteration evaluation: word accuracy (WA) and character accuracy (CA) (Hall and Dowling, 1980). In all of our experiments, CA based metrics closely mirrored WA based metrics, and so conclusions drawn from the data would be the same whether WA metrics or CA metrics were used. Hence we only discuss and report WA based metrics in this paper.

For each source word in the test corpus of K words, word accuracy calculates the percentage of correctly transliterated terms. Hence for the majority case, where every source word in the corpus only has one target word, the word accuracy is defined as

$$MWA = |\{s_i | L_1^i = t_{i1}, 1 \leq i \leq K\}|/K,$$

and for the *Uniform* case, where every target variant is included with equal weight in the corpus, the word accuracy is defined as

$$UWA = |\{s_i | L_1^i \in \{t_{ij}\}, 1 \leq i \leq K, 1 \leq j \leq d_i\}|/K.$$

2.2 Human Evaluation

To evaluate the level of agreement between transliterators, we use an agreement measure based on Mun and Eye (2004).

For any source word s_i, there are d_i different transliterations made by the n_i human transliterators ($n_i = \sum_{j=1}^{d_i} n_{ij}$, where n_{ij} is the number of times source word s_i was transliterated into target word t_{ij}). When any two transliterators agree on the same target word, there are two agreements being made: transliterator one agrees with transliterator two, and vice versa. In general, therefore, the total number of agreements made on source word s_i is $\sum_{j=1}^{d_i} n_{ij}(n_{ij}-1)$. Hence the total number of actual agreements made on the entire corpus of K words is

$$A_{act} = \sum_{i=1}^{K} \sum_{j=1}^{d_i} n_{ij}(n_{ij}-1).$$

The total number of possible agreements (that is, when all human transliterators agree on a single target word for each source word), is

$$A_{poss} = \sum_{i=1}^{K} n_i(n_i-1).$$

The proportion of overall agreement is therefore

$$P_A = \frac{A_{act}}{A_{poss}}.$$

2.3 Corpora

Seven transliterators (T1, T2, …, T7: all native Persian speakers from Iran) were recruited to transliterate 1500 proper names that we provided. The names were taken from lists of names written in English on English Web sites. Five hundred of these names also appeared in lists of names on Arabic Web sites, and five hundred on Dutch name lists. The transliterators were not told of the origin of each word. The entire corpus, therefore, was easily separated into three sub-corpora of 500 words each based on the origin of each word. To distinguish these collections, we use E_7, A_7 and D_7 to denote the English, Arabic and Dutch sub-corpora, respectively. The whole 1500 word corpus is referred to as EDA_7.

Dutch and Arabic were chosen with an assumption that most Iranian Persian speakers have little knowledge of Dutch, while their familiarity with Arabic should be in the second rank after English. All of the participants held at least a Bachelors degree. Table 1 summarizes the information about the transliterators and their perception of the given task. Participants were asked to scale the difficulty of the transliteration of each sub-corpus, indicated as a scale from 1 (*hard*) to 3 (*easy*). Similarly, the participants' confidence in performing the task was rated from 1 (*no confidence*) to 3 (*quite confident*). The level of familiarity with second languages was also reported based on a scale of zero (*not familiar*) to 3 (*excellent knowledge*).

The information provided by participants confirms our assumption of transliterators knowledge of second languages: high familiarity with English, some knowledge of Arabic, and little or no prior knowledge of Dutch. Also, the majority of them found the transliteration of English terms of medium difficulty, Dutch was considered mostly hard, and Arabic as easy to medium.

Transliterator	Second Language Knowledge				Difficulty,Confidence		
	English	Dutch	Arabic	Other	English	Dutch	Arabic
1	2	0	1	-	1,1	1,2	2,3
2	2	0	2	-	2,2	2,3	3,3
3	2	0	1	-	2,2	1,2	2,2
4	2	0	1	-	2,2	2,1	3,3
5	2	0	2	Turkish	2,2	1,1	3,2
6	2	0	1	-	2,2	1,1	3,3
7	2	0	1	-	2,2	1,1	2,2

Table 1: Transliterator's language knowledge (0=not familiar to 3=excellent knowledge), perception of difficulty (1=hard to 3=easy) and confidence (1=no confidence to 3=quite confident) in creating the corpus.

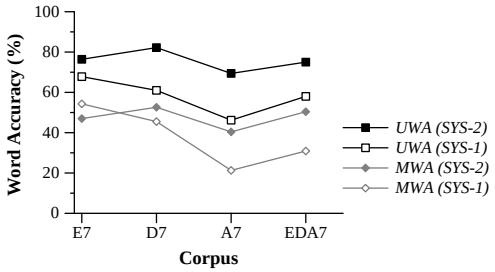

Figure 1: Comparison of the two evaluation metrics using the two systems on four corpora. (Lines were added for clarity, and do not represent data points.)

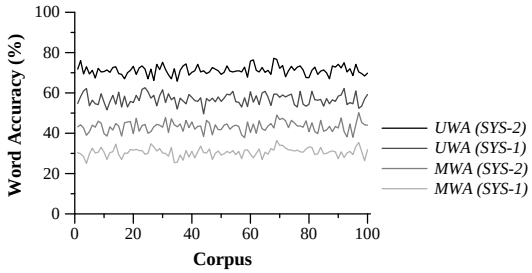

Figure 2: Comparison of the two evaluation metrics using the two systems on 100 randomly generated sub-corpora.

3 Results

Figure 1 shows the values of UWA and MWA for E_7, A_7, D_7 and EDA_7 using the two transliteration systems. Immediately obvious is that varying the corpora (x-axis) results in different values for word accuracy, whether by the *UWA* or *MWA* method. For example, if you chose to evaluate SYS-2 with the *UWA* metric on the D_7 corpus, you would obtain a result of 82%, but if you chose to evaluate it with the A_7 corpus you would receive a result of only 73%. This makes comparing systems that report results obtained on different corpora very difficult. Encouragingly, however, SYS-2 consistently outperforms the SYS-1 on all corpora for both metrics except *MWA* on $E7$. This implies that ranking system performance on the same corpus most likely yields a system ranking that is transferable to other corpora. To further investigate this, we randomly extracted 100 corpora of 500 word pairs from EDA_7 and ran the two systems on them and evaluated the results using both *MWA* and *UWA*. Both of the measures ranked the systems consistently using all these corpora (Figure 2).

As expected, the *UWA* metric is consistently higher than the *MWA* metric; it allows for the top transliteration to appear in any of the possible variants for that word in the corpus, unlike the *MWA* metric which insists upon a single target word. For example, for the E_7 corpus using the SYS-2 approach, *UWA* is 76.4% and *MWA* is 47.0%.

Each of the three sub-corpora can be further divided based on the seven individual transliterators, in different combinations. That is, construct a sub-corpus from T1's transliterations, T2's, and so on; then take all combinations of two transliterators, then three, and so on. In general we can construct ${}^7C_r$ such corpora from r transliterators in this fashion, all of which have 500 source words, but may have between one to seven different transliterations for each of those words.

Figure 3 shows the *MWA* for these sub-corpora. The x-axis shows the number of transliterators used to form the sub-corpora. For example, when $x = 3$, the performance figures plotted are achieved on corpora when taking all triples of the seven transliterator's transliterations.

From the boxplots it can be seen that performance varies considerably when the number of transliterators used to determine a majority vote is varied.

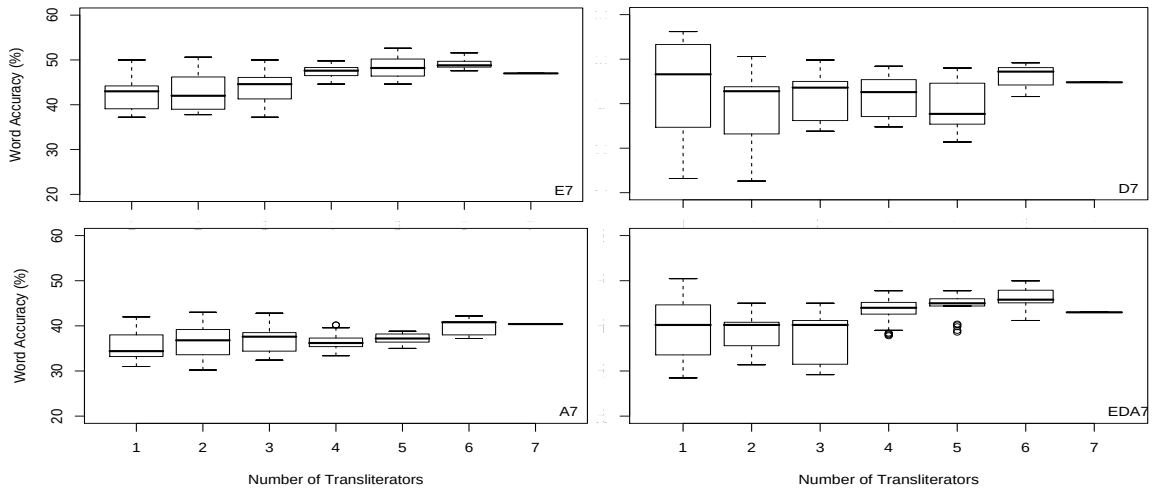

Figure 3: Performance on sub-corpora derived by combining the number of transliterators shown on the x-axis. Boxes show the 25th and 75th percentile of the *MWA* for all ${}^7C_x$ combinations of transliterators using SYS-2, with whiskers showing extreme values.

However, the changes do not follow a fixed trend across the languages. For E_7, the range of accuracies achieved is high when only two or three transliterators are involved, ranging from 37.0% to 50.6% in SYS-2 method and from 33.8% to 48.0% in SYS-1 (not shown) when only two transliterators' data are available. When more than three transliterators are used, the range of performance is noticeably smaller. Hence if at least four transliterators are used, then it is more likely that a system's *MWA* will be stable. This finding is supported by Papineni et al. (2002) who recommend that four people should be used for collecting judgments for machine translation experiments.

The corpora derived from A_7 show consistent median increases as the number of transliterators increases, but the median accuracy is lower than for other languages. The D_7 collection does not show any stable results until at least six transliterator's are used.

The results indicate that creating a collection used for the evaluation of transliteration systems, based on a "gold standard" created by only one human transliterator may lead to word accuracy results that could show a 10% absolute difference compared to results on a corpus derived using a different transliterator. This is evidenced by the leftmost box in each panel of the figure which has a wide range of results.

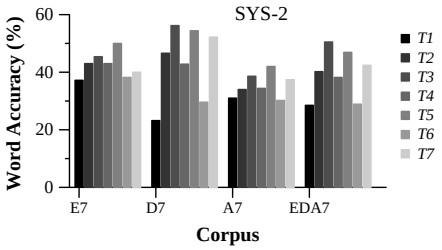

Figure 4: Word accuracy on the sub-corpora using only a single transliterator's transliterations.

Figure 4 shows this box in more detail for each collection, plotting the word accuracy for each user for all sub-corpora for SYS-2. The accuracy achieved varies significantly between transliterators; for example, for E_7 collections, word accuracy varies from 37.2% for T1 to 50.0% for T5. This variance is more obvious for the D_7 dataset where the difference ranges from 23.2% for $T1$ to 56.2% for $T3$. Origin language also has an effect: accuracy for the Arabic collection (A_7) is generally less than that of English (E_7). The Dutch collection (D_7), shows an unstable trend across transliterators. In other words, accuracy differs in a narrower range for Arabic and English, but in wider range for Dutch.

This is likely due to the fact that most transliterators found Dutch a difficult language to work with, as reported in Table 1.

3.1 Transliterator Consistency

To investigate the effect of invididual transliterator consistency on system accuracy, we consider the number of Persian characters used by each transliterator on each sub-corpus, and the average number of rules generated by SYS-2 on the ten training sets derived in the ten-fold cross validation process, which are shown in Table 2. For example, when transliterating words from E_7 into Persian, T3 only ever used 21 out of 32 characters available in the Persian alphabet; T7, on the other hand, used 24 different Persian characters. It is expected that an increase in number of characters or rules provides more "noise" for the automated system, hence may lead to lower accuracy. Superficially the opposite seems true for rules: the mean number of rules generated by SYS-2 is much higher for the EDA_7 corpus than for the A_7 corpus, and yet Figure 1 shows that word accuracy is higher on the EDA_7 corpus. A correlation test, however, reveals that there is no significant relationship between either the number of characters used, nor the number of rules generated, and the resulting word accuracy of SYS-2 (Spearman correlation, $p = 0.09$ (characters) and $p = 0.98$ (rules)).

A better indication of "noise" in the corpus may be given by the consistency with which a transliterator applies a certain rule. For example, a large number of rules generated from a particular transliterator's corpus may not be problematic if many of the rules get applied with a low probability. If, on the other hand, there were many rules with approximately equal probabilities, the system may have difficulty distinguishing when to apply some rules, and not others. One way to quantify this effect is to compute the *self entropy* of the rule distribution for each segment in the corpus for an individual. If p_{ij} is the probability of applying rule $1 \leq j \leq m$ when confronted with source segment i, then $H_i = -\sum_{j=1}^{m} p_{ij} \log_2 p_{ij}$ is the entropy of the probability distribution for that rule. H is maximized when the probabilities p_{ij} are all equal, and minimized when the probabilities are very skewed (Shannon, 1948). As an example, consider the rules: $t \rightarrow <$ت,0.5$>$, $t \rightarrow <$ط,0.3$>$ and $t \rightarrow <$د,0.2$>$; for which $H_t = 0.79$.

The expected entropy can be used to obtain a single entropy value over the whole corpus,

$$E = -\sum_{i=1}^{R} \frac{f_i}{S} H_i,$$

where H_i is the entropy of the rule probabilities for segment i, R is the total number of segments, f_i is the frequency with which segment i occurs at any position in all source words in the corpus, and S is the sum of all f_i.

The expected entropy for each transliterator is shown in Figure 5, separated by corpus. Comparison of this graph with Figure 4 shows that generally transliterators that have used rules inconsistently generate a corpus that leads to low accuracy for the systems. For example, T1 who has the lowest accuracy for all the collections in both methods, also has the highest expected entropy of rules for all the collections. For the E_7 collection, the maximum accuracy of 50.0%, belongs to $T5$ who has the minimum expected entropy. The same applies to the D_7 collection, where the maximum accuracy of 56.2% and the minimum expected entropy both belong to $T3$. These observations are confirmed by a statistically significant Spearman correlation between expected rule entropy and word accuracy ($r = -0.54, p = 0.003$). Therefore, the consistency with which transliterators employ their own internal rules in developing a corpus has a direct effect on system performance measures.

3.2 Inter-Transliterator Agreement and Perceived Difficulty

Here we present various agreement proportions (P_A from Section 2.2), which give a measure of consistency in the corpora across all users, as opposed to the entropy measure which gives a consistency measure for a single user. For E_7, P_A was 33.6%, for A_7 it was 33.3% and for D_7, agreement was 15.5%. In general, humans agree less than 33% of the time when transliterating English to Persian.

In addition, we examined agreement among transliterators based on their perception of the task difficulty shown in Table 1. For A_7, agreement among those who found the task *easy* was higher (22.3%) than those who found it in *medium* level

	E_7		D_7		A_7		EDA_7	
	Char	Rules	Char	Rules	Char	Rules	Char	Rules
T1	23	523	23	623	28	330	31	1075
T2	22	487	25	550	29	304	32	956
T3	21	466	20	500	28	280	31	870
T4	23	497	22	524	28	307	30	956
T5	21	492	22	508	28	296	29	896
T6	24	493	21	563	25	313	29	968
T7	24	495	21	529	28	299	30	952
Mean	23	493	22	542	28	304	30	953

Table 2: Number of characters used and rules generated using SYS-2, per transliterator.

(18.8%). P_A is 12.0% for those who found the D_7 collection *hard* to transliterate; while the six transliterators who found the E_7 collection difficulty *medium* had $P_A = 30.2\%$. Hence, the harder participants rated the transliteration task, the lower the agreement scores tend to be for the derived corpus.

Finally, in Table 3 we show word accuracy results for the two systems on corpora derived from transliterators grouped by perceived level of difficulty on A_7. It is readily apparent that SYS-2 outperforms SYS-1 on the corpus comprised of human transliterations from people who saw the task as easy with both word accuracy metrics; the relative improvement of over 50% is statistically significant (paired t-test on ten-fold cross validation runs). However, on the corpus composed of transliterations that were perceived as more difficult, "Medium", the advantage of SYS-2 is significantly eroded, but is still statistically significant for *UWA*. Here again, using only one transliteration, *MWA*, did not distinguish the performance of each system.

4 Discussion

We have evaluated two English to Persian transliteration systems on a variety of controlled corpora using evaluation metrics that appear in previous transliteration studies. Varying the evaluation corpus in a controlled fashion has revealed several interesting facts.

We report that human agreement on the English to Persian transliteration task is about 33%. The effect that this level of disagreement on the evaluation of systems has, can be seen in Figure 4, where word accuracy is computed on corpora derived from single transliterators. Accuracy can vary by up to 30% in absolute terms depending on the transliterator chosen. To our knowledge, this is the first paper

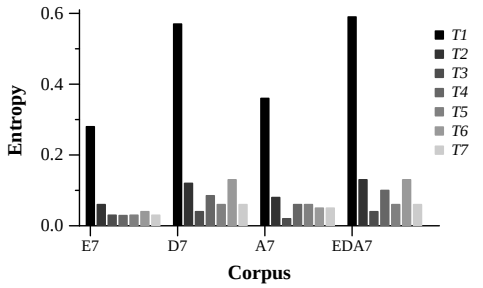

Figure 5: Entropy of the generated segments based on the collections created by different transliterators.

to report human agreement, and examine its effects on transliteration accuracy.

In order to alleviate some of these effects on the stability of word accuracy measures across corpora, we recommend that at least four transliterators are used to construct a corpus. Figure 3 shows that constructing a corpus with four or more transliterators, the range of possible word accuracies achieved is less than that of using fewer transliterators.

Some past studies do not use more than a single target word for every source word in the corpus (Bilac and Tanaka, 2005; Oh and Choi, 2006). Our results indicate that it is unlikely that these results would translate onto a corpus other than the one used in these studies, except in rare cases where human transliterators are in 100% agreement for a given language pair.

Given the nature of the English language, an English corpus can contain English words from a variety of different origins. In this study we have used English words from an Arabic and Dutch origin to show that word accuracy of the systems can vary by up to 25% (in absolute terms) depending on the origin of English words in the corpus, as demonstrated in Figure 1.

In addition to computing agreement, we also in-

	Perception	SYS-1	SYS-2	Relative Improvement (%)	
UWA	Easy	33.4	55.4	54.4	($p < 0.001$)
	Medium	44.6	48.4	8.52	($p < 0.001$)
MWA	Easy	23.2	36.2	56.0	($p < 0.001$)
	Medium	30.6	37.4	22.2	($p = 0.038$)

Table 3: System performance when A_7 is split into sub-corpora based on transliterators perception of the task (Easy or Medium).

vestigated the transliterator's perception of difficulty of the transliteration task with the ensuing word accuracy of the systems. Interestingly, when using corpora built from transliterators that perceive the task to be easy, there is a large difference in the word accuracy between the two systems, but on corpora built from transliterators who perceive the task to be more difficult, the gap between the systems narrows. Hence, a corpus applied for evaluation of transliteration should either be made carefully with transliterators with a variety of backgrounds, or should be large enough and be gathered from various sources so as to simulate different expectations of its expected non-homogeneous users.

The self entropy of rule probability distributions derived by the automated transliteration system can be used to measure the consistency with which individual transliterators apply their own rules in constructing a corpus. It was demonstrated that when systems are evaluated on corpora built by transliterators who are less consistent in their application of transliteration rules, word accuracy is reduced.

Given the large variations in system accuracy that are demonstrated by the varying corpora used in this study, we recommend that extreme care be taken when constructing corpora for evaluating transliteration systems. Studies should also give details of their corpora that would allow any of the effects observed in this paper to be taken into account.

Abstract

We propose a novel algorithm for English to Persian transliteration. Previous methods proposed for this language pair apply a word alignment tool for training. By contrast, we introduce an alignment algorithm particularly designed for transliteration. Our new model improves the English to Persian transliteration accuracy by 14% over an n-gram baseline. We also propose a novel back-transliteration method for this language pair, a previously unstudied problem. Experimental results demonstrate that our algorithm leads to an absolute improvement of 25% over standard transliteration approaches.

1 Introduction

Translation of a text from a source language to a target language requires dealing with technical terms and proper names. These occur in almost any text, but rarely appear in bilingual dictionaries. The solution is the transliteration of such *out-of-dictionary* terms: a word from the source language is transformed to a word in the target language, preserving its pronunciation. Recovering the original word from the transliterated target is called back-transliteration. Automatic transliteration is important for many different applications, including machine translation, cross-lingual information retrieval and cross-lingual question answering.

Transliteration methods can be categorized into grapheme-based (AbdulJaleel and Larkey, 2003; Li et al., 2004), phoneme-based (Knight and Graehl, 1998; Jung et al., 2000), and combined (Bilac and Tanaka, 2005) approaches. Grapheme-based methods perform a direct orthographical mapping between source and target words, while phoneme-based approaches use an intermediate phonetic representation. Both grapheme- or phoneme-based methods usually begin by breaking the source word into segments, and then use a source segment to target segment mapping to generate the target word. The rules of this mapping are obtained by aligning already available transliterated word pairs (training data); alternatively, such rules can be handcrafted. From this perspective, past work is roughly divided into those methods which apply a word alignment tool such as GIZA++ (Och and Ney, 2003), and approaches that combine the alignment step into their main transliteration process.

Transliteration is language dependent, and methods that are effective for one language pair may not work as well for another. In this paper, we investigate the English-Persian transliteration problem. Persian (Farsi) is an Indo-European language, written in Arabic script from right to left, but with an extended alphabet and different pronunciation from Arabic. Our previous approach to English-Persian transliteration introduced the grapheme-based *collapsed-vowel* method, employing GIZA++ for source to target alignment (Karimi et al., 2006). We propose a new transliteration approach that extends the *collapsed-vowel* method. To meet Persian language transliteration requirements, we also propose a novel alignment algorithm in our training stage, which makes use of statistical information of

the corpus, transliteration specifications, and simple language properties. This approach handles possible consequences of elision (omission of sounds to make the word easier to read) and epenthesis (adding extra sounds to a word to make it fluent) in written target words that happen due to the change of language. Our method shows an absolute accuracy improvement of 14.2% over an n-gram baseline.

In addition, we investigate the problem of back-transliteration from Persian to English. To our knowledge, this is the first report of such a study. There are two challenges in Persian to English transliteration that makes it particularly difficult. First, written Persian omits short vowels, while only long vowels appear in texts. Second, monophthongization (changing diphthongs to monophthongs) is popular among Persian speakers when adapting foreign words into their language. To take these into account, we propose a novel method to form transformation rules by changing the normal segmentation algorithm. We find that this method significantly improves the Persian to English transliteration effectiveness, demonstrating an absolute performance gain of 25.1% over standard transliteration approaches.

2 Background

In general, transliteration consists of a training stage (running on a bilingual training corpus), and a generation – also called testing – stage.

The training step of a transliteration develops transformation rules mapping characters in the source to characters in the target language using knowledge of corresponding characters in transliterated pairs provided by an alignment. For example, for the source-target word pair (pat,پات), an alignment may map "p" to "پ" and "a" to "ا", and the training stage may develop the rule $pa \rightarrow$ا, with "ا" as the transliteration of "a" in the context of "pa". The generation stage applies these rules on a segmented source word, transforming it to a word in the target language.

Previous work on transliteration either employs a word alignment tool (usually GIZA++), or develops specific alignment strategies. Transliteration methods that use GIZA++ as their word pair aligner (AbdulJaleel and Larkey, 2003; Virga and Khudanpur, 2003; Karimi et al., 2006) have based their work on the assumption that the provided alignments are reliable. Gao et al. (2004) argue that precise alignment can improve transliteration effectiveness, experimenting on English-Chinese data and comparing IBM models (Brown et al., 1993) with phoneme-based alignments using direct probabilities.

Other transliteration systems focus on alignment for transliteration, for example the joint source-channel model suggested by Li et al. (2004). Their method outperforms the noisy channel model in direct orthographical mapping for English-Chinese transliteration. Li et al. also find that grapheme-based methods that use the joint source-channel model are more effective than phoneme-based methods due to removing the intermediate phonetic transformation step. Alignment has also been investigated for transliteration by adopting Covington's algorithm on cognate identification (Covington, 1996); this is a character alignment algorithm based on matching or skipping of characters, with a manually assigned cost of association. Covington considers consonant to consonant and vowel to vowel correspondence more valid than consonant to vowel. Kang and Choi (2000) revise this method for transliteration where a skip is defined as inserting a null in the target string when two characters do not match based on their phonetic similarities or their consonant and vowel nature. Oh and Choi (2002) revise this method by introducing *binding*, in which many to many correspondences are allowed. However, all of these approaches rely on the manually assigned penalties that need to be defined for each possible matching.

In addition, some recent studies investigate discriminative transliteration methods (Klementiev and Roth, 2006; Zelenko and Aone, 2006) in which each segment of the source can be aligned to each segment of the target, where some restrictive conditions based on the distance of the segments and phonetic similarities are applied.

3 The Proposed Alignment Approach

We propose an alignment method based on segment occurrence frequencies, thereby avoiding predefined matching patterns and penalty assignments. We also apply the observed tendency of aligning consonants

to consonants, and vowels to vowels, as a substitute for phonetic similarities. Many to many, one to many, one to null and many to one alignments can be generated.

3.1 Formulation

Our alignment approach consists of two steps: the first is based on the consonant and vowel nature of the word's letters, while the second uses a frequency-based sequential search.

Definition 1 *A bilingual corpus $\mathcal{B}$ is the set $\{(S,T)\}$, where $S = s_1..s_\ell$, $T = t_1..t_m$, s_i is a letter in the source language alphabet, and t_j is a letter in the target language alphabet.*

Definition 2 *Given some word, w, the consonant-vowel sequence $p = (C|V)^+$ for w is obtained by replacing each consonant with C and each vowel with V.*

Definition 3 *Given some consonant-vowel sequence, p, a reduced consonant-vowel sequence q replaces all runs of C's with $\mathcal{C}$, and all runs of V's with $\mathcal{V}$; hence $q = q'|q''$, $q' = \mathcal{V}(\mathcal{CV})^*(\mathcal{C}|\epsilon)$ and $q'' = \mathcal{C}(\mathcal{VC})^*(\mathcal{V}|\epsilon)$.*

For each natural language word, we can determine the *consonant-vowel* sequence (p) from which the *reduced consonant-vowel* sequence (q) can be derived, giving a common notation between two different languages, no matter which script either of them use. To simplify, semi-vowels and approximants (sounds intermediate between consonants and vowels, such as "w" and "y" in English) are treated according to their target language counterparts.

In general, for all the word pairs (S,T) in a corpus $\mathcal{B}$, an alignment can be achieved using the function

$$f : \mathcal{B} \rightarrow \mathcal{A}; (S,T) \mapsto (\hat{S}, \hat{T}, r).$$

The function f maps the word pair $(S,T) \in \mathcal{B}$ to the triple $(\hat{S}, \hat{T}, r) \in \mathcal{A}$ where $\hat{S}$ and $\hat{T}$ are substrings of S and T respectively. The frequency of this correspondence is denoted by r. $\mathcal{A}$ represents a set of substring alignments, and we use a per word alignment notation of a_{e2p} when aligning English to Persian and a_{p2e} for Persian to English.

3.2 Algorithm Details

Our algorithm consists of two steps.

Step 1 **(Consonant-Vowel based)**

For any word pair $(S,T) \in \mathcal{B}$, the corresponding *reduced consonant-vowel* sequences, q_S and q_T, are generated. If the sequences match, then the aligned consonant clusters and vowel sequences are added to the alignment set $\mathcal{A}$. If q_S does not match with q_T, the word pair remains unaligned in *Step 1*.

The assumption in this step is that transliteration of each vowel sequence of the source is a vowel sequence in the target language, and similarly for consonants. However, consonants do not always map to consonants, or vowels to vowels (for example, the English letter "s" may be written as "اس" in Persian which consists of one vowel and one consonant). Alternatively, they might be omitted altogether, which can be specified as the null string, ε. We therefore require a second step.

Step 2 **(Frequency based)**

For most natural languages, the maximum length of corresponding phonemes of each grapheme is a digraph (two letters) or at most a trigraph. Hence, alignment can be defined as a search problem that seeks for units with a maximum length of two or three in both strings that need to be aligned. In our approach, we search based on statistical occurrence data available from *Step 1*.

In *Step 2*, only those words that remain unaligned at the end of *Step 1* need to be considered. For each pair of words (S,T), matching proceeds from left to right, examining one of the three possible options of transliteration: single letter to single letter, digraph to single letter and single letter to digraph. Trigraphs are unnecessary in alignment as they can be effectively captured during transliteration generation, as we explain below.

We define four different valid alignments for the source ($S = s_1 s_2 \ldots s_i \ldots s_l$) and target ($T = t_1 t_2 \ldots t_j \ldots t_m$) strings: (s_i, t_j, r), $(s_i s_{i+1}, t_j, r)$, $(s_i, t_j t_{j+1}, r)$ and (s_i, ε, r). These four options are considered as the only possible valid alignments, and the most frequently occurring alignment (highest r) is chosen. These frequencies are dynamically updated after successfully aligning a pair. For exceptional situations, where there is no character in the target string to match with the source character s_i, it is aligned with the empty string.

It is possible that none of the four valid alignment

options have occurred previously (that is, $r = 0$ for each). This situation can arise in two ways: first, such a tuple may simply not have occurred in the training data; and, second, the previous alignment in the current string pair may have been incorrect. To account for this second possibility, a partial backtracking is considered. Most misalignments are derived from the simultaneous comparison of alignment possibilities, giving the highest priority to the most frequent. For example if S=bbc, T=بس and $\mathcal{A} = \{$(b,ب,100),(bb,ب,40),(c,س,60)$\}$, starting from the initial position s_1 and t_1, the first alignment choice is (b,ب,101). However immediately after, we face the problem of aligning the second "b". There are two solutions: inserting ε and adding the triple (b,ε,1), or backtracking the previous alignment and substituting that with the less frequent but possible alignment of (bb,ب,41). The second solution is a better choice as it adds less ambiguous alignments containing ε. At the end, the alignment set is updated as $\mathcal{A} = \{$(b,ب,100),(bb,ب,41),(c,س,61)$\}$.

In case of equal frequencies, we check possible subsequent alignments to decide on which alignment should be chosen. For example, if (b,ب,100) and (bb,ب,100) both exist as possible options, we consider if choosing the former leads to a subsequent ε insertion. If so, we opt for the latter.

At the end of a string, if just one character in the target string remains unaligned while the last alignment is a ε insertion, that final alignment will be substituted for ε. This usually happens when the alignment of final characters is not yet registered in the alignment set, mainly because Persian speakers tend to transliterate the final vowels to consonants to preserve their existence in the word. For example, in the word "Jose" the final "e" might be transliterated to "ه" which is a consonant ("h") and therefore is not captured in *Step 1*.

Backparsing

The process of aligning words explained above can handle words with already known components in the alignment set $\mathcal{A}$ (the frequency of occurrence is greater than zero). However, when this is not the case, the system may repeatedly insert ε while part or all of the target characters are left intact (unsuccessful alignment). In such cases, processing the source and target backwards helps to find the problematic substrings: *backparsing*.

The poorly aligned substrings of the source and target are taken as new pairs of strings, which are then reintroduced into the system as new entries. Note that they themselves are not subject to backparsing. Most strings of repeating nulls can be broken up this way, and in the worst case will remain as one tuple in the alignment set.

To clarify, consider the example given in Figure 1. For the word pair (patricia,ایشیرتپ), where an association between "c" and "ش" is not yet registered. Forward parsing, as shown in the figure, does not resolve all target characters; after the incorrect alignment of "c" with "ε", subsequent characters are also aligned with null, and the substring "ایش" remains intact. Backward parsing, shown in the next line of the figure, is also not successful. It is able to correctly align the last two characters of the string, before generating repeated null alignments. Therefore, the central region — substrings of the source and target which remained unaligned plus one extra aligned segment to the left and right — is entered as a new pair to the system (ici,یشی), as shown in the line labelled *Input 2* in the figure. This new input meets *Step 1* requirements, and is aligned successfully. The resulting tuples are then merged with the alignment set $\mathcal{A}$.

An advantage of our backparsing strategy is that it takes care of casual transliterations happening due to elision and epenthesis (adding or removing extra sounds). It is not only in translation that people may add extra words to make fluent target text; for transliteration also, it is possible that spurious characters are introduced for fluency. However, this often follows patterns, such as adding vowels to the target form. These irregularities are consistently covered in the backparsing strategy, where they remain connected to their previous character.

4 Transliteration Method

Transliteration algorithms use aligned data (the output from the alignment process, a_{e2p} or a_{p2e} alignment tuples) for training to derive transformation rules. These rules are then used to generate a target word T given a new input source word S.

Initial alignment set:	
$\mathcal{A}$ = {(p,پ,42),(a,ا,320),(a,ε,99),(a,ا‌ی,10),(a,ی,35),(r,ر,200),(i,ی,60),(i,ε,5),(c,س,80),(c,چ,25),(t,ت,51)}	
Input:	(patricia,پ‌ت‌ر‌ی‌ش‌ا) $q_S = \mathcal{CVCVCVC}$ $q_T = \mathcal{CVCVC}$
Step 1:	$q_S \neq q_T$
Forward alignment:	(p,پ,43), (a,ε,100), (t,ت,52), (r,ر,201), (i,ی,61), (c,ε,1), (i,ε,6), (a,ε,100)
Backward alignment:	(a,ا,321), (i,ی,61), (c,ε,1), (i,ε,6), (r,ε,1), (t,ε,1), (a,ε,100), (p,ε,1)
Input 2:	(ici,ی‌ش‌ی) $q_S = \mathcal{VCV}$ $q_T = \mathcal{VCV}$
Step 1:	(i,ی,61),(c,ش,1), (i,ی,61)
Final Alignment:	a_{e2p} = ((p,پ),(a,ε),(t,ت),((r,ر),(i,ی),(c,ش),(i,ی),(a,ا))
Updated alignment set:	
$\mathcal{A}$ = {(p,پ,43),(a,ا,321),(a,ε,100),(a,ا‌ی,10),(a,ی,35),(r,ر,201),(i,ی,62),(i,ε,5),(c,س,80),(c,چ,25),(c,ش,1),(t,ت,52)}	

Figure 1: A backparsing example. Note middle tuples in forward and backward parsings are not merged in $\mathcal{A}$ till the alignment is successfully completed.

Method	Intermediate Sequence	Segment(Pattern)	Backoff
Bigram	N/A	#s, sh, he, el, ll, le, ey	s,h,e,l,e,y
CV-MODEL1	$CCVCCV$	sh(CC), hel(CVC), ll(CC), lley($\mathcal{CV}$)	s(C), h(C), e($\mathcal{V}$), l(C), e($\mathcal{V}$), y($\mathcal{V}$)
CV-MODEL2	$CCVCCV$	sh(CC), e(CVC), ll(CC), ey($\overline{\mathcal{CV}}$)	As Above.
CV-MODEL3	$\mathcal{CVCV}$	#sh($\mathcal{C}$), e($\mathcal{CVC}$), ll($\mathcal{C}$), ey($\overline{\mathcal{CV}}$)	sh($\mathcal{C}$), s($\mathcal{C}$), h($\mathcal{C}$), e($\mathcal{V}$), l($\mathcal{C}$), e($\mathcal{V}$), y($\mathcal{V}$)

Figure 2: An example of transliteration for the word pair (shelley,ش‌ل‌ی). Underlined characters are actually transliterated for each segment.

4.1 Baseline

Most transliteration methods reported in the literature — either grapheme- or phoneme-based — use n-grams (AbdulJaleel and Larkey, 2003; Jung et al., 2000). The n-gram-based methods differ mainly in the way that words are segmented, both for training and transliteration generation. A simple n-gram based method works only on single characters (unigram) and transformation rules are defined as $s_i \rightarrow t_j$, while an advanced method may take the surrounding context into account (Jung et al., 2000). We found that using one past symbol (bigram model) works better than other n-gram based methods for English to Persian transliteration (Karimi et al., 2006).

Our collapsed-vowel methods consider language knowledge to improve the string segmentation of n-gram techniques (Karimi et al., 2006). The process begins by generating the *consonant-vowel* sequence (Definition 2) of a source word. For example, the word "shelley" is represented by the sequence $p = CCVCCVV$. Then, following the collapsed vowel concept (Definition 3), this sequence becomes "$CCVCCV$". These approaches, which we refer to as CV-MODEL1 and CV-MODEL2 respectively, partition these sequences using basic patterns (C and $\mathcal{V}$) and main patterns (CC, CVC, $\mathcal{V}C$ and $C\mathcal{V}$). In the training phase, transliteration rules are formed according to the boundaries of the defined patterns and their aligned counterparts (based on a_{e2p} or a_{p2e}) in the target language word T. Similar segmentation is applied during the transliteration generation stage.

4.2 The Proposed Transliteration Approach

The restriction on the context length of consonants imposed by CV-MODEL1 and CV-MODEL2 makes the transliteration of consecutive consonants mapping to a particular character in the target language difficult. For example, "ght" in English maps to only one character in Persian: "ت". Dealing with languages which have different alphabets, and for which the number of characters in their alphabets also differs (such as 26 and 32 for English and Persian), increases the possibility of facing these cases, especially when moving from the language with smaller alphabet size to the one with a larger size. To more effectively address this, we propose a *collapsed consonant and vowel* method (CV-MODEL3) which uses the full reduced sequence (Definition 3), rather than simply reduced vowel sequences. Although recognition of consonant segments is based on the vowel positions, consonants are considered as independent blocks in each string. Conversely, vowels are transliterated in the context of surrounding

consonants, as demonstrated in the example below.

A special symbol is used to indicate the start and/or end of each word if the beginning and end of the word is a consonant respectively. Therefore, for the words starting or ending with consonants, the symbol "#" is added, which is treated as a consonant and therefore grouped in the consonant segment. An example of applying this technique is shown in Figure 2 for the string "shelley". In this example, "sh" and "ll" are treated as two consonant segments, where the transliteration of individual characters inside a segment is dependent on the other members but not the surrounding segments. However, this is not the case for vowel sequences which incorporate a level of knowledge about any segment neighbours. Therefore, for the example "shelley", the first segment is "sh" which belongs to $\mathcal{C}$ pattern. During transliteration, if "#sh" does not appear in any existing rules, a backoff splits the segment to smaller segments: "#" and "sh", or "s"and "h". The second segment contains the vowel "e". Since this vowel is surrounded by consonants, the segment pattern is $\mathcal{CVC}$. In this case, backoff only applies for vowels as consonants are supposed to be part of their own independent segments. That is, if search in the rules of pattern $\mathcal{CVC}$ was unsuccessful, it looks for "e" in $\mathcal{V}$ pattern. Similarly, segmentation for this word continues with "ll" in $\mathcal{C}$ pattern and "ey" in $\mathcal{CV}$ pattern ("y" is an *approximant*, and therefore considered as a vowel when transliterating English to Persian).

4.3 Rules for Back-Transliteration

Written Persian ignores short vowels, and only long vowels appear in text. This causes most English vowels to disappear when transliterating from English to Persian; hence, these vowels must be restored during back-transliteration.

When the initial transliteration happens from English to Persian, the transliterator (whether human or machine) uses the rules of transliterating from English as the source language. Therefore, transliterating back to the original language should consider the original process, to avoid losing essential information. In terms of segmentation in *collapsed-vowel* models, different patterns define segment boundaries in which vowels are necessary clues. Although we do not have most of these vowels in the transliteration generation phase, it is possible to benefit from their existence in the training phase. For example, using CV-MODEL3, the pair (مرکل,merkel) with q_S=$\mathcal{C}$ and a_{p2e}=((م,me),(ر,r),(ک,ke),(ل,l)), produces just one transformation rule "مرکل → merkel" based on a $\mathcal{C}$ pattern. That is, the Persian string contains no vowel characters. If, during the transliteration generation phase, a source word "ممرکل" (S=مرکل) is entered, there would be one and only one output of "merkel", while an alternative such as "mercle" might be required instead. To avoid overfitting the system by long consonant clusters, we perform segmentation based on the English q sequence, but categorise the rules based on their Persian segment counterparts. That is, for the pair (مرکل,merkel) with a_{e2p}=((m,م),(e,ε),(r,ر),(k,ک),(e,ε),(l,ل)), these rules are generated (with category patterns given in parenthesis): م → m ($\mathcal{C}$), کر → rk ($\mathcal{C}$), ل → l ($\mathcal{C}$), کرم → merk ($\mathcal{C}$), لکر → rkel ($\mathcal{C}$). We call the suggested training approach *reverse segmentation*.

Reverse segmentation avoids clustering all the consonants in one rule, since many English words might be transliterated to all-consonant Persian words.

4.4 Transliteration Generation and Ranking

In the transliteration generation stage, the source word is segmented following the same process of segmenting words in training stage, and a probability is computed for each generated target word:

$$P(T|S) = \prod_{k=1}^{|K|} P(\hat{T}_k|\hat{S}_k),$$

where $|K|$ is the number of distinct source segments. $P(\hat{T}_k|\hat{S}_k)$ is the probability of the $\hat{S}_k \rightarrow \hat{T}_k$ transformation rule, as obtained from the training stage:

$$P(\hat{T}_k|\hat{S}_k) = \frac{\text{frequency of } \hat{S}_k \rightarrow \hat{T}_k}{\text{frequency of } \hat{S}_k},$$

where frequency of $\hat{S}_k$ is the number of its occurrence in the transformation rules. We apply a tree structure, following Dijkstra's α-shortest path, to generate the α highest scoring (most probable) transliterations, ranked based on their probabilities.

Corpus		Baseline			CV-MODEL3	
		Bigram	CV-MODEL1	CV-MODEL2	GIZA++	New Alignment
Small Corpus

5 Experiments

To investigate the effectiveness of CV-MODEL3 and the new alignment approach on transliteration, we first compare CV-MODEL3 with baseline systems, employing GIZA++ for alignment generation during system training. We then evaluate the same systems, using our new alignment approach. Back-transliteration is also investigated, applying both alignment systems and *reverse segmentation*. In all our experiments, we used ten-fold cross-validation. The statistical significance of different performance levels are evaluated using a paired t-test. The notation TOP-X indicates the first X transliterations prodcued by the automatic methods.

We used two corpora of word pairs in English and Persian: the first, called *Large*, contains 16,670 word pairs; the second, *Small*, contains 1,857 word pairs, and are described fully in our previous paper (Karimi et al., 2006).

The results of transliteration experiments are evaluated using word accuracy (Kang and Choi, 2000) which measures the proportion of transliterations that are correct out of the test corpus.

5.1 Accuracy of Transliteration Approaches

The results of our experiments for transliterating English to Persian, using GIZA++ for alignment generation, are shown in Table 1. CV-MODEL3 outperforms all three baseline systems significantly in TOP-1 and TOP-5 results, for both Persian corpora. TOP-1 results were improved by 9.2% to 16.2% ($p<0.0001$, paired t-test) relative to the baseline systems for the *Small* corpus. For the *Large* corpus, CV-MODEL3 was 9.3% to 17.2% ($p<0.0001$) more accurate relative to the baseline systems.

The results of applying our new alignment algorithm are presented in the last column of Table 1, comparing word accuracy of CV-MODEL3 using GIZA++ and the new alignment for English to Persian transliteration. Transliteration accuracy increases in TOP-1 for both corpora (a relative increase of 7.1% ($p=0.002$) for the *Small* corpus and 8.1% ($p<0.0001$) for the *Large* corpus). The TOP-10 results of the Large corpus again show a relative increase of 3.5% ($p=0.004$). Although the new alignment also increases the performance for TOP-5 and TOP-10 of the *Small* corpus, these increases are not statistically significant.

5.2 Accuracy of Back-Transliteration

The results of back-transliteration are shown in Table 2. We first consider performance improvements gained from using CV-MODEL3: CV-MODEL3 using GIZA++ outperforms Bigram, CV-MODEL1 and CV-MODEL2 by 12.8% to 40.7% ($p<0.0001$) in TOP-1 for the *Small* corpus. The corresponding improvement for the *Large* corpus is 12.8% to 74.2% ($p<0.0001$).

The fifth column of the table shows the performance increase when using CV-MODEL3 with the new alignment algorithm: for the *Large* corpus, the new alignment approach gives a relative increase in accuracy of 15.5% for TOP-5 ($p<0.0001$) and 10% for TOP-10 ($p=0.005$). The new alignment method does not show a significant difference using CV-MODEL3 for the *Small* corpus.

The final column of Table 2 shows the performance of the CV-MODEL3 with the new reverse segmentation approach. Reverse segmentation leads to a significant improvement over the new alignment approach in TOP-1 results for the *Small* corpus by 40.1% ($p<0.0001$), and 49.4% ($p<0.0001$) for the *Large* corpus.

Corpus		Bigram	CV-MODEL1	CV-MODEL2	CV-MODEL3		
					GIZA++	New Alignment	Reverse
Small Corpus

6 Conclusions

We have presented a new algorithm for English to Persian transliteration, and a novel alignment algorithm applicable for transliteration. Our new transliteration method (CV-MODEL3) outperforms the previous approaches for English to Persian, increasing word accuracy by a relative 9.2% to 17.2% (TOP-1), when using GIZA++ for alignment in training. This method shows further 7.1% to 8.1% increase in word accuracy (TOP-1) with our new alignment algorithm.

Persian to English back-transliteration is also investigated, with CV-MODEL3 significantly outperforming other methods. Enriching this model with a new reverse segmentation algorithm gives rise to further accuracy gains in comparison to directly applying English to Persian methods.

In future work we will investigate whether phonetic information can help refine our CV-MODEL3, and experiment with manually constructed rules as a baseline system.

Alignment-Based Discriminative String Similarity

Shane Bergsma and Grzegorz Kondrak

{bergsma,kondrak}@cs.ualberta.ca

Abstract

A character-based measure of similarity is an important component of many natural language processing systems, including approaches to transliteration, coreference, word alignment, spelling correction, and the identification of cognates in related vocabularies. We propose an alignment-based *discriminative* framework for string similarity. We gather features from substring pairs consistent with a character-based alignment of the two strings. This approach achieves exceptional performance; on nine separate cognate identification experiments using six language pairs, we more than double the precision of traditional orthographic measures like Longest Common Subsequence Ratio and Dice's Coefficient. We also show strong improvements over other recent discriminative and heuristic similarity functions.

1 Introduction

String similarity is often used as a means of quantifying the likelihood that two pairs of strings have the same underlying meaning, based purely on the character composition of the two words. Strube et al. (2002) use Edit Distance as a feature for determining if two words are coreferent. Taskar et al. (2005) use French-English common letter sequences as a feature for discriminative word alignment in bilingual texts. Brill and Moore (2000) learn misspelled-word to correctly-spelled-word similarities for spelling correction. In each of these examples, a similarity measure can make use of the recurrent substring pairings that reliably occur between words having the same meaning.

Across natural languages, these recurrent substring correspondences are found in word pairs known as cognates: words with a common form and meaning across languages. Cognates arise either from words in a common ancestor language (e.g. *light/Licht, night/Nacht* in English/German) or from foreign word borrowings (e.g. *trampoline/toranporin* in English/Japanese). Knowledge of cognates is useful for a number of applications, including sentence alignment (Melamed, 1999) and learning translation lexicons (Mann and Yarowsky, 2001; Koehn and Knight, 2002).

We propose an alignment-based, discriminative approach to string similarity and evaluate this approach on cognate identification. Section 2 describes previous approaches and their limitations. In Section 3, we explain our technique for automatically creating a cognate-identification training set. A novel aspect of this set is the inclusion of *competitive counter-examples* for learning. Section 4 shows how discriminative features are created from a character-based, minimum-edit-distance alignment of a pair of strings. In Section 5, we describe our bitext and dictionary-based experiments on six language pairs, including three based on non-Roman alphabets. In Section 6, we show significant improvements over traditional approaches, as well as significant gains over more recent techniques by Ristad and Yianilos (1998), Tiedemann (1999), Kondrak (2005), and Klementiev and Roth (2006).

2 Related Work

String similarity is a fundamental concept in a variety of fields and hence a range of techniques

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 656–663,
Prague, Czech Republic, June 2007.

have been developed. We focus on approaches that have been applied to words, i.e., uninterrupted sequences of characters found in natural language text. The most well-known measure of the similarity of two strings is the Edit Distance or Levenshtein Distance (Levenshtein, 1966): the number of insertions, deletions and substitutions required to transform one string into another. In our experiments, we use Normalized Edit Distance (NED): Edit Distance divided by the length of the longer word. Other popular measures include Dice's Coefficient (DICE) (Adamson and Boreham, 1974), and the length-normalized measures Longest Common Subsequence Ratio (LCSR) (Melamed, 1999), and Longest Common Prefix Ratio (PREFIX) (Kondrak, 2005). These baseline approaches have the important advantage of not requiring training data. We can also include in the non-learning category Kondrak (2005)'s Longest Common Subsequence Formula (LCSF), a probabilistic measure designed to mitigate LCSR's preference for shorter words.

Although simple to use, the untrained measures cannot adapt to the specific spelling differences between a pair of languages. Researchers have therefore investigated adaptive measures that are learned from a set of known cognate pairs. Ristad and Yianilos (1998) developed a stochastic transducer version of Edit Distance learned from unaligned string pairs. Mann and Yarowsky (2001) saw little improvement over Edit Distance when applying this transducer to cognates, even when filtering the transducer's probabilities into different weight classes to better approximate Edit Distance. Tiedemann (1999) used various measures to learn the recurrent spelling changes between English and Swedish, and used these changes to re-weight LCSR to identify more cognates, with modest performance improvements. Mulloni and Pekar (2006) developed a similar technique to improve NED for English/German.

Essentially, all these techniques improve on the baseline approaches by using a set of positive (true) cognate pairs to re-weight the costs of edit operations or the score of sequence matches. Ideally, we would prefer a more flexible approach that can learn positive *or* negative weights on *substring* pairings in order to better identify related strings. One system that can potentially provide this flexibility is a discriminative string-similarity approach to named-entity transliteration by Klementiev and Roth (2006). Although not compared to other similarity measures in the original paper, we show that this discriminative technique can strongly outperform traditional methods on cognate identification.

Unlike many recent generative systems, the Klementiev and Roth approach does not exploit the known positions in the strings where the characters match. For example, Brill and Moore (2000) combine a character-based alignment with the Expectation Maximization (EM) algorithm to develop an improved probabilistic error model for spelling correction. Rappoport and Levent-Levi (2006) apply this approach to learn substring correspondences for cognates. Zelenko and Aone (2006) recently showed a Klementiev and Roth (2006)-style discriminative approach to be superior to alignment-based generative techniques for name transliteration. Our work successfully uses the alignment-based methodology of the generative approaches to enhance the feature set for discriminative string similarity.

3 The Cognate Identification Task

Given two string lists, E and F, the task of cognate identification is to find all pairs of strings (e, f) that are cognate. In other similarity-driven applications, E and F could be misspelled and correctly spelled words, or the orthographic and the phonetic representation of words, etc. The task remains to link strings with common meaning in E and F using only the string similarity measure.

We can facilitate the application of string similarity to cognates by using a definition of cognation not dependent on etymological analysis. For example, Mann and Yarowsky (2001) define a word pair (e, f) to be cognate if they are a translation pair (same meaning) and their Edit Distance is less than three (same form). We adopt an improved definition (suggested by Melamed (1999) for the French-English Canadian Hansards) that does not over-propose shorter word pairs: (e, f) are cognate if they are translations and their LCSR $\geq$ 0.58. Note that this cutoff is somewhat conservative: the English/German cognates *light/Licht* (LCSR=0.8) are included, but not the cognates *eight/acht* (LCSR=0.4).

If two words must have LCSR $\geq$ 0.58 to be cog-

Foreign Language F	Words $f \in F$	Cognates E_{f+}	False Friends E_{f-}
Japanese (Rômaji)	napukin	napkin	nanking, pumpkin, snacking, sneaking
French	abondamment	abundantly	abandonment, abatement, ... wonderment
German	prozyklische	procyclical	polished, prophylactic, prophylaxis

Table 1: Foreign-English cognates and false friend training examples.

nate, then for a given word $f \in F$, we need only consider as possible cognates the subset of words in E having an LCSR with f larger than 0.58, a set we call E_f. The portion of E_f with the same meaning as f, E_{f+}, are cognates, while the part with different meanings, E_{f-}, are not cognates. The words E_{f-} with similar spelling but different meaning are sometimes called *false friends*. The cognate identification task is, for every word $f \in F$, and a list of similarly spelled words E_f, to distinguish the cognate subset E_{f+} from the false friend set E_{f-}.

To create training data for our learning approaches, and to generate a high-quality labelled test set, we need to annotate some of the $(f, e_f \in E_f)$ word pairs for whether or not the words share a common meaning. In Section 5, we explain our two high-precision automatic annotation methods: checking if each pair of words (a) were aligned in a word-aligned bitext, or (b) were listed as translation pairs in a bilingual dictionary.

Table 1 provides some labelled examples with non-empty cognate and false friend lists. Note that despite these examples, this is not a ranking task: even in highly related languages, most words in F have empty E_{f+} lists, and many have empty E_{f-} as well. Thus one natural formulation for cognate identification is a pairwise (and symmetric) cognation classification that looks at each pair (f, e_f) separately and individually makes a decision:

+(napukin,napkin)
– (napukin,nanking)
– (napukin,pumpkin)

In this formulation, the benefits of a discriminative approach are clear: it must find substrings that distinguish cognate pairs from word pairs with otherwise similar form. Klementiev and Roth (2006), although using a discriminative approach, do not provide their infinite-attribute perceptron with competitive counter-examples. They instead use transliterations as positives and randomly-paired English and Russian words as negative examples. In the following section, we also improve on Klementiev and Roth (2006) by using a character-based string alignment to focus the features for discrimination.

4 Features for Discriminative Similarity

Discriminative learning works by providing a training set of labelled examples, each represented as a set of features, to a module that learns a classifier. In the previous section we showed how labelled word pairs can be collected. We now address methods of representing these word pairs as sets of features useful for determining cognation.

Consider the Rômaji Japanese/English cognates: *(sutoresu,stress)*. The LCSR is 0.625. Note that the LCSR of *sutoresu* with the English false friend *stories* is higher: 0.75. LCSR alone is too weak a feature to pick out cognates. We need to look at the actual character substrings.

Klementiev and Roth (2006) generate features for a pair of words by splitting both words into all possible substrings of up to size two:
sutoresu $\Rightarrow$ { *s, u, t, o, r, e, s, u, su, ut, to, ... su* }
stress $\Rightarrow$ { *s, t, r, e, s, s, st, tr, re, es, ss* }
Then, a feature vector is built from all substring pairs from the two words such that the difference in positions of the substrings is within one:
{*s-s, s-t, s-st, su-s, su-t, su-st, su-tr... r-s, r-s, r-es...*}
This feature vector provides the feature representation used in supervised machine learning.

This example also highlights the limitations of the Klementiev and Roth approach. The learner can provide weight to features like *s-s* or *s-st* at the beginning of the word, but because of the gradual accumulation of positional differences, the learner never sees the *tor-tr* and *es-es* correspondences that really help indicate the words are cognate.

Our solution is to use the minimum-edit-distance alignment of the two strings as the basis for feature extraction, rather than the positional correspondences. We also include beginning-of-word (^) and end-of-word ($) markers (referred to as *boundary*

markers) to highlight correspondences at those positions. The pair $(sutoresu, stress)$ can be aligned:

For the feature representation, we only extract substring pairs that are consistent with this alignment.[1] That is, the letters in our pairs can only be aligned to each other and not to letters outside the pairing:
{ *ˆ-ˆ, ˆs-ˆs, s-s, su-s, ut-t, t-t,... es-es, s-s, su-ss...*}
We define *phrase* pairs to be the pairs of substrings consistent with the alignment. A similar use of the term "phrase" exists in machine translation, where phrases are often pairs of word sequences consistent with word-based alignments (Koehn et al., 2003).

By limiting the substrings to only those pairs that are consistent with the alignment, we generate fewer, more-informative features. Using more precise features allows a larger maximum substring size L than is feasible with the positional approach. Larger substrings allow us to capture important recurring deletions like the "u" in *sut-st*.

Tiedemann (1999) and others have shown the importance of using the mismatching portions of cognate pairs to learn the recurrent spelling changes between two languages. In order to capture mismatching segments longer than our maximum substring size will allow, we include special features in our representation called *mismatches*. *Mismatches* are phrases that span the entire sequence of unaligned characters between two pairs of aligned end characters (similar to the "rules" extracted by Mulloni and Pekar (2006)). In the above example, *su$-ss$* is a mismatch with "s" and "$" as the aligned end characters. Two sets of features are taken from each mismatch, one that includes the beginning/ending aligned characters as context and one that does not. For example, for the endings of the French/English pair *(économique,economic)*, we include both the substring pairs *ique$:ic$* and *que:c* as features.

One consideration is whether substring features should be binary presence/absence, or the count of the feature in the pair normalized by the length of the longer word. We investigate both of these approaches in our experiments. Also, there is no reason not to include the scores of baseline approaches like NED, LCSR, PREFIX or DICE as features in the representation as well. Features like the lengths of the two words and the difference in lengths of the words have also proved to be useful in preliminary experiments. Semantic features like frequency similarity or contextual similarity might also be included to help determine cognation between words that are not present in a translation lexicon or bitext.

5 Experiments

Section 3 introduced two high-precision methods for generating labelled cognate pairs: using the word alignments from a bilingual corpus or using the entries in a translation lexicon. We investigate both of these methods in our experiments. In each case, we generate sets of labelled word pairs for training, testing, and development. The proportion of positive examples in the bitext-labelled test sets range between 1.4% and 1.8%, while ranging between 1.0% and 1.6% for the dictionary data.[2]

For the discriminative methods, we use a popular Support Vector Machine (SVM) learning package called SVM^{light} (Joachims, 1999). SVMs are maximum-margin classifiers that achieve good performance on a range of tasks. In each case, we learn a linear kernel on the training set pairs and tune the parameter that trades-off training error and margin on the development set. We apply our classifier to the test set and score the pairs by their positive distance from the SVM classification hyperplane (also done by Bilenko and Mooney (2003) with their token-based SVM similarity measure).

We also score the test sets using traditional orthographic similarity measures PREFIX, DICE, LCSR, and NED, an average of these four, and Kondrak (2005)'s LCSF. We also use the log of the edit probability from the stochastic decoder of Ristad and Yianilos (1998) (normalized by the length of the longer word) and Tiedemann (1999)'s highest performing system (Approach #3). Both use only the positive examples in our training set. Our evaluation metric is 11-pt average precision on the score-sorted pair lists (also used by Kondrak and Sherif (2006)).

[1] If the words are from different alphabets, we can get the alignment by mapping the letters to their closest Roman equivalent, or by using the EM algorithm to learn the edits (Ristad and Yianilos, 1998).

[2] The cognate data sets used in our experiments are available at http://www.cs.ualberta.ca/˜bergsma/Cognates/

5.1 Bitext Experiments

For the bitext-based annotation, we use publicly-available word alignments from the Europarl corpus, automatically generated by GIZA++ for French-English (Fr), Spanish-English (Es) and German-English (De) (Koehn and Monz, 2006). Initial cleaning of these noisy word pairs is necessary. We thus remove all pairs with numbers, punctuation, a capitalized English word, and all words that occur fewer than ten times. We also remove many incorrectly aligned words by filtering pairs where the pairwise Mutual Information between the words is less than 7.5. This processing leaves vocabulary sizes of 39K for French, 31K for Spanish, and 60K for German.

Our labelled set is then generated from pairs with LCSR ≥ 0.58 (using the cutoff from Melamed (1999)). Each labelled set entry is a triple of a) the foreign word f, b) the cognates E_{f+} and c) the false friends E_{f-}. For each language pair, we randomly take 20K triples for training, 5K for development and 5K for testing. Each triple is converted to a set of pairwise examples for learning and classification.

5.2 Dictionary Experiments

For the dictionary-based cognate identification, we use French, Spanish, German, Greek (Gr), Japanese (Jp), and Russian (Rs) to English translation pairs from the Freelang program.[3] The latter three pairs were chosen so that we can evaluate on more distant languages that use non-Roman alphabets (although the Rômaji Japanese is Romanized by definition). We take 10K labelled-set triples for training, 2K for testing and 2K for development.

The baseline approaches and our definition of cognation require comparison in a common alphabet. Thus we use a simple context-free mapping to convert every Russian and Greek character in the word pairs to their nearest Roman equivalent. We then label a translation pair as cognate if the LCSR between the words' Romanized representations is greater than 0.58. We also operate all of our comparison systems on these Romanized pairs.

6 Results

We were interested in whether our working definition of cognation (translations and LCSR ≥ 0.58) reflects true etymological relatedness. We looked at the LCSR histogram for translation pairs in one of our translation dictionaries (Figure 1). The trendline suggests a bimodal distribution, with two distinct distributions of translation pairs making up the dictionary: incidental letter agreement gives low LCSR for the larger, non-cognate portion and high LCSR characterizes the likely cognates. A threshold of 0.58 captures most of the cognate distribution while excluding non-cognate pairs. This hypothesis was confirmed by checking the LCSR values of a list of known French-English cognates (randomly collected from a dictionary for another project): 87.4% were above 0.58. We also checked cognation on 100 randomly-sampled, positively-labelled French-English pairs (i.e. translated or aligned and having LCSR ≥ 0.58) from both the dictionary and bitext data. 100% of the dictionary pairs and 93% of the bitext pairs were cognate.

Table 3: Bitext, Dictionary Foreign-to-English cognate identification 11-pt average precision (%).

be improved by normalizing the feature count by the longer string length and including the boundary markers. This is therefore done with all the alignment-based approaches. Also, because of the way its features are constructed, the KR system is limited to a maximum substring length of two (L≤2). A maximum length of three (L≤3) in the KR framework produces millions of features and prohibitive training times, while L≤3 is computationally feasible in the phrasal case, and increases precision by 4.1% over the *phrases L≤2* system.[4] Including *mismatches* results in another small boost in performance (0.5%), while using an Edit Distance feature again increases performance by a slight margin (0.2%). This ranking of configurations is consistent across all the bitext-based development sets; we therefore take the configuration of the highest scoring system as our Alignment-Based Discriminative system for the remainder of this paper.

We next compare the Alignment-Based Discriminative scorer to the various other implemented approaches across the three bitext and six dictionary-based cognate identification test sets (Table 3). The table highlights the top system among both the non-adaptive and adaptive similarity scorers.[5] In each language pair, the alignment-based discriminative approach outperforms all other approaches, but the KR system also shows strong gains over non-adaptive techniques and their re-weighted extensions. This is in contrast to previous comparisons which have only demonstrated minor improvements with adaptive over traditional similarity measures (Kondrak and Sherif, 2006).

We consistently found that the original KR performance could be surpassed by a system that normalizes the KR feature count and adds boundary markers. Across all the test sets, this modification results in a 6% average gain in performance over baseline KR, but is still on average 5% below the Alignment-Based Discriminative technique, with a statistically significantly difference on each of the nine sets.[6]

Figure 2 shows the relationship between training data size and performance in our bitext-based French-English data. Note again that the Tiedemann and Ristad & Yanilos systems only use the positive examples in the training data. Our alignment-based similarity function outperforms all the other systems across nearly the entire range of training data. Note also that the discriminative learning curves show no signs of slowing down: performance grows logarithmically from 1K to 846K word pairs.

For insight into the power of our discriminative approach, we provide some of our classifiers' highest and lowest-weighted features (Table 4).

[4]Preliminary experiments using even longer phrases (beyond L≤3) currently produce a computationally prohibitive number of features for SVM learning. Deploying current feature selection techniques might enable the use of even more expressive and powerful feature sets with longer phrase lengths.

[5]Using the training data and the SVM to weight the components of the PREFIX+DICE+LCSR+NED scorer resulted in negligible improvements over the simple average on our development data.

[6]Following Evert (2004), significance was computed using Fisher's exact test (at $p = 0.05$) to compare the n-best word pairs from the scored test sets, where n was taken as the number of positive pairs in the set.

Table 4: Example features and weights for various Alignment-Based Discriminative classifiers (Foreign-English, negative pairs in *italics*).

Note the expected correspondences between foreign spellings and English (*k-c*, *f-ph*), but also features that leverage derivational and inflectional morphology. For example, Greek-English pairs with the adjective-ending correspondence *kos-c*, e.g. *anarchikos:anarchic*, are favoured, but pairs with the adjective ending in Greek and noun ending in English, *os$-y$*, are penalized; indeed, by our definition, *anarchikos:anarchy* is not cognate. In a bitext, the feature *ées-ed* captures that feminine-plural inflection of past tense verbs in French corresponds to regular past tense in English. On the other hand, words ending in the Spanish first person plural verb suffix *-amos* are rarely translated to English words ending with the suffix *-s*, causing *mos-s* to be penalized. The ability to leverage negative features, learned from appropriate counter examples, is a key innovation of our discriminative framework.

Gr-En (*Dict.*)	Es-En (*Bitext*)

spasmodikos:spasmodic	radón:radon
amvrosia:ambrosia	higiénico:hygienic

Table 5: Highest scored pairs by Alignment-Based Discriminative classifier (negative pairs in *italics*).

Table 5 gives the top pairs scored by our system on two of the sets. Notice that unlike traditional similarity measures that always score identical words higher than all other pairs, by virtue of our feature weighting, our discriminative classifier prefers some pairs with very characteristic spelling changes.

We performed error analysis by looking at all the pairs our system scored quite confidently (highly positive or highly negative similarity), but which were labelled oppositely. Highly-scored false positives arose equally from 1) actual cognates not linked as translations in the data, 2) related words with diverged meanings, e.g. the error in Table 5: *makaroni* in Greek actually means *spaghetti* in English, and 3) the same word stem, a different part of speech (e.g. the Greek/English adjective/noun *synonymos:synonym*). Meanwhile, inspection of the highly-confident false negatives revealed some (often erroneously-aligned in the bitext) positive pairs with incidental letter match (e.g. the French/English *recettes:proceeds*) that we would not actually deem to be cognate. Thus the errors that our system makes are often either linguistically interesting or point out mistakes in our automatically-labelled bitext and (to a lesser extent) dictionary data.

7 Conclusion

This is the first research to apply discriminative string similarity to the task of cognate identification. We have introduced and successfully applied an alignment-based framework for discriminative similarity that consistently demonstrates improved performance in both bitext and dictionary-based cog-

nate identification on six language pairs. Our improved approach can be applied in any of the diverse applications where traditional similarity measures like Edit Distance and LCSR are prevalent. We have also made available our cognate identification data sets, which will be of interest to general string similarity researchers.

Furthermore, we have provided a natural framework for future cognate identification research. Phonetic, semantic, or syntactic features could be included within our discriminative infrastructure to aid in the identification of cognates in text. In particular, we plan to investigate approaches that do not require the bilingual dictionaries or bitexts to generate training data. For example, researchers have automatically developed translation lexicons by seeing if words from each language have similar frequencies, contexts (Koehn and Knight, 2002), burstiness, inverse document frequencies, and date distributions (Schafer and Yarowsky, 2002). Semantic and string similarity might be learned jointly with a co-training or bootstrapping approach (Klementiev and Roth, 2006). We may also compare alignment-based discriminative string similarity with a more complex discriminative model that learns the alignments as latent structure (McCallum et al., 2005).

Abstract

Current research in text mining favours the quantity of texts over their quality. But for bilingual terminology mining, and for many language pairs, large comparable corpora are not available. More importantly, as terms are defined vis-à-vis a specific domain with a restricted register, it is expected that the quality rather than the quantity of the corpus matters more in terminology mining. Our hypothesis, therefore, is that the quality of the corpus is more important than the quantity and ensures the quality of the acquired terminological resources. We show how important the type of discourse is as a characteristic of the comparable corpus.

1 Introduction

Two main approaches exist for compiling corpora: "Big is beautiful" or "Insecurity in large collections". Text mining research commonly adopts the first approach and favors data quantity over quality. This is normally justified on the one hand by the need for large amounts of data in order to make use of statistic or stochastic methods (Manning and Schütze, 1999), and on the other by the lack of operational methods to automatize the building of a corpus answering to selected criteria, such as domain, register, media, style or discourse.

For lexical alignment from comparable corpora, good results on single words can be obtained from large corpora — several millions words — the accuracy of proposed translation is about 80% for the top 10-20 candidates (Fung, 1998; Rapp, 1999; Chiao and Zweigenbaum, 2002). (Cao and Li, 2002) have achieved 91% accuracy for the top three candidates using the Web as a comparable corpus. But for specific domains, and many pairs of languages, such huge corpora are not available. More importantly, as terms are defined vis-à-vis a specific domain with a restricted register, it is expected that the quality rather than the quantity of the corpus matters more in terminology mining. For terminology mining, therefore, our hypothesis is that the quality of the corpora is more important than the quantity and that this ensures the quality of the acquired terminological resources.

Comparable corpora are "sets of texts in different languages, that are not translations of each other" (Bowker and Pearson, 2002, p. 93). The term *comparable* is used to indicate that these texts share some characteristics or features: topic, period, media, author, register (Biber, 1994), discourse... This corpus comparability is discussed by lexical alignment researchers but never demonstrated: it is often reduced to a specific domain, such as the medical (Chiao and Zweigenbaum, 2002) or financial domains (Fung, 1998), or to a register, such as newspaper articles (Fung, 1998). For terminology

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 664–671,
Prague, Czech Republic, June 2007.

mining, the comparability of the corpus should be based on the domain or the sub-domaine, but also on the type of discourse. Indeed, discourse acts semantically upon the lexical units. For a defined topic, some terms are specific to one discourse or another. For example, for French, within the sub-domain of obesity in the domain of medicine, we find the term *excès de poids* (overweight) only inside texts sharing a popular science discourse, and the synonym *excès pondéral* (overweight) only in scientific discourse. In order to evaluate how important the discourse criterion is for building bilingual terminological lists, we carried out experiments on French-Japanese comparable corpora in the domain of medicine, more precisely on the topic of diabetes and nutrition, using texts collected from the Web and manually selected and classified into two discourse categories: one contains only scientific documents and the other contains both scientific and popular science documents.

We used a state-of-the-art multilingual terminology mining chain composed of two term extraction programs, one in each language, and an alignment program. The term extraction programs are publicly available and both extract multi-word terms that are more precise and specific to a particular scientific domain than single word terms. The alignment program makes use of the direct context-vector approach (Fung, 1998; Peters and Picchi, 1998; Rapp, 1999) slightly modified to handle both single- and multi-word terms. We evaluated the candidate translations of multi-word terms using a reference list compiled from publicly available resources. We found that taking discourse type into account resulted in candidate translations of a better quality even when the corpus size is reduced by half. Thus, even using a state-of-the-art alignment method well-known as data greedy, we reached the conclusion that the quantity of data is not sufficient to obtain a terminological list of high quality and that a real comparability of corpora is required.

2 Multilingual terminology mining chain

Taking as input a comparable corpora, the multilingual terminology chain outputs a list of single- and multi-word candidate terms along with their candidate translations. Its architecture is summarized in Figure 1 and comprises term extraction and alignment programs.

2.1 Term extraction programs

The terminology extraction programs are available for both French[1] (Daille, 2003) and Japanese[2] (Takeuchi et al., 2004). The terminological units that are extracted are multi-word terms whose syntactic patterns correspond either to a canonical or a variation structure. The patterns are expressed using part-of-speech tags: for French, Brill's POS tagger[3] and the FLEM lemmatiser[4] are utilised, and for Japanese, CHASEN[5]. For French, the main patterns are N N, N Prep N et N Adj and for Japanese, N N, N Suff, Adj N and Pref N. The variants handled are morphological for both languages, syntactical only for French, and compounding only for Japanese. We consider as a morphological variant a morphological modification of one of the components of the base form, as a syntactical variant the insertion of another word into the components of the base form, and as a compounding variant the agglutination of another word to one of the components of the base form. For example, in French, the candidate MWT *sécrétion d'insuline* (insulin secretion) appears in the following forms:

- **base form** of N Prep N pattern: *sécrétion d'insuline* (insulin secretion);
- **inflexional variant**: *sécrétions d'insuline* (insulin secretions);
- **syntactic variant** (insertion inside the base form of a modifier): *sécrétion pancréatique d'insuline* (pancreatic insulin secretion);
- **syntactic variant** (expansion coordination of base form): *secrétion de peptide et d'insuline* (insulin and peptide secretion).

The MWT candidates *secrétion insulinique* (insulin secretion) and *hypersécrétion insulinique* (insulin

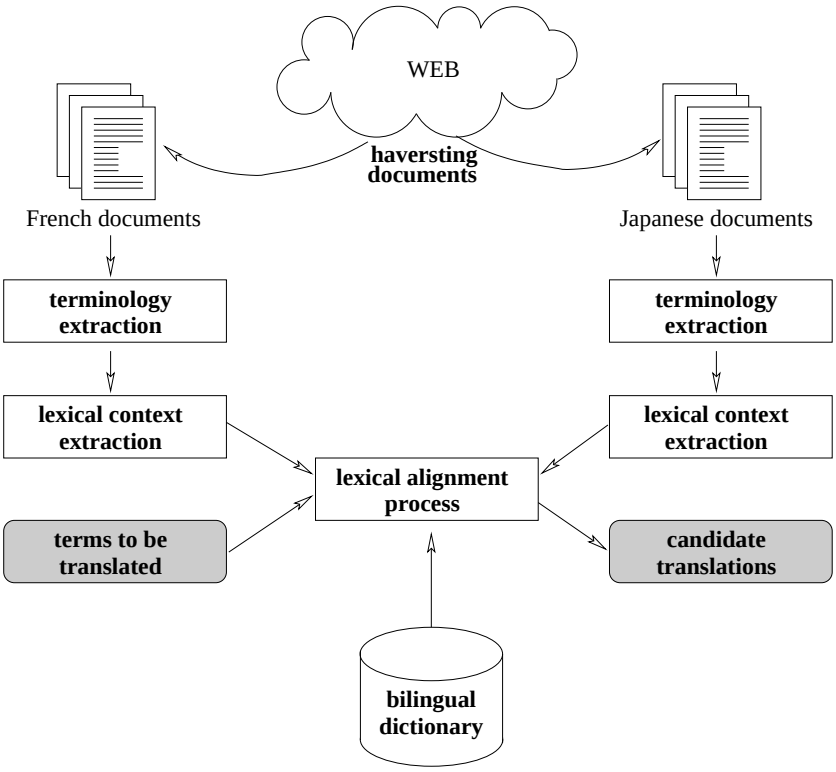

Figure 1: Architecture of the multilingual terminology mining chain

hypersecretion) have also been identified and lead together with *sécrétion d'insuline* (insulin secretion) to a cluster of semantically linked MWTs.

In Japanese, the MWT インスリン.分泌[6] (insulin secretion) appears in the following forms:

- **base form** of NN pattern: インスリン/N_1.分泌/N_2 (insulin secretion);
- **compounding variant** (agglutination of a word at the end of the base form): インスリン/N_1.分泌/N_2.能力/N_3 (insulin secretion ability)

At present, the Japanese term extraction program does not cluster terms.

2.2 Term alignment

The lexical alignment program adapts the direct context-vector approach proposed by (Fung, 1998) for single-word terms (SWTs) to multi-word terms (MWTs). It aligns source MWTs with target single words, SWTs or MWTs. From now on, we will refer to lexical units as words, SWTs or MWTs.

2.2.1 Implementation of the direct context-vector method

Our implementation of the direct context-vector method consists of the following 4 steps:

1. We collect all the lexical units in the context of each lexical unit i and count their occurrence frequency in a window of n words around i. For each lexical unit i of the source and the target language, we obtain a context vector v_i which gathers the set of co-occurrence units j associated with the number of times that j and i occur together occ_j^i. We normalise context vectors using an association score such as Mutual Information or Log-likelihood. In order to reduce the arity of context vectors, we keep only the co-occurrences with the highest association scores.

2. Using a bilingual dictionary, we translate the lexical units of the source context vector.

[6] For all Japanese examples, we explicitly segment the compound into its component parts through the use of the "." symbol.

3. For a word to be translated, we compute the similarity between the translated context vector and all target vectors through vector distance measures such as Cosine (Salton and Lesk, 1968) or Jaccard (Tanimoto, 1958).

4. The candidate translations of a lexical unit are the target lexical units closest to the translated context vector according to vector distance.

2.2.2 Translation of lexical units

The translation of the lexical units of the context vectors, which depends on the coverage of the bilingual dictionary vis-à-vis the corpus, is an important step of the direct approach: more elements of the context vector are translated more the context vector will be discrimating for selecting translations in the target language. If the bilingual dictionary provides several translations for a lexical unit, we consider all of them but weight the different translations by their frequency in the target language. If an MWT cannot be directly translated, we generate possible translations by using a compositional method (Grefenstette, 1999). For each element of the MWT found in the bilingual dictionary, we generate all the translated combinations identified by the term extraction program. For example, in the case of the MWT *fatigue chronique* (chronic fatigue), we have the following four translations for *fatigue*: 疲れ, 疲労, 倦怠, 飽き and the following two translations for *chronique*: 記事番組, 慢性. Next, we generate all combinations of translated elements (See Table 1[7]) and select those which refer to an existing MWT in the target language. Here, only one term has been identified by the Japanese terminology extraction program: 慢性.疲労. In this approach, when it is not possible to translate all parts of an MWT, or when the translated combinations are not identified by the term extraction program, the MWT is not taken into account in the translation process.

This approach differs from that used by (Robitaille et al., 2006) for French/Japanese translation. They first decompose the French MWT into combinations of shorter multi-word units (MWU) elements. This approach makes the direct translation of a subpart of the MWT possible if it is present in the bilingual dictionary. For an MWT of length n, (Robitaille et al., 2006) produce all the combinations of MWU elements of a length less than or equal to n. For example, the French term *syndrome de fatigue chronique* (chronic fatigue disease) yields the following four combinations: i) [*syndrome de fatigue chronique*], ii) [*syndrome de fatigue*] [*chronique*], iii) [*syndrome*] [*fatigue chronique*] and iv) [*syndrome*] [*fatigue*] [*chronique*]. We limit ourselves to the combination of type iv) above since 90% of the candidate terms provided by the term extraction process, after clustering, are only composed of two content words.

chronique	*fatigue*
記事番組	疲れ
慢性	疲れ
記事番組	疲労
慢性	疲労
記事番組	倦怠
慢性	倦怠
記事番組	飽き
慢性	飽き

Table 1: Illustration of the compositional method. The underlined Japanese MWT actually exists.

3 Linguistic resources

In this section we outline the different textual resources used for our experiments: the comparable corpora, bilingual dictionary and reference lexicon.

3.1 Comparable corpora

The French and Japanese documents were harvested from the Web by native speakers of each language who are not domain specialists. The texts are from the medical domain, within the sub-domain of diabetes and nutrition. Document harvesting was carried out by a domain-based search, then by manual selection. The search for documents sharing the same domain can be achieved using keywords reflecting the specialized domain: for French, *diabète and obésité* (diabetes and obesity); for Japanese, 糖尿病 and 肥満. Then the documents were classified according to the type of discourse: scientific or popularized science. At present, the selection and classification phases are carried out manually although

[7] the French word order is inverted to take into account the different constraints between French and Japanese.

research into how to automatize these two steps is ongoing. Table 2 shows the main features of the harvested comparable corpora: the number of documents, and the number of words for each language and each type of discourse.

	French		Japanese	
	doc.	words	doc.	words
Scientific	65	425,781	119	234,857
Popular science	183	267,885	419	572,430
Total	248	693,666	538	807,287

Table 2: Comparable corpora statistics

From these documents, we created two comparable corpora:

- [scientific corpora], composed only of scientific documents;
- [mixed corpora], composed of both popular and scientific documents.

3.2 Bilingual dictionary

The French-Japanese bilingual dictionary required for the translation phase is composed of four dictionaries freely available from the Web[8], and of the French-Japanese Scientific Dictionary (1989). It contains about 173,156 entries (114,461 single words and 58,695 multi words) with an average of 2.1 translations per entry.

3.3 Terminology reference lists

To evaluate the quality of the terminology mining chain, we built two bilingual terminology reference lists which include either SWTs or SMTs and MWTs:

- [lexicon 1] 100 French SWTs of which the translation are Japanese SWTs.
- [lexicon 2] 60 French SWTs and MWTs of which the translation could be Japanese SWTs or MWTs.

These lexicons contains terms that occur at least twice in the scientific corpus, have been identified monolingually by both the French and the Japanese term extraction programs, and are found in either the UMLS[9] thesaurus or in the French part of the *Grand dictionnaire terminologique*[10] in the domain of medicine. These constraints prevented us from obtaining 100 French SWTs and MWTs for lexicon 2. The main reasons for this are the small number of UMLS terms dealing with the sub-domain of diabetes and the great difference between the linguistic structures of French and Japanese terms: French pattern definitions tend to cover more phrasal units while Japanese pattern definitions focus more narrowly on compounds. So, even if monolingually the same percentage of terms are detected in both languages, this does not guarantee a good result in bilingual terminology extraction. For example, the French term *diabète de type 1* (Diabetes mellitus type I) extracted by the French term extraction program and found in UMLS was not extracted by the Japanese term extraction program although it appears frequently in the Japanese corpus (一 型 糖 尿 病).

In bilingual terminology mining from specialized comparable corpora, the terminology reference lists are often composed of a hundred words (180 SWTs in (Déjean and Gaussier, 2002) and 97 SWTs in (Chiao and Zweigenbaum, 2002)).

4 Experiments

In order to evaluate the influence of discourse type on the quality of bilingual terminology extraction, two experiments were carried out. Since the main studies relating to bilingual lexicon extraction from comparable corpora concentrate on finding translation candidates for SWTs, we first perform an experiment using [lexicon 1], which is composed of SWTs. In order to evaluate the hypothesis of this study, we then conducted a second experiment using [lexicon 2], which is composed of MWTs.

4.1 Alignment results for [lexicon 1]

Table 3 shows the results obtained. The first three columns indicate the number of translations found

[8] http://kanji.free.fr/, http://quebec-japon.com/lexique/index.php?a=index&d=25, http://dico.fj.free.fr/index.php, http://quebec-japon.com/lexique/index.php?a=index&d=3

[9] http://www.nlm.nih.gov/research/umls

[10] http://www.granddictionnaire.com/

	NB_{trans}	AVG_{pos}	$STDDEV_{pos}$	TOP_{10}	TOP_{20}
[scientific corpora]	64	11.6	20.2	49	52
[mixed corpora]	76	11.5	16.3	51	60

Table 3: Bilingual terminology extraction results for [lexicon 1]

	NB_{trans}	AVG_{pos}	$STDDEV_{pos}$	TOP_{10}	TOP_{20}
[scientific corpora]	32	16.1	21.9	18	25
[mixed corpora]	32	23.9	27.6	17	20

Table 4: Bilingual terminology extraction results for [lexicon 2]

(NB_{trans}), and the average (AVG_{pos}) and standard deviation ($STDDEV_{pos}$) positions for the translations in the ranked list of candidate translations. The other two columns indicate the percentage of French terms for which the correct translation was obtained among the top ten and top twenty candidates (TOP_{10}, TOP_{20}).

The results of this experiment (see Table 3) show that the terms belonging to [lexicon 1] were more easily identified in the corpus of scientific and popular documents (51% and 60% respectively for TOP_{10} and TOP_{20}) than in the corpus of scientific documents (49% and 52%). Since [lexicon 1] is composed of SWTs, these terms are not more characteristic of popular discourse than scientific discourse.

The frequency of the terms to be translated is an important factor in the vectorial approach. In fact, the higher the frequency of the term to be translated, the more the associated context vector will be discriminant. Table 5 confirms this hypothesis since the most frequent terms, such as *insuline* (#occ. 364 - *insulin*: インスリン), *obésité* (#occ. 333 - *obesity*: 肥満), and *prévention* (#occ. 120 - *prevention*: 予防), were the best translated.

	[2,10]	**[11,50]**	**[51,100]**	**[101,...]**
fr	3/17	12/29	17/23	28/31
jp	4/26	32/41	14/20	10/13

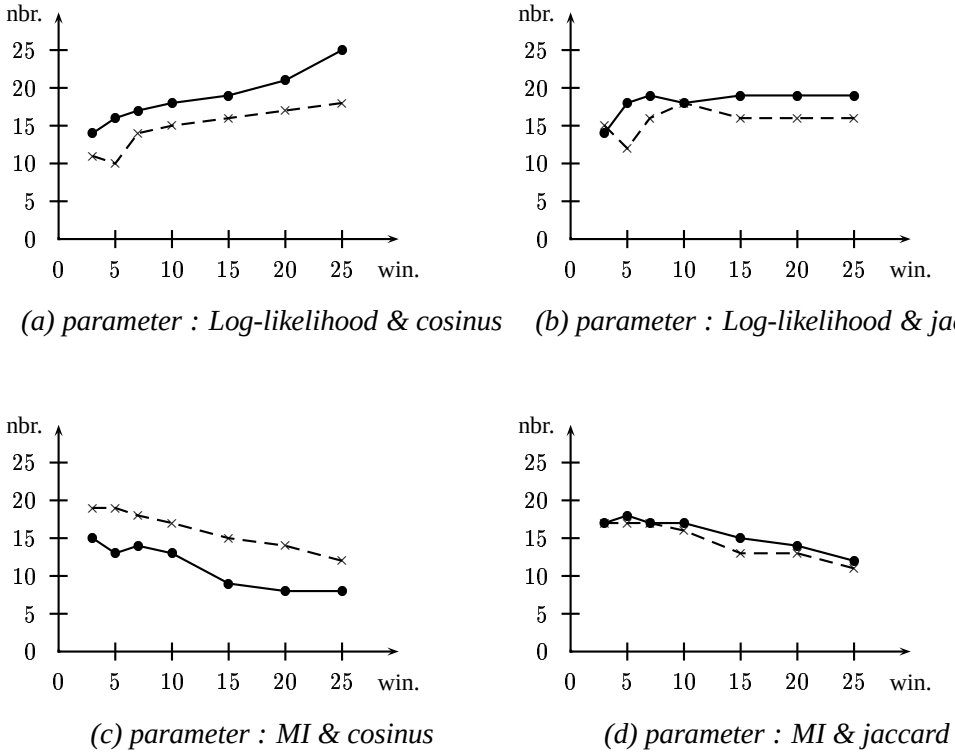
Table 5: Frequency in [corpus 2] of the terms translated belonging to [lexicon 1] (for TOP_{20})

As a baseline, (Déjean et al., 2002) obtain 43% and 51% for the first 10 and 20 candidates respectively in a 100,000-word medical corpus, and 79% and 84% in a multi-domain 8 million-word corpus. For single-item French-English words applied on a medical corpus of 0.66 million words, (Chiao and Zweigenbaum, 2002) obtained 61% and 94% precision on the top-10 and top-20 candidates. In our case, we obtained 51% and 60% precision for the top 10 and 20 candidates in a 1.5 million-word French/Japanese corpus.

4.2 Alignment results for [lexicon 2]

The analysis results in table 4 indicate only a small number of the terms in [lexicon 2] were found. Since we work with small-size corpora, this result is not surprising. Because multi-word terms are more specific than single-word terms, they tend to occur less frequently in a corpus and are more difficult to translate. Here, the terms belonging [lexicon 2] were more accurately identified from the corpus which consists of scientific documents than the corpus which consists of scientific and popular documents. In this instance, we obtained 30% and 42% precision for the top 10 and top 20 candidates in a 0.84 million-word scientific corpus. Moreover, if we count the number of terms which are correctly translated between [scientific corpora] and [mixed corpora], we find the majority of the translated terms with [mixed corpora] in those obtained with [scientific corpora][11] By combining parameters

[11] Here, $TOP_{10}18 \cap 17 = 15$, $TOP_{20}25 \cap 20 = 18$ and $NB_{trad}32 \cap 32 = 28$.



(a) parameter : Log-likelihood & cosinus

(b) parameter : Log-likelihood & jaccard

(c) parameter : MI & cosinus

(d) parameter : MI & jaccard

Figure 2: Evolution of the number of translations found in TOP_{20} according to the size of the contextual window for several combinations of parameters with [lexicon 2] ([scientific corpora] ——; [mixed corpora] - - -, the points indicated are the computed values)

such as the window size of the context vector, association score, and vector distance measure, the terms were often identified with more precision from the corpus consisting of scientific documents than the corpus consisting of scientific and popular documents (see Figure 2).

Here again, the most frequent terms (see Table 6), such as *diabète* (#occ. 899 - *diabetes*: 糖尿.病), *facteur de risque* (#occ. 267 - *risk factor*: 危険.因子), *hyperglycémie* (#occ. 127 - *hyperglycaemia*: 高.血糖), *tissu adipeux* (#occ. 62 - *adipose tissue*: 脂肪.組織) were the best translated. On the other hand, some terms with low frequency, such as *édulcorant* (#occ. 13 - *sweetener*: 甘味.料) and *choix alimentaire* (#occ. 11 - *feeding preferences*: 食品.選択), or very low frequency, such as *obésité massive* (#occ. 6 - *massive obesity*: 高度.肥満), were also identified with this approach.

	[2,10]	**[11,50]**	**[51,100]**	**[101,...]**
fr	1/11	11/25	6/14	7/10
jp	5/21	13/25	5/9	2/5

Table 6: Frequency in [scientific corpora] of translated terms belonging to [lexicon 2] (for TOP_{20})

5 Conclusion

This article describes a first attempt at compiling French-Japanese terminology from comparable corpora taking into account both single- and multi-word terms. Our claim was that a real comparability of the corpora is required to obtain relevant terms of the domain. This comparability should be based not only on the domain and the sub-domain but also on the type of discourse, which acts semantically upon the lexical units. The discourse categorization of documents allows lexical acquisition to increase pre-

cision despite the data sparsity problem that is often encountered for terminology mining and for language pairs not involving the English language, such as French-Japanese. We carried out experiments using two corpora of the specialised domain concerning diabetes and nutrition: one gathering documents from both scientific and popular science discourses, the other limited to scientific discourse. Our alignment results are close to previous works involving the English language, and are of better quality for the scientific corpus despite a corpus size that was reduced by half. The results demonstrate that the more frequent a term and its translation, the better the quality of the alignment will be, but also that the data sparsity problem could be partially solved by using comparable corpora of high quality.

{ffliu,yangl}@hlt.utdallas.edu

Abstract

Language model (LM) adaptation is important for both speech and language processing. It is often achieved by combining a generic LM with a topic-specific model that is more relevant to the target document. Unlike previous work on unsupervised LM adaptation, this paper investigates how effectively using named entity (NE) information, instead of considering all the words, helps LM adaptation. We evaluate two latent topic analysis approaches in this paper, namely, clustering and Latent Dirichlet Allocation (LDA). In addition, a new dynamically adapted weighting scheme for topic mixture models is proposed based on LDA topic analysis. Our experimental results show that the NE-driven LM adaptation framework outperforms the baseline generic LM. The best result is obtained using the LDA-based approach by expanding the named entities with syntactically filtered words, together with using a large number of topics, which yields a perplexity reduction of 14.23% compared to the baseline generic LM.

1 Introduction

Language model (LM) adaptation plays an important role in speech recognition and many natural language processing tasks, such as machine translation and information retrieval. Statistical N-gram LMs have been widely used; however, they capture only local contextual information. In addition, even with the increasing amount of LM training data, there is often a mismatch problem because of differences in domain, topics, or styles. Adaptation of LM, therefore, is very important in order to better deal with a variety of topics and styles.

Many studies have been conducted for LM adaptation. One method is supervised LM adaptation, where topic information is typically available and a topic specific LM is interpolated with the generic LM (Kneser and Steinbiss, 1993; Suzuki and Gao, 2005). In contrast, various unsupervised approaches perform latent topic analysis for LM adaptation. To identify implicit topics from the unlabeled corpus, one simple technique is to group the documents into topic clusters by assigning only one topic label to a document (Iyer and Ostendorf, 1996). Recently several other methods in the line of latent semantic analysis have been proposed and used in LM adaptation, such as latent semantic analysis (LSA) (Bellegarda, 2000), probabilistic latent semantic analysis (PLSA) (Gildea and Hofmann, 1999), and LDA (Blei et al., 2003). Most of these existing approaches are based on the "bag of words" model to represent documents, where all the words are treated equally and no relation or association between words is considered.

Unlike prior work in LM adaptation, this paper investigates how to effectively leverage named entity information for latent topic analysis. Named entities are very common in domains such as newswire or broadcast news, and carry valuable information, which we hypothesize is topic indicative and useful for latent topic analysis. We compare different latent topic generation approaches as well as model adaptation methods, and propose an LDA based dynamic weighting method for the topic mixture model. Furthermore, we expand

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 672–679,
Prague, Czech Republic, June 2007.

named entities by incorporating other content words, in order to capture more topic information. Our experimental results show that the proposed method of incorporating named information in LM adaptation is effective. In addition, we find that for the LDA based adaptation scheme, adding more content words and increasing the number of topics can further improve the performance significantly.

The paper is organized as follows. In Section 2 we review some related work. Section 3 describes in detail our unsupervised LM adaptation approach using named entities. Experimental results are presented and discussed in Section 4. Conclusion and future work appear in Section 5.

2 Related Work

There has been a lot of previous related work on LM adaptation. Suzuki and Gao (2005) compared different supervised LM adaptation approaches, and showed that three discriminative methods significantly outperform the maximum a posteriori (MAP) method. For unsupervised LM adaptation, an earlier attempt is a cache-based model (Kuhn and Mori, 1990), developed based on the assumption that words appearing earlier in a document are likely to appear again. The cache concept has also been used to increase the probability of unseen but topically related words, for example, the trigger-based LM adaptation using the maximum entropy approach (Rosenfeld, 1996).

Latent topic analysis has recently been investigated extensively for language modeling. Iyer and Ostendorf (1996) used hard clustering to obtain topic clusters for LM adaptation, where a single topic is assigned to each document. Bellegarda (2000) employed Latent Semantic Analysis (LSA) to map documents into implicit topic sub-spaces and demonstrated significant reduction in perplexity and word error rate (WER). Its probabilistic extension, PLSA, is powerful for characterizing topics and documents in a probabilistic space and has been used in LM adaptation. For example, Gildea and Hofmann (1999) reported noticeable perplexity reduction via a dynamic combination of many unigram topic models with a generic trigram model. Proposed by Blei et al. (2003), Latent Dirichlet Allocation (LDA) loosens the constraint of the document-specific fixed weights by using a prior distribution and has quickly become one of the most popular probabilistic text modeling techniques. LDA can overcome the drawbacks in the PLSA model, and has been shown to outperform PLSA in corpus perplexity and text classification experiments (Blei et al., 2003). Tam and Schultz (2005) successfully applied the LDA model to unsupervised LM adaptation by interpolating the background LM with the dynamic unigram LM estimated by the LDA model. Hsu and Glass (2006) investigated using hidden Markov model with LDA to allow for both topic and style adaptation. Mrva and Woodland (2006) achieved WER reduction on broadcast conversation recognition using an LDA based adaptation approach that effectively combined the LMs trained from corpora with different styles: broadcast news and broadcast conversation data.

In this paper, we investigate unsupervised LM adaptation using clustering and LDA based topic analysis. Unlike the clustering based interpolation method as in (Iyer and Ostendorf, 1996), we explore different distance measure methods for topic analysis. Different from the LDA based framework as in (Tam and Schultz, 2005), we propose a novel dynamic weighting scheme for the topic adapted LM. More importantly, the focus of our work is to investigate the role of named entity information in LM adaptation, which to our knowledge has not been explored.

3 Unsupervised LM Adaptation Integrating Named Entities (NEs)

3.1 Overview of the NE-driven LM Adaptation Framework

Figure 1 shows our unsupervised LM adaptation framework using NEs. For training, we use the text collection to train the generic word-based N-gram LM. Then we apply named entity recognition (NER) and topic analysis to train multiple topic specific N-gram LMs. During testing, NER is performed on each test document, and then a dynamically adaptive LM based on the topic analysis result is combined with the general LM. Note that in this figure, we evaluate the performance of LM adaptation using the perplexity measure. We will evaluate this framework for N-best or lattice rescoring in speech recognition in the future.

In our experiments, different topic analysis methods combined with different topic matching and adaptive schemes result in several LM adapta-

tion paradigms, which are described below in details.

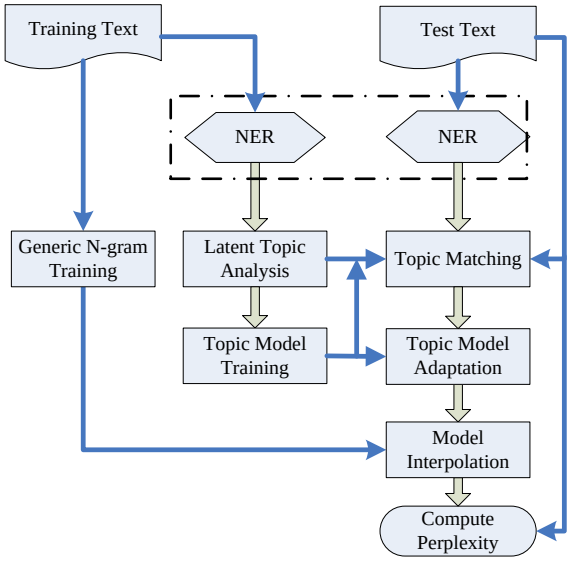

Figure 1. Framework of NE-driven LM adaptation.

3.2 NE-based Clustering for LM Adaptation

Clustering is a simple unsupervised topic analysis method. We use NEs to construct feature vectors for the documents, rather than considering all the words as in most previous work. We use the CLUTO[1] toolkit to perform clustering. It finds a predefined number of clusters based on a specific criterion, for which we chose the following function:

$$(S_1 S_2 \cdots S_k)^* = \arg\max \sum_{i=1}^{K} \sqrt{\sum_{v,u \in S_i} sim(v,u)}$$

where K is the desired number of clusters, S_i is the set of documents belonging to the i^{th} cluster, v and u represent two documents, and $sim(v, u)$ is the similarity between them. We use the cosine distance to measure the similarity between two documents:

$$sim(v,u) = \frac{\vec{v} \cdot \vec{u}}{\| \vec{v} \| \cdot \| \vec{u} \|} \quad (1)$$

where $\vec{v}$ and $\vec{u}$ are the feature vectors representing the two documents respectively, in our experiments composed of NEs. For clustering, the elements in every feature vector are scaled based on their term frequency and inverse document frequency, a concept widely used in information retrieval.

After clustering, we train an N-gram LM, called a topic LM, for each cluster using the documents in it.

During testing, we identify the 'topic' for the test document, and interpolate the topic specific LM with the background LM, that is, if the test document belongs to the cluster S^*, we can predict a word w_k in the document given the word's history h_k using the following equation:

$$p(w_k \mid h_k) = \lambda p_{General}(w_k \mid h_k) + (1-\lambda) p_{Topic-S^*}(w_k \mid h_k) \quad (2)$$

where λ is the interpolation weight.

We investigate two approaches to find the topic assignment S^* for a given test document.

(A) cross-entropy measure

For a test document $d=w_1,w_2,\ldots,w_n$ with a word distribution $p_d(w)$ and a cluster S with a topic LM $p_s(w)$, the cross entropy $CE(d, S)$ can be computed as:

$$CE(d,S) = H(p_d, p_s) = -\sum_{i=1}^{n} p_d(w_i) \log_2 (p_s(w_i))$$

From the information theoretic perspective, the cluster with the lower cross entropy value is expected to be more topically correlated to the test document. For each test document, we compute the cross entropy values according to different clusters, and select the cluster S^* that satisfies:

$$S^* = \arg\min_{1 \le i \le K} CE(d, S_i)$$

(B) cosine similarity

For each cluster, its centroid can be obtained by:

$$cv_i = \frac{1}{n_i} \sum_{k=1}^{n_i} u_{ik}$$

where u_{ik} is the vector for the k^{th} document in the i^{th} cluster, and n_i is the number of documents in the i^{th} cluster. The distance between the test document and a cluster can then be easily measured by the cosine similarity function as in Equation (1). Our goal here is to find the cluster S* which the test document is closest to, that is,

$$S^* = \arg\max_{1 \le i \le K} \frac{\vec{d} \cdot \overrightarrow{cv_i}}{\| \vec{d} \| \cdot \| \overrightarrow{cv_i} \|}$$

[1] Available at http://glaros.dtc.umn.edu/gkhome/views/cluto

where $\vec{d}$ is the feature vector for the test document.

3.3 NE-based LDA for LM Adaptation

LDA model (Blei et al., 2003) has been introduced as a new, semantically consistent generative model, which overcomes overfitting and the problem of generating new documents in PLSA. It is a three-level hierarchical Bayesian model. Based on the LDA model, a document *d* is generated as follows.

- Sample a vector of *K* topic mixture weights θ from a prior Dirichlet distribution with parameter α:

$$f(\theta;\alpha)=\prod_{k=1}^{K}\theta_k^{\alpha_k-1}$$

- For each word *w* in *d*, pick a topic *k* from the multinomial distribution θ.
- Pick a word *w* from the multinomial distribution $\beta_{w,k}$ given the k^{th} topic.

For a document $d=w_1,w_2,\ldots w_n$, the LDA model assigns it the following probability:

$$p(d)=\int_\theta\left(\prod_{i=1}^{n}\sum_{k=1}^{K}\beta_{w_i k}\cdot\theta_k\right)f(\theta;\alpha)d\theta$$

We use the MATLAB topic Toolbox 1.3 (Griffiths et al., 2004) in the training set to obtain the document-topic matrix, DP, and the word-topic matrix, WP. Note that here "words" correspond to the elements in the feature vector used to represent the document (e.g., NEs). In the DP matrix, an entry c_{ik} represents the counts of words in a document d_i that are from a topic z_k (k=1,2,…,K). In the WP matrix, an entry f_{jk} represents the frequency of a word w_j generated from a topic z_k (k=1,2,…,K) over the training set.

For training, we assign a topic z_i^* to a document d_i such that $z_i^*=\underset{1\le k\le K}{\arg\max}\, c_{ik}$. Based on the documents belonging to the different topics, *K* topic N-gram LMs are trained. This "hard clustering" strategy allows us to train an LM that accounts for all the words rather than simply those NEs used in LDA analysis, as well as use higher order N-gram LMs, unlike the 'unigram' based LDA in previous work.

For a test document $d = w_1,w_2,\ldots,w_n$ that is generated by multiple topics under the LDA assumption, we formulate a dynamically adapted topic model using the mixture of LMs from different topics:

$$p_{LDA-adapt}(w_k\mid h_k)=\sum_{i=1}^{K}\gamma_i\times p_{z_i}(w_k\mid h_k)$$

where $p_{z_i}(w_k\mid h_k)$ stands for the i^{th} topic LM, and γ_i is the mixture weight. Different from the idea of dynamic topic adaptation in (Tam and Schultz, 2005), we propose a new weighting scheme to calculate γ_i that directly uses the two resulting matrices from LDA analysis during training:

$$\gamma_k=\sum_{j=1}^{n}p(z_k\mid w_j)p(w_j\mid d)$$

$$p(z_k\mid w_j)=\frac{f_{jk}}{\sum_{p=1}^{K}f_{jp}},\quad p(w_j\mid d)=\frac{freq(w_j)}{\sum_{q=1}^{n}freq(w_q)}$$

where $freq(w_j)$ is the frequency of a word w_j in the document *d*. Other notations are consistent with the previous definitions.

Then we interpolate this adapted topic model with the generic LM, similar to Equation (2):

$$\begin{aligned}p(w_k\mid h_k)=&\lambda p_{General}(w_k\mid h_k)\\&+(1-\lambda)p_{LDA-adapt}(w_k\mid h_k)\end{aligned}\qquad(3)$$

4 Experiments

4.1 Experimental Setup

	# of files	# of words	# of NEs
Training Data	23,985	7,345,644	590,656
Test Data	2,661	831,283	65,867

Table 1. Statistics of our experimental data.

The data set we used is the LDC Mandarin TDT4 corpus, consisting of 337 broadcast news shows with transcriptions. These files were split into small pieces, which we call documents here, according to the topic segmentation information marked in the LDC's transcription. In total, there are 26,646 such documents in our data set. We randomly chose 2661 files as the test data (which is balanced for different news sources). The rest was used for topic analysis and also generic LM training. Punctuation marks were used to determine sentences in the transcriptions. We used the NYU NE tagger (Ji and Grishman, 2005) to recognize four kinds of NEs: Person, Location, Organi-

zation, and Geo-political. Table 1 shows the statistics of the data set in our experiments.

We trained trigram LMs using the SRILM toolkit (Stolcke, 2002). A fixed weight (i.e., λ in Equation (2) and (3)) was used for the entire test set when interpolating the generic LM with the adapted topic LM. Perplexity was used to measure the performance of different adapted LMs in our experiments.

4.2 Latent Topic Analysis Results

	Topic	# of Files	Top 10 Descriptive Items (Translated from Chinese)
Clustering Based	1	3526	U.S., Israel, Washington, Palestine, Bush, Clinton, Gore, Voice of America, Mid-East, Republican Party
	2	3067	Taiwan, Taipei, Mainland, Taipei City, Chinese People's Broadcasting Station, Shuibian Chen, the Executive Yuan, the Legislative Yuan, Democratic Progressive Party, Nationalist Party
	3	4857	Singapore, Japan, Hong Kong, Indonesia, Asia, Tokyo, Malaysia, Thailand, World, China
	4	4495	World, German, Landon, Russia, France, England, Xinhua News Agency, Europe, U.S., Italy
	5	7586	China, Beijing, Nation, China Central Television Station, Xinhua News Agency, Shanghai, World, State Council, Zemin Jiang, Beijing City
LDA Based	1	5859	China, Japan, Hong Kong, Beijing, Shanghai, World, Zemin Jiang, Macao, China Central Television Station, Africa
	2	3794	U.S., Bush, World, Gore, South Korea, North Korea, Clinton, George Walker Bush, Asia, Thailand
	3	4640	Singapore, Indonesia, Team, Israel, Europe, Germany, England, France, Palestine, Wahid
	4	4623	Taiwan, Russia, Mainland, India, Taipei, Shuibian Chen, Philippine, Estrada, Communist Party of China, RUS.
	5	4729	Xinhua News Agency, Nation, Beijing, World, Canada, Sydney, Brazil, Beijing City, Education Ministry, Cuba

Table 2. Topic analysis results using clustering and LDA (the number of documents and the top 10 words (NEs) in each cluster).

For latent topic analysis, we investigated two approaches using named entities, i.e., clustering and LDA. 5 latent topics were used in both approaches. Table 2 illustrates the resulting topics using the top 10 words in each topic. We can see that the words in the same cluster share some similarity and that the words in different clusters seem to be 'topically' different. Note that errors from automatic NE recognition may impact the clustering results. For example, '队/team' in the table (in topic 3 in LDA results) is an error and is less discriminative for topic analysis.

Table 3 shows the perplexity of the test set using the background LM (baseline) and each of the topic LMs, from clustering and LDA respectively. We can see that for the entire test set, a topic LM generally performs much worse than the generic LM. This is expected, since the size of a topic cluster is much smaller than that of the entire training set, and the test set may contain documents from different topics. However, we found that when using an optimal topic model (i.e., the topic LM that yields the lowest perplexity among the 5 topic LMs), 23.45% of the documents in the test set have a lower perplexity value than that obtained from the generic LM. This suggests that a topic model could benefit LM adaptation and motivates a dynamic topic adaptation approach for different test documents.

	Perplexity
Baseline	502.02
CL-1	1054.36
CL-2	1399.16
CL-3	919.237
CL-4	962.996
CL-5	981.072
LDA-1	1224.54
LDA-2	1375.97
LDA-3	1330.44
LDA-4	1328.81
LDA-5	1287.05

Table 3. Perplexity results using the baseline LM vs. the single topic LMs.

4.3 Clustering vs. LDA Based LM Adaptation

In this section, we compare three LM adaptation paradigms. As we discussed in Section 3, two of them are clustering based topic analysis, but using different strategies to choose the optimal cluster; and the third one is based on LDA analysis that

uses a dynamic weighting scheme for adapted topic mixture model.

Figure 2 shows the perplexity results using different interpolation parameters with the general LM. 5 topics were used in both clustering and LDA based approaches (as in Section 4.2). "CL-CE" means clustering based topic analysis via cross entropy criterion, "CL-Cos" represents clustering based topic analysis via cosine distance criterion, and "LDA-MIX" denotes LDA based topic mixture model, which uses 5 mixture topic LMs.

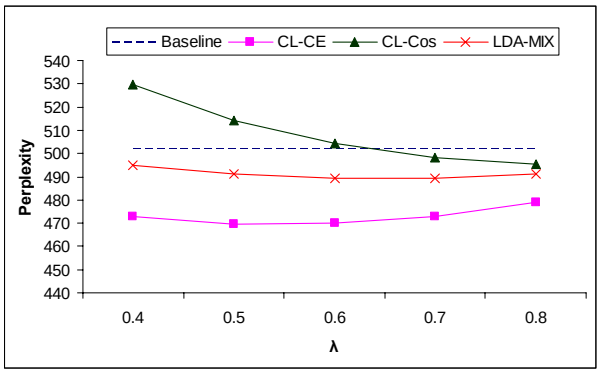

Figure 2. Perplexity using different LM adaptation approaches and different interpolation weights λ with the general LM.

We observe that all three adaptation approaches outperform the baseline when using a proper interpolation weight. "CL-CE" yields the best perplexity of 469.75 when λ is 0.5, a reduction of 6.46% against the baseline perplexity of 502.02. For clustering based adaptation, between the two strategies used to determine the topic for a test document, "CL-CE" outperforms "CL-Cos". This indicates that the cosine distance measure using only names is less effective than cross entropy for LM adaptation. In addition, cosine similarity does not match perplexity as well as the CE-based distance measure. Similarly, for the LDA based approach, using only NEs may not be sufficient to find appropriate weights for the topic model. This also explains the bigger interpolation weight for the general LM in CL-Cos and LDA-MIX than that in "CL-CE".

For a fair comparison between the clustering and LDA based LM adaptation approaches, we also evaluated using the topic mixture model for the clustering based approach and using only one topic in the LDA based method. For clustering based adaptation, we constructed topic mixture models using the weights obtained from a linear normalization of the two distance measures presented in Section 3.2. In order to use only one topic model in LDA based adaptation, we chose the topic cluster that has the largest weight in the adapted topic mixture model (as in Sec 3.3). Table 4 shows the perplexity for the three approaches (CL-Cos, CL-CE, and LDA) using the mixture topic models versus a single topic LM. We observe similar trends as in Figure 2 when changing the interpolation weight λ with the generic LM; therefore, in Table 4 we only present results for one optimal interpolation weight.

	Single-Topic	Mixture-Topic
CL-Cos (λ =0.7)	498.01	497.86
CL-CE (λ =0.5)	469.75	483.09
LDA (λ =0.7)	488.96	489.14

Table 4. Perplexity results using the adapted topic model (single vs. mixture) for clustering and LDA based approaches.

We can see from Table 4 that using the mixture model in clustering based adaptation does not improve performance. This may be attributed to how the interpolation weights are calculated. For example, only names are used in cosine distance, and the normalized distance may not be appropriate weights. We also notice negligible difference when only using one topic in the LDA based framework. This might be because of the small number of topics currently used. Intuitively, using a mixture model should yield better performance, since LDA itself is based on the assumption of generating words from multiple topics. We will investigate the impact of the number of topics on LM adaptation in Section 4.5.

4.4 Effect of Different Feature Configurations on LM Adaptation

We suspect that using only named entities may not provide enough information about the 'topics' of the documents, therefore we investigate expanding the feature vectors with other words. Since generally content words are more indicative of the topic of a document than function words, we used a POS tagger (Hillard et al., 2006) to select words for latent topic analysis. We kept words with three POS classes: noun (NN, NR, NT), verb (VV), and modi-

fier (JJ), selected from the LDC POS set[2]. This is similar to the removal of stop words widely used in information retrieval.

Figure 3 shows the perplexity results for three different feature configurations, namely, all-words (w), names (n), and names plus syntactically filtered items (n+), for the CL-CE and LDA based approaches. The LDA based LM adaptation paradigm supports our hypothesis. Using named information instead of all the words seems to efficiently eliminate redundant information and achieve better performance. In addition, expanding named entities with syntactically filtered items yields further improvement. For CL-CE, using named information achieves the best result among the three configurations. This might be because that the clustering method is less powerful in analyzing the principal components as well as dealing with redundant information than the LDA model.

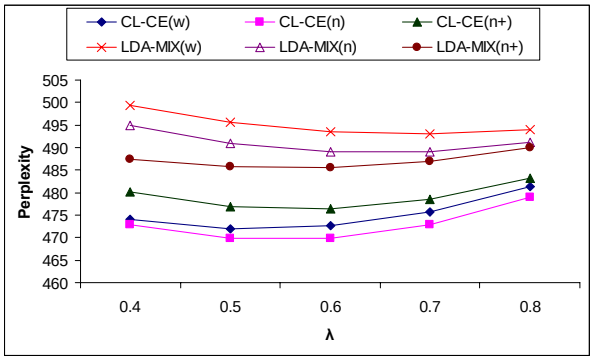

Figure 3. Comparison of perplexity using different feature configurations.

4.5 Impact of Predefined Topic Number on LM Adaptation

LDA based topic analysis typically uses a large number of topics to capture the fine grained topic space. In this section, we evaluate the effect of the number of topics on LM adaptation. For comparison, we evaluate this for both LDA and CL-CE, similar to Section 4.3. We use the "n+" feature configuration as in Section 4.4, that is, names plus POS filtered items. When using a single-topic adapted model in the LDA or CL-CE based approach, finer-grained topic analysis (i.e., increasing the number of topics) leads to worse performance mainly because of the smaller clusters for each topic; therefore, we only show results here using the mixture topic adapted models. Figure 4 shows the perplexity results using different numbers of topics. The interpolation weight λ with the general LM is 0.5 in all the experiments. For the topic mixture LMs, we used a maximum of 9 mixtures (a limitation in the current SRILM toolkit) when the number of topics is greater than 9.

We observe that as the number of topics increases, the perplexity reduces significantly for LDA. When the number of topics is 50, the adapted LM using LDA achieves a perplexity reduction of 11.35% compared to using 5 topics, and 14.23% against the baseline generic LM. Therefore, using finer-grained multiple topics in dynamic adaptation improves system performance. When the number of topics increases further, e.g., to 100, the performance degrades slightly. This might be due to the limitation of the number of the topic mixtures used. A similar trend is observable for the CL-CE approach, but the effect of the topic number is much greater in LDA than CL-CE.

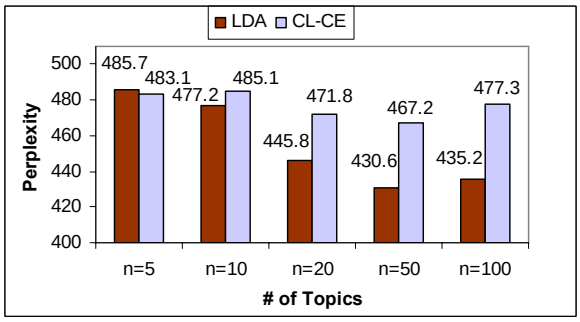

Figure 4. Perplexity results using different predefined numbers of topics for LDA and CL-CE.

4.6 Discussion

As we know, although there is an increasing amount of training data available for LM training, it is still only for limited domains and styles. Creating new training data for different domains is time consuming and labor intensive, therefore it is very important to develop algorithms for LM adaptation. We investigate leveraging named entities in the LM adaptation task. Though some errors of NER may be introduced, our experimental results have shown that exploring named information for topic analysis is promising for LM adaptation.

Furthermore, this framework may have other advantages. For speech recognition, using NEs for topic analysis can be less vulnerable to recognition

[2] See http://www.cis.upenn.edu/~chinese/posguide.3rd.ch.pdf

errors. For instance, we may add a simple module to compute the similarity between two NEs based on the word tokens or phonetics, and thus compensate the recognition errors inside NEs. Whereas, word-based models, such as the traditional cache LMs, may be more sensitive to recognition errors that are likely to have a negative impact on the prediction of the current word. From this point of view, our framework can potentially be more robust in the speech processing task. In addition, the number of NEs in a document is much smaller than that of the words, as shown in Table 1; hence, using NEs can also reduce the computational complexity, in particular in topic analysis for training.

5 Conclusion and Future Work

We compared several unsupervised LM adaptation methods leveraging named entities, and proposed a new dynamic weighting scheme for topic mixture model based on LDA topic analysis. Experimental results have shown that the NE-driven LM adaptation approach outperforms using all the words, and yields perplexity reduction compared to the baseline generic LM. In addition, we find that for the LDA based method, adding other content words, combined with an increased number of topics, can further improve the performance, achieving up to 14.23% perplexity reduction compared to the baseline LM.

The experiments in this paper combine models primarily through simple linear interpolation. Thus one direction of our future work is to develop algorithms to automatically learn appropriate interpolation weights. In addition, our work in this paper has only showed promising results in perplexity reduction. We will investigate using this framework of LM adaptation for N-best or lattice rescoring in speech recognition.

Coordinate Noun Phrase Disambiguation in a Generative Parsing Model

Deirdre Hogan*
Computer Science Department
Trinity College Dublin
Dublin 2, Ireland
dhogan@computing.dcu.ie

Abstract

In this paper we present methods for improving the disambiguation of noun phrase (NP) coordination within the framework of a lexicalised history-based parsing model. As well as reducing noise in the data, we look at modelling two main sources of information for disambiguation: symmetry in conjunct structure, and the dependency between conjunct lexical heads. Our changes to the baseline model result in an increase in NP coordination dependency *f*-score from 69.9% to 73.8%, which represents a relative reduction in *f*-score error of 13%.

1 Introduction

Coordination disambiguation is a relatively little studied area, yet the correct bracketing of coordination constructions is one of the most difficult problems for natural language parsers. In the Collins parser (Collins, 1999), for example, dependencies involving coordination achieve an *f*-score as low as 61.8%, by far the worst performance of all dependency types.

Take the phrase *busloads of executives and their wives* (taken from the WSJ treebank). The coordinating conjunction (CC) *and* and the noun phrase *their wives* could attach to the noun phrase *executives*, as illustrated in Tree 1, Figure 1. Alternatively, *their wives* could be incorrectly conjoined to the noun phrase *busloads of executives* as in Tree 2, Figure 1.

As with PP attachment, most previous attempts at tackling coordination as a subproblem of parsing have treated it as a separate task to parsing and it is not always obvious how to integrate the methods proposed for disambiguation into existing parsing models. We therefore approach coordination disambiguation, not as a separate task, but from within the framework of a generative parsing model.

As noun phrase coordination accounts for over 50% of coordination dependency error in our baseline model we focus on NP coordination. Using a model based on the generative parsing model of (Collins, 1999) Model 1, we attempt to improve the ability of the parsing model to make the correct coordination decisions. This is done in the context of parse reranking, where the *n*-best parses output from Bikel's parser (Bikel, 2004) are reranked according to a generative history-based model.

In Section 2 we summarise previous work on coordination disambiguation. There is often a considerable bias toward symmetry in the syntactic structure of two conjuncts and in Section 3 we introduce new parameter classes to allow the model to prefer symmetry in conjunct structure. Section 4 is concerned with modelling the dependency between conjunct head words and begins by looking at how the different handling of coordination in noun phrases and base noun phrases (NPB) affects coordination disambiguation.[1] We look at how we might improve the model's handling of coordinate head-head dependencies by altering the model so that a common

[1] A base noun phrase, as defined in (Collins, 1999), is a noun phrase which does not directly dominate another noun phrase, unless that noun phrase is possessive.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 680–687,
Prague, Czech Republic, June 2007.

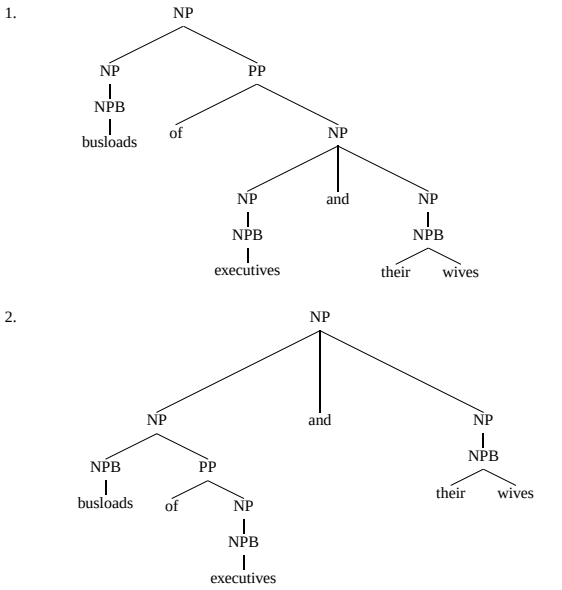

Figure 1: Tree 1. The correct noun phrase parse. Tree 2. The incorrect parse for the noun phrase.

parameter class is used for coordinate word probability estimation in both NPs and NPBs. In Section 4.2 we focus on improving the estimation of this parameter class by incorporating BNC data, and a measure of word similarity based on vector cosine similarity, to reduce data sparseness. In Section 5 we suggest a new head-finding rule for NPBs so that the lexicalisation process for coordinate NPBs is more similar to that of other NPs.

Section 6 examines inconsistencies in the annotation of coordinate NPs in the Penn Treebank which can lead to errors in coordination disambiguation. We show how some coordinate noun phrase inconsistencies can be automatically detected and cleaned from the data sets. Section 7 details how the model is evaluated, presents the experiments made and gives a breakdown of results.

2 Previous Work

Most previous attempts at tackling coordination have focused on a particular type of NP coordination to disambiguate. Both Resnik (1999) and Nakov and Hearst (2005) consider NP coordinations of the form *n1 and n2 n3* where two structural analyses are possible: *((n1 and n2) n3)* and *((n1) and (n2 n3))*. They aim to show more structure than is shown in trees following the Penn guidelines, whereas in our approach we aim to reproduce Penn guideline trees. To resolve the ambiguities, Resnik combines number agreement information of candidate conjoined nouns, an information theoretic measure of semantic similarity, and a measure of the appropriateness of noun-noun modification. Nakov and Hearst (2005) disambiguate by combining Web-based statistics on head word co-occurrences with other mainly heuristic information sources.

A probabilistic approach is presented in (Goldberg, 1999), where an unsupervised maximum entropy statistical model is used to disambiguate coordinate noun phrases of the form *n1 preposition n2 cc n3*. Here the problem is framed as an attachment decision: does *n3* attach 'high' to the first noun, *n1*, or 'low' to *n2*?

In (Agarwal and Boggess, 1992) the task is to identify pre-CC conjuncts which appear in text that has been part-of-speech (POS) tagged and semi-parsed, as well as tagged with semantic labels specific to the domain. The identification of the pre-CC conjunct is based on heuristics which choose the pre-CC conjunct that maximises the symmetry between pre- and post-CC conjuncts.

Insofar as we do not separate coordination disambiguation from the overall parsing task, our approach resembles the efforts to improve coordination disambiguation in (Kurohashi, 1994; Ratnaparkhi, 1994; Charniak and Johnson, 2005). In (Kurohashi, 1994) coordination disambiguation is carried out as the first component of a Japanese dependency parser using a technique which calculates similarity between series of words from the left and right of a conjunction. Similarity is measured based on matching POS tags, matching words and a thesaurus-based measure of semantic similarity. In both the discriminative reranker of Ratnaparkhi et al. (1994) and that of Charniak and Johnson (2005) features are included to capture syntactic parallelism across conjuncts at various depths.

3 Modelling Symmetry Between Conjuncts

There is often a considerable bias toward symmetry in the syntactic structure of two conjuncts, see for example (Dubey et al., 2005). Take Figure 2: If we take as level 0 the level in the coordinate sub-

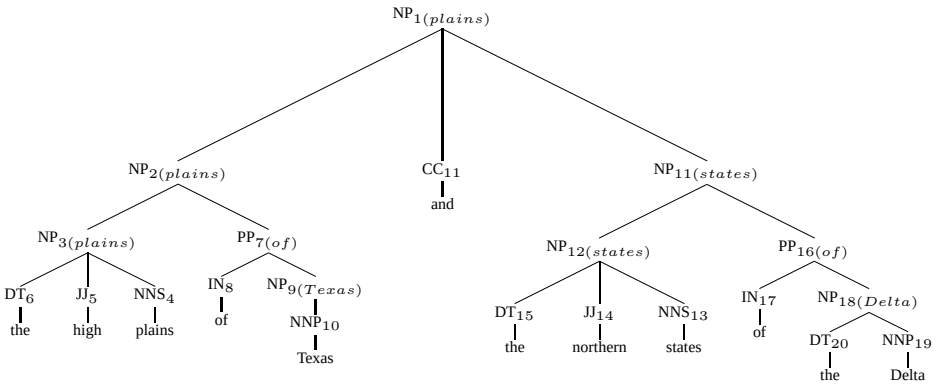

Figure 2: Example of symmetry in conjunct structure in a lexicalised subtree.

tree where the coordinating conjunction *CC* occurs, then there is exact symmetry in the two conjuncts in terms of non-terminal labels and head word part-of-speech tags for levels 0, 1 and 2. Learning a bias toward parallelism in conjuncts should improve the parsing model's ability to correctly attach a coordination conjunction and second conjunct to the correct position in the tree.

In history-based models, features are limited to being functions of the tree generated so far. The task is to incorporate a feature into the model that captures a particular bias yet still adheres to derivation-based restrictions. Parses are generated top-down, head-first, left-to-right. Each node in the tree in Figure 2 is annotated with the order the nodes are generated (we omit, for the sake of clarity, the generation of the *STOP* nodes). Note that when the decision to attach the second conjunct to the head conjunct is being made (i.e. Step 11, when the *CC* and *NP(states)* nodes are being generated) the subtree rooted at *NP(states)* has not yet been generated. Thus at the point that the conjunct attachment decision is made it is not possible to use information about symmetry of conjunct structure, as the structure of the second conjunct is not yet known.

It is possible, however, to condition on structure of the already generated head conjunct when building the internal structure of the second conjunct. In our model when the structure of the second conjunct is being generated we condition on features which are functions of the first conjunct. When generating a node N_i in the second conjunct, we retrieve the corresponding node $N_{i_{preCC}}$ in the first conjunct, via a left to right traversal of the first conjunct. For example, from Figure 2 the pre-*CC* node *NP(Texas)* is the node corresponding to *NP(Delta)* in the post-*CC* conjunct. From $N_{i_{preCC}}$ we extract information, such as its part-of-speech, for use as a feature when predicting a POS tag for the corresponding node in the post-*CC* conjunct.

When generating a second conjunct, instead of the usual parameter classes for estimating the probability of the head label C_h and the POS label of a dependent node t_i, we created two new parameter classes which are used only in the generation of second conjunct nodes:

$$P_{ccC_h}(C_h|\gamma(headC), C_p, w_p, t_p, t_{gp}, depth) \quad (1)$$

$$P_{cct_i}(t_i|\alpha(headC), dir, C_p, w_p, t_p, dist, t_{i\_1}, t_{i\_2}, depth) \quad (2)$$

where $\gamma(headC)$ returns the non-terminal label of $N_{i_{preCC}}$ for the node in question and $\alpha(headC)$ returns the POS tag of $N_{i_{preCC}}$. Both functions return *+NOMATCH+* if there is no $N_{i_{preCC}}$ for the node. Depth is the level of the post-*CC* conjunct node being generated.

4 Modelling Coordinate Head Words

Some noun pairs are more likely to be conjoined than others. Take again the trees in Figure 1. The two head nouns coordinated in Tree 1 are *executives* and *wives*, and in Tree 2: *busloads* and *wives*. Clearly, the former pair of head nouns is more likely and, for the purpose of discrimination, the model would benefit if it could learn that *executives and wives* is a more likely combination than *busloads and wives*.

Bilexical head-head dependencies of the type found in coordinate structures are a somewhat dif-

ferent class of dependency to modifier-head dependencies. In *the fat cat*, for example, there is clearly one head to the noun phrase: *cat*. In *cats and dogs* however there are two heads, though in the parsing model just one is chosen, somewhat arbitrarily, to head the entire noun phrase.

In the baseline model there is essentially one parameter class for the estimation of word probabilities:

$$P_{word}(w_i|H(i)) \quad (3)$$

where w_i is the lexical head of constituent i and $H(i)$ is the history of the constituent. The history is made up of conditioning features chosen from structure that has already been determined in the top-down derivation of the tree.

In Section 4.1 we discuss how though the coordinate head-head dependency is captured for NPs, it is not captured for NPBs. We look at how we might improve the model's handling of coordinate head-head dependencies by altering the model so that a common parameter class in (4) is used for coordinate word probability estimation in both NPs and NPBs.

$$P_{coordWord}(w_i|w_p, H(i)) \quad (4)$$

In Section 4.2 we focus on improving the estimation of this parameter class by reducing data sparseness.

4.1 Extending $P_{coordWord}$ to Coordinate NPBs

In the baseline model each node in the tree is annotated with a coordination flag which is set to true for the node immediately following the coordinating conjunction. For coordinate NPs the head-head dependency is captured when this flag is set to true. In Figure 1, discarding for simplicity the other features in the history, the probability of the coordinate head *wives*, is estimated in Tree 1 as:

$$P_{word}(w_i = wives|coord = true, w_p = executives, ...) \quad (5)$$

and in Tree 2:

$$P_{word}(w_i = wives|coord = true, w_p = busloads, ...) \quad (6)$$

where w_p is the head word of the node to which the node headed by w_i is attaching and $coord$ is the coordination flag.

Unlike NPs, in NPBs (i.e. flat, non-recursive NPs) the coordination flag is not used to mark whether a node is a coordinated head or not. This flag is always set to false for NPBs. In addition, modifiers within NPBs are conditioned on the previously generated modifier rather than the head of the phrase.[2] This means that in an NPB such as *(cats and dogs)*, the estimate for the word *cats* will look like:

$$P_{word}(w_i = cats|coord = false, w_p = and, ...) \quad (7)$$

In our new model, for NPs, when the coordination flag is set to true, we use the parameter class in (4) to estimate the probability of one lexical head noun, given another. For NPBs, if a noun is generated directly after a CC then it is taken to be a coordinate head, w_i, and conditioned on the noun generated before the coordinating conjunction, which is chosen as w_p, and also estimated using (4).

4.2 Estimating the $P_{coordWord}$ parameter class

Data for bilexical statistics are particularly sparse. In order to decrease the sparseness of the coordinate head noun data, we extracted from the BNC examples of coordinate head noun pairs. We extracted all noun pairs occurring in a pattern of the form: *noun cc noun*, as well as lists of any number of nouns separated by commas and ending in *cc noun*.[3] To this data we added all head noun pairs from the WSJ that occurred together in a coordinate noun phrase, identified when the coordination flag was set to true. Every occurrence n_i *CC* n_j was also counted as an occurrence of n_j *CC* n_i. This further helps reduce sparseness.

The probability of one noun, n_i being coordinated with another n_j can be calculated simply as:

$$P_{lex}(n_i|n_j) = \frac{|n_i n_j|}{|n_j|} \quad (8)$$

Again to reduce data sparseness, we introduce a measure of word similarity. A word can be represented as a vector where every dimension of the vector represents another word type. The values of the vector components, the term weights, are derived from word co-occurrence counts. Cosine similarity between two word vectors can then be used to measure the similarity of two words. Measures of

[2] A full explanation of the handling of coordination in the model is given in (Bikel, 2004).

[3] Extracting coordinate noun pairs from the BNC in such a fashion follows work on networks of concepts described in (Widdows, 2004).

similarity between words based on similarity of co-occurrence vectors have been used before, for example, for word sense disambiguation (Schütze, 1998) and for PP-attachment disambiguation (Zhao and Lin, 2004). Our measure resembles that of (Caraballo, 99) where co-occurrence is also defined with respect to coordination patterns, although the experimental details in terms of data collection and vector term weights differ.

We can now incorporate the similarity measure into the probability estimate of (8) to give a new *k*-NN style method of estimating bilexical statistics based on weighting events according to the word similarity measure:

$$P_{sim}(n_i|n_j) = \frac{\sum_{n_x \in N(n_j)} sim(n_j, n_x)|n_i n_x|}{\sum_{n_x \in N(n_j)} sim(n_j, n_x)|n_x|} \quad (9)$$

where $sim(n_j, n_x)$ is a similarity score between words n_j and n_x and $N(n_j)$ is the set of words in the neighbourhood of n_j. This neighbourhood can be based on the k-nearest neighbours of n_j, where nearness is measured with the similarity function.

In order to smooth the bilexical estimate in (9) we combine it with another estimate, trained from WSJ data, by way of linear interpolation:

$$P_{coordWord}(n_i|n_j) = \lambda_{n_j} P_{sim}(n_i|n_j) + (1 - \lambda_{n_j}) P_{MLE}(n_i|t_i) \quad (10)$$

where t_i is the POS tag of word n_i, $P_{MLE}(n_i|t_i)$ is the maximum-likelihood estimate calculated from annotated WSJ data, and λ_{n_j} is calculated as in (11). In (11) we adapt the Witten-Bell method for the calculation of the weight λ, as used in the Collins parser, so that it incorporates the similarity measure for all words in the neighbourhood of n_j.

$$\lambda_{n_j} = \frac{\sum_{n_x \in N(n_j)} sim(n_j, n_x)|n_x|}{\sum_{n_x \in N(n_j)} sim(n_j, n_x)(|n_x| + CD(n_x))} \quad (11)$$

where C is a constant that can be optimised using held-out data and $D(n_j)$ is the diversity of a word n_j: the number of distinct words with which n_j has been coordinated in the training set.

The estimate in (9) can be viewed as the estimate with the more general history context than that of (8) because the context includes not only n_j but also words similar to n_j. The final probability estimate for $P_{coordWord}$ is calculated as the most specific estimate, P_{lex}, combined via regular Witten-Bell interpolation with the estimate in (10).

5 NPB Head-Finding Rules

Head-finding rules for coordinate NPBs differ from coordinate NPs.[4] Take the following two versions of the noun phrase *hard work and harmony*: (c) *(NP (NPB hard work and harmony))* and (d) *(NP (NP (NPB hard work)) and (NP (NPB harmony)))*. In the first example, *harmony* is chosen as head word of the NP; in example (d) the head of the entire NP is *work*. The choice of head affects the various dependencies in the model. However, in the case of two coordinate NPs which, as in the above example, cover the same span of words and differ only in whether the coordinate noun phrase is flat as in (c) or structured as in (d), the choice of head for the phrase is not particularly informative. In both cases the head words being coordinated are the same and either word could plausibly head the phrase; discrimination between trees in such cases should not be influenced by the choice of head, but rather by other, salient features that distinguish the trees.[5]

We would like to alter the head-finding rules for coordinate NPBs so that, in cases like those above, the word chosen to head the entire coordinate noun phrase would be the same for both base and non-base noun phrases. We experiment with slightly modified head-finding rules for coordinate NPBs. In an NPB such as *NPB → n1 CC n2 n3*, the head rules remain unchanged and the head of the phrase is (usually) the rightmost noun in the phrase. Thus, when *n2* is immediately followed by another noun the default is to assume nominal modifier coordination and the head rules stay the same. The modification we make to the head rules for NPBs is as follows: when *n2* is *not* immediately followed by a noun then the noun chosen to head the entire phrase is *n1*.

6 Inconsistencies in WSJ Coordinate NP Annotation

An inspection of NP coordination error in the baseline model revealed inconsistencies in WSJ annota-

[4] See (Collins, 1999) for the rules used in the baseline model.

[5] For example, it would be better if discrimination was largely based on whether *hard* modifies both *work* and *harmony* (c), or whether it modifies *work* alone (d).

tion. In this section we outline some types of coordinate NP inconsistency and outline a method for detecting some of these inconsistencies, which we later use to automatically clean noise from the data. Eliminating noise from treebanks has been previously used successfully to increase overall parser accuracy (Dickinson and Meurers, 2005).

The annotation of NPs in the Penn Treebank (Bies et al., 1995) follows somewhat different guidelines to that of other syntactic categories. Because their interpretation is so ambiguous, no internal structure is shown for nominal modifiers. For NPs with more than one head noun, if the only unshared modifiers in the constituent are nominal modifiers, then a flat structure is also given. Thus in *(NP the Manhattan phone book and tour guide)*[6] a flat structure is given because although *the* is a non-nominal modifier, it is shared, modifying both *tour guide* and *phone book*, and all other modifiers in the phrase are nominal.

However, we found that out of 1,417 examples of NP coordination in sections 02 to 21, involving phrases containing only nouns (common nouns or a mixture of common and proper nouns) and the coordinating conjunction, as many as 21.3%, contrary to the guidelines, were given internal structure, instead of a flat annotation. When all proper nouns are involved this phenomenon is even more common.[7]

Another common source of inconsistency in coordinate noun phrase bracketing occurs when a non-nominal modifier appears in the coordinate noun phrase. As previously discussed, according to the guidelines the modifier is annotated flat if it is shared. When the non-nominal modifier is unshared, more internal structure is shown, as in: *(NP (NP (NNS fangs)) (CC and) (NP (JJ pointed) (NNS ears)))*. However, the following two structured phrases, for example, were given a completely flat structure in the treebank: (a) *(NP (NP (NN oversight))(CC and) (NP (JJ disciplinary)(NNS procedures)))*, (b) *(NP (ADJP (JJ moderate)(CC and)(JJ low-cost))(NN housing))*. If we follow the guidelines then any coordinate NPB which ends with the following tag sequence can be automatically detected as incorrectly bracketed: *CC/non-nominal modifier/noun*. This is because either the non-nominal modifier, which is unambiguously unshared, is part of a noun phrase as (a) above, or it conjoined with another modifier as in (b). We found 202 examples of this in the training set, out of a total of 4,895 coordinate base noun phrases.

Finally, inconsistencies in POS tagging can also lead to problems with coordination. Take the bigram *executive officer*. We found 151 examples in the training set of a base noun phrase which ended with this bigram. 48% of the cases were POS tagged *JJ NN*, 52% tagged *NN NN*. [8] This has repercussions for coordinate noun phrase structure, as the presence of an adjectival pre-modifier indicates a structured annotation should be given.

These inconsistencies pose problems both for training and testing. With a relatively large amount of noise in the training set the model learns to give structures, which should be very unlikely, too high a probability. In testing, given inconsistencies in the gold standard trees, it becomes more difficult to judge how well the model is doing. Although it would be difficult to automatically detect the POS tagging errors, the other inconsistencies outlined above can be detected automatically by simple pattern matching. Automatically eliminating such examples is a simple method of cleaning the data.

7 Experimental Evaluation

We use a parsing model similar to that described in (Hogan, 2005) which is based on (Collins, 1999) Model 1 and uses *k*-NN for parameter estimation. The *n*-best output from Bikel's parser (Bikel, 2004) is reranked according to this *k*-NN parsing model, which achieves an *f*-score of 89.4% on section 23. For the coordination experiments, sections 02 to 21 are used for training, section 23 for testing and the remaining sections for validation. Results are for sentences containing 40 words or less.

As outlined in Section 6, the treebank guidelines are somewhat ambiguous as to the appropriate bracketing for coordinate NPs which consist entirely of proper nouns. We therefore do not include, in the coordination test and validation sets, coordinate NPs where in the gold standard NP the leaf nodes consist entirely of proper nouns (or CCs or commas). In do-

[6] In this section we do not show the NPB levels.

[7] In the guidelines it is recognised however that proper names are frequently annotated with internal structure.

[8] According to the POS bracketing guidelines (Santorini, 1991) the correct sequence of POS tags should be *NN NN*.

ing so we hope to avoid a situation whereby the success of the model is measured in part by how well it can predict the often inconsistent bracketing decisions made for a particular portion of the treebank.

In addition, and for the same reasons, if a gold standard tree is inconsistent with the guidelines in either of the following two ways the tree is not used when calculating coordinate precision and recall of the model: the gold tree is a noun phrase which ends with the sequence *CC/non-nominal modifier/noun*; the gold tree is a structured coordinate noun phrase where each word in the noun phrase is a noun.[9] Call these inconsistencies type *a* and type *b* respectively. This left us with a coordination validation set consisting of 1064 coordinate noun phrases and a test set of 416 coordinate NPs from section 23.

A coordinate phrase was deemed correct if the parent constituent label, and the two conjunct node labels (at level 0) match those in the gold subtree and if, in addition, each of the conjunct head words are the same in both test and gold tree. This follows the definition of a coordinate dependency in (Collins, 1999). Based on these criteria, the baseline *f*-scores for test and validation set were 69.1% and 67.1% respectively. The coordination *f*-score for the oracle trees on section 23 is 83.56%. In other words: if an 'oracle' were to choose from each set of *n*-best trees the tree that maximised constituent precision and recall, then the resulting set of oracle trees would have a NP coordination dependency *f*-score of 83.56%. For the validation set the oracle trees coordination dependency *f*-score is 82.47%.

7.1 Experiments and Results

We first eliminated from the training set all coordinate noun phrase subtrees, of type *a* and type *b* described in Section 7. The effect of this on the validation set is outlined in Table 1, step 2.

For the new parameter class in (1) we found that the best results occurred when it was used only in conjuncts of depth 1 and 2, although the case base for this parameter class contained head events from all post-*CC* conjunct depths. Parameter class (2) was used for predicting POS tags at level 1 in right-of-head conjuncts, although again the sample contained events from all depths.

Model	*f*-score	significance
1. Baseline	67.1	
2. NoiseElimination	68.7	$\gg 1$
3. Symmetry	69.9	$> 2, \gg 1$
4. NPB head rule	70.6	NOT $> 3, > 2, \gg 1$
5. $P_{coordWord}$ WSJ	71.7	NOT $> 4, > 3, \gg 2$
6. BNC data	72.1	NOT $> 5, > 4, \gg 3$
7. $sim(w_i, w_p)$	72.4	NOT > 6, NOT $> 5, \gg 4$

Table 1: Results on the Validation Set. 1064 coordinate noun phrase dependencies. In the significance column $>$ means at level .05 and $\gg$ means at level .005, for McNemar's test of significance. Results are cumulative.

For the $P_{coordWord}$ parameter class we extracted 9961 coordinate noun pairs from the WSJ training set and 815,323 pairs from the BNC. As pairs are considered symmetric this resulted in a total of 1,650,568 coordinate noun events. The term weights for the word vectors were dampened co-occurrence counts, of the form: $1 + log(count)$. For the estimation of $P_{sim}(n_i|n_j)$ we found it too computationally expensive to calculate similarity measures between n_j and each word token collected. The best results were obtained when the neighbourhood of n_j was taken to be the k-nearest neighbours of n_j from among the set of word that had previously occurred in a coordination pattern with n_j, where *k* is 1000. Table 1 shows the effect of the $P_{coordWord}$ parameter class estimated from WSJ data only (step 5), with the addition of BNC data (step 6) and finally with the word similarity measure (step 7).

The result of these experiments, as well as that involving the change in the head-finding heuristics, outlined in Section 5, was an increase in coordinate noun phrase *f*-score from 69.9% to 73.8% on the test set. This represents a 13% relative reduction in coordinate *f*-score error over the baseline, and, using McNemar's test for significance, is significant at the 0.05 level ($p = 0.034$). The reranker *f*-score for all constituents (not excluding any coordinate NPs) for section 23 rose slightly from 89.4% to 89.6%, a small but significant increase in *f*-score.[10]

Finally, we report results on an unaltered coordination test set, that is, a test set from which no

[9] Recall from §6 that for this latter case the noun phrase should be flat - an NPB - rather than a noun phrase with internal structure.

[10] Significance was calculated using the software available at www.cis.upenn.edu/ dbikel/software.html.

noisy events were eliminated. The baseline coordination dependency *f*-score for all NP coordination dependencies (550 dependencies) from section 23 is 69.27%. This rises to 72.74% when all experiments described in Section 7 are applied, which is also a statistically significant increase ($p = 0.042$).

8 Conclusion and Future Work

This paper outlined a novel method for modelling symmetry in conjunct structure, for modelling the dependency between noun phrase conjunct head words and for incorporating a measure of word similarity in the estimation of a model parameter. We also demonstrated how simple pattern matching can be used to reduce noise in WSJ noun phrase coordination data. Combined, these techniques resulted in a statistically significant improvement in noun phrase coordination accuracy.

Coordination disambiguation necessitates information from a variety of sources. Another information source important to NP coordinate disambiguation is the dependency between non-nominal modifiers and nouns which cross CCs in NPBs. For example, modelling this type of dependency could help the model learn that the phrase *the cats and dogs* should be bracketed flat, whereas the phrase *the U.S. and Washington* should be given structure.

Abstract

This paper addresses the issue of text normalization, an important yet often overlooked problem in natural language processing. By text normalization, we mean converting 'informally inputted' text into the canonical form, by eliminating 'noises' in the text *and* detecting paragraph and sentence boundaries in the text. Previously, text normalization issues were often undertaken in an ad-hoc fashion or studied separately. This paper first gives a formalization of the entire problem. It then proposes a unified tagging approach to perform the task using Conditional Random Fields (CRF). The paper shows that with the introduction of a small set of tags, most of the text normalization tasks can be performed within the approach. The accuracy of the proposed method is high, because the subtasks of normalization are interdependent and should be performed together. Experimental results on email data cleaning show that the proposed method significantly outperforms the approach of using cascaded models and that of employing independent models.

1 Introduction

More and more 'informally inputted' text data becomes available to natural language processing, such as raw text data in emails, newsgroups, forums, and blogs. Consequently, how to effectively process the data and make it suitable for natural language processing becomes a challenging issue. This is because informally inputted text data is usually very noisy and is not properly segmented. For example, it may contain extra line breaks, extra spaces, and extra punctuation marks; and it may contain words badly cased. Moreover, the boundaries between paragraphs and the boundaries between sentences are not clear.

We have examined 5,000 randomly collected emails and found that 98.4% of the emails contain noises (based on the definition in Section 5.1).

In order to perform high quality natural language processing, it is necessary to perform 'normalization' on informally inputted data first, specifically, to remove extra line breaks, segment the text into paragraphs, add missing spaces and missing punctuation marks, eliminate extra spaces and extra punctuation marks, delete unnecessary tokens, correct misused punctuation marks, restore badly cased words, correct misspelled words, and identify sentence boundaries.

Traditionally, text normalization is viewed as an engineering issue and is conducted in a more or less ad-hoc manner. For example, it is done by using rules or machine learning models at different levels. In natural language processing, several issues of text normalization were studied, but were only done separately.

This paper aims to conduct a thorough investigation on the issue. First, it gives a formalization of

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 688–695,
Prague, Czech Republic, June 2007.

the problem; specifically, it defines the subtasks of the problem. Next, it proposes a unified approach to the whole task on the basis of tagging. Specifically, it takes the problem as that of assigning tags to the input texts, with a tag representing deletion, preservation, or replacement of a token. As the tagging model, it employs Conditional Random Fields (CRF). The unified model can achieve better performances in text normalization, because the subtasks of text normalization are often interdependent. Furthermore, there is no need to define specialized models and features to conduct different types of cleaning; all the cleaning processes have been formalized and conducted as assignments of the three types of tags.

Experimental results indicate that our method significantly outperforms the methods using cascaded models or independent models on normalization. Our experiments also indicate that with the use of the tags defined, we can conduct most of the text normalization in the unified framework.

Our contributions in this paper include: (a) formalization of the text normalization problem, (b) proposal of a unified tagging approach, and (c) empirical verification of the effectiveness of the proposed approach.

The rest of the paper is organized as follows. In Section 2, we introduce related work. In Section 3, we formalize the text normalization problem. In Section 4, we explain our approach to the problem and in Section 5 we give the experimental results. We conclude the paper in Section 6.

2 Related Work

Text normalization is usually viewed as an engineering issue and is addressed in an ad-hoc manner. Much of the previous work focuses on processing texts in clean form, not texts in informal form. Also, prior work mostly focuses on processing one type or a small number of types of errors, whereas this paper deals with many different types of errors.

Clark (2003) has investigated the problem of preprocessing noisy texts for natural language processing. He proposes identifying token boundaries and sentence boundaries, restoring cases of words, and correcting misspelled words by using a source channel model.

Minkov et al. (2005) have investigated the problem of named entity recognition in informally inputted texts. They propose improving the performance of personal name recognition in emails using two machine-learning based methods: Conditional Random Fields and Perceptron for learning HMMs. See also (Carvalho and Cohen, 2004).

Tang et al. (2005) propose a cascaded approach for email data cleaning by employing Support Vector Machines and rules. Their method can detect email headers, signatures, program codes, and extra line breaks in emails. See also (Wong et al., 2007).

Palmer and Hearst (1997) propose using a Neural Network model to determine whether a period in a sentence is the ending mark of the sentence, an abbreviation, or both. See also (Mikheev, 2000; Mikheev, 2002).

Lita et al. (2003) propose employing a language modeling approach to address the case restoration problem. They define four classes for word casing: all letters in lower case, first letter in uppercase, all letters in upper case, and mixed case, and formalize the problem as assigning class labels to words in natural language texts. Mikheev (2002) proposes using not only local information but also global information in a document in case restoration.

Spelling error correction can be formalized as a classification problem. Golding and Roth (1996) propose using the Winnow algorithm to address the issue. The problem can also be formalized as that of data conversion using the source channel model. The source model can be built as an n-gram language model and the channel model can be constructed with confusing words measured by edit distance. Brill and Moore, Church and Gale, and Mayes et al. have developed different techniques for confusing words calculation (Brill and Moore, 2000; Church and Gale, 1991; Mays et al., 1991).

Sproat et al. (1999) have investigated normalization of non-standard words in texts, including numbers, abbreviations, dates, currency amounts, and acronyms. They propose a taxonomy of non-standard words and apply n-gram language models, decision trees, and weighted finite-state transducers to the normalization.

3 Text Normalization

In this paper we define text normalization at three levels: paragraph, sentence, and word level. The subtasks at each level are listed in Table 1. For example, at the paragraph level, there are two sub-

tasks: extra line-break deletion and paragraph boundary detection. Similarly, there are six (three) subtasks at the sentence (word) level, as shown in Table 1. Unnecessary token deletion refers to deletion of tokens like '-----' and '====', which are not needed in natural language processing. Note that most of the subtasks conduct 'cleaning' of noises, except paragraph boundary detection and sentence boundary detection.

Level	Task	Percentages of Noises
Paragraph	Extra line break deletion	49.53
	Paragraph boundary detection	
Sentence	Extra space deletion	15.58
	Extra punctuation mark deletion	0.71
	Missing space insertion	1.55
	Missing punctuation mark insertion	3.85
	Misused punctuation mark correction	0.64
	Sentence boundary detection	
Word	Case restoration	15.04
	Unnecessary token deletion	9.69
	Misspelled word correction	3.41

Table 1. Text Normalization Subtasks

As a result of text normalization, a text is segmented into paragraphs; each paragraph is segmented into sentences with clear boundaries; and each word is converted into the canonical form. After normalization, most of the natural language processing tasks can be performed, for example, part-of-speech tagging and parsing.

We have manually cleaned up some email data (cf., Section 5) and found that nearly all the noises can be eliminated by performing the subtasks defined above. Table 1 gives the statistics.

1. i'm thinking about buying a pocket
2. pc device for my wife this christmas,.
3. the worry that i have is that she won't
4. be able to sync it to her outlook express
5. contacts…

Figure 1. An example of informal text

I'm thinking about buying a Pocket PC device for my wife this Christmas.// The worry that I have is that she won't be able to sync it to her Outlook Express contacts.//

Figure 2. Normalized text

Figure 1 shows an example of informally inputted text data. It includes many typical noises. From line 1 to line 4, there are four extra line breaks at the end of each line. In line 2, there is an extra comma after the word 'Christmas'. The first word in each sentence and the proper nouns (e.g., 'Pocket PC' and 'Outlook Express') should be capitalized. The extra spaces between the words 'PC' and 'device' should be removed. At the end of line 2, the line break should be removed and a space is needed after the period. The text should be segmented into two sentences.

Figure 2 shows an ideal output of text normalization on the input text in Figure 1. All the noises in Figure 1 have been cleaned and paragraph and sentence endings have been identified.

We must note that dependencies (sometimes even strong dependencies) exist between different types of noises. For example, word case restoration needs help from sentence boundary detection, and vice versa. An ideal normalization method should consider processing all the tasks together.

4 A Unified Tagging Approach

4.1 Process

In this paper, we formalize text normalization as a tagging problem and employ a unified approach to perform the task (no matter whether the processing is at paragraph level, sentence level, or word level).

There are two steps in the method: preprocessing and tagging. In preprocessing, (A) we separate the text into paragraphs (i.e., sequences of tokens), (B) we determine tokens in the paragraphs, and (C) we assign possible tags to each token. The tokens form the basic units and the paragraphs form the sequences of units in the tagging problem. In tagging, given a sequence of units, we determine the most likely corresponding sequence of tags by using a trained tagging model. In this paper, as the tagging model, we make use of CRF.

Next we describe the steps (A)-(C) in detail and explain why our method can accomplish many of the normalization subtasks in Table 1.

(A). We separate the text into paragraphs by taking two or more consecutive line breaks as the endings of paragraphs.

(B). We identify tokens by using heuristics. There are five types of tokens: 'standard word', 'non-standard word', punctuation mark, space, and line break. Standard words are words in natural language. Non-standard words include several general 'special words' (Sproat et al., 1999), email address, IP address, URL, date, number, money, percentage, unnecessary tokens (e.g., '===' and

'###'), etc. We identify non-standard words by using regular expressions. Punctuation marks include period, question mark, and exclamation mark. Words and punctuation marks are separated into different tokens if they are joined together. Natural spaces and line breaks are also regarded as tokens.

(C). We assign tags to each token based on the type of the token. Table 2 summarizes the types of tags defined.

Token Type	Tag	Description
Line break	PRV	Preserve line break
	RPA	Replace line break by space
	DEL	Delete line break
Space	PRV	Preserve space
	DEL	Delete space
Punctuation mark	PSB	Preserve punctuation mark and view it as sentence ending
	PRV	Preserve punctuation mark without viewing it as sentence ending
	DEL	Delete punctuation mark
Word	AUC	Make all characters in uppercase
	ALC	Make all characters in lowercase
	FUC	Make the first character in uppercase
	AMC	Make characters in mixed case
Special token	PRV	Preserve the special token
	DEL	Delete the special token

Table 2. Types of tags

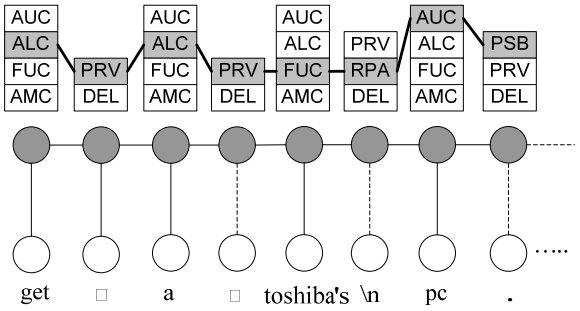

Figure 3. An example of tagging

Figure 3 shows an example of the tagging process. (The symbol '□' indicates a space). In the figure, a white circle denotes a token and a gray circle denotes a tag. Each token can be assigned several possible tags.

Using the tags, we can perform most of the text normalization processing (conducting seven types of subtasks defined in Table 1 and cleaning 90.55% of the noises).

In this paper, we do not conduct three subtasks, although we could do them in principle. These include missing space insertion, missing punctuation mark insertion, and misspelled word correction. In our email data, it corresponds to 8.81% of the noises. Adding tags for insertions would increase the search space dramatically. We did not do that due to computation consideration. Misspelled word correction can be done in the same framework easily. We did not do that in this work, because the percentage of misspelling in the data is small.

We do not conduct misused punctuation mark correction as well (e.g., correcting '.' with '?'). It consists of 0.64% of the noises in the email data. To handle it, one might need to parse the sentences.

4.2 CRF Model

We employ Conditional Random Fields (CRF) as the tagging model. CRF is a conditional probability distribution of a sequence of tags given a sequence of tokens, represented as $P(Y|X)$, where X denotes the token sequence and Y the tag sequence (Lafferty et al., 2001).

In tagging, the CRF model is used to find the sequence of tags Y^* having the highest likelihood $Y^* = \max_Y P(Y|X)$, with an efficient algorithm (the Viterbi algorithm).

In training, the CRF model is built with labeled data and by means of an iterative algorithm based on Maximum Likelihood Estimation.

Transition Features	
$y_{i-1}=y', y_i=y$	
$y_{i-1}=y', y_i=y, w_i=w$	
$y_{i-1}=y', y_i=y, t_i=t$	
State Features	
$w_i=w, y_i=y$	$t_i=t, y_i=y$
$w_{i-1}=w, y_i=y$	$t_{i-1}=t, y_i=y$
$w_{i-2}=w, y_i=y$	$t_{i-2}=t, y_i=y$
$w_{i-3}=w, y_i=y$	$t_{i-3}=t, y_i=y$
$w_{i-4}=w, y_i=y$	$t_{i-4}=t, y_i=y$
$w_{i+1}=w, y_i=y$	$t_{i+1}=t, y_i=y$
$w_{i+2}=w, y_i=y$	$t_{i+2}=t, y_i=y$
$w_{i+3}=w, y_i=y$	$t_{i+3}=t, y_i=y$
$w_{i+4}=w, y_i=y$	$t_{i+4}=t, y_i=y$
$w_{i-1}=w', w_i=w, y_i=y$	$t_{i-2}=t'', t_{i-1}=t', y_i=y$
$w_{i+1}=w', w_i=w, y_i=y$	$t_{i-1}=t', t_i=t, y_i=y$
	$t_i=t, t_{i+1}=t', y_i=y$
	$t_{i+1}=t', t_{i+2}=t'', y_i=y$
	$t_{i-2}=t'', t_{i-1}=t', t_i=t, y_i=y$
	$t_{i-1}=t'', t_i=t, t_{i+1}=t', y_i=y$
	$t_i=t, t_{i+1}=t', t_{i+2}=t'', y_i=y$

Table 3. Features used in the unified CRF model

4.3 Features

Two sets of features are defined in the CRF model: transition features and state features. Table 3 shows the features used in the model.

Suppose that at position i in token sequence x, w_i is the token, t_i the type of token (see Table 2), and y_i the possible tag. Binary features are defined as described in Table 3. For example, the transition feature $y_{i-1}=y'$, $y_i=y$ implies that if the current tag is y and the previous tag is y', then the feature value is true; otherwise false. The state feature $w_i=w$, $y_i=y$ implies that if the current token is w and the current label is y, then the feature value is true; otherwise false. In our experiments, an actual feature might be the word at position 5 is 'PC' and the current tag is AUC. In total, 4,168,723 features were used in our experiments.

4.4 Baseline Methods

We can consider two baseline methods based on previous work, namely cascaded and independent approaches. The independent approach performs text normalization with several passes on the text. All of the processes take the raw text as input and output the normalized/cleaned result independently. The cascaded approach also performs normalization in several passes on the text. Each process carries out cleaning/normalization from the output of the previous process.

4.5 Advantages

Our method offers some advantages.

(1) As indicated, the text normalization tasks are interdependent. The cascaded approach or the independent approach cannot simultaneously perform the tasks. In contrast, our method can effectively overcome the drawback by employing a unified framework and achieve more accurate performances.

(2) There are many specific types of errors one must correct in text normalization. As shown in Figure 1, there exist four types of errors with each type having several correction results. If one defines a specialized model or rule to handle each of the cases, the number of needed models will be extremely large and thus the text normalization processing will be impractical. In contrast, our method naturally formalizes all the tasks as assignments of different types of tags and trains a unified model to tackle all the problems at once.

5 Experimental Results

5.1 Experiment Setting

Data Sets

We used email data in our experiments. We randomly chose in total 5,000 posts (i.e., emails) from 12 newsgroups. DC, Ontology, NLP, and ML are from newsgroups at Google (http://groups-beta.google.com/groups). Jena is a newsgroup at Yahoo (http://groups.yahoo.com/group/jena-dev). Weka is a newsgroup at Waikato University (https://list.scms.waikato.ac.nz). Protégé and OWL are from a project at Stanford University (http://protege.stanford.edu/). Mobility, WinServer, Windows, and PSS are email collections from a company.

Five human annotators conducted normalization on the emails. A spec was created to guide the annotation process. All the errors in the emails were labeled and corrected. For disagreements in the annotation, we conducted "majority voting". For example, extra line breaks, extra spaces, and extra punctuation marks in the emails were labeled. Unnecessary tokens were deleted. Missing spaces and missing punctuation marks were added and marked. Mistakenly cased words, misspelled words, and misused punctuation marks were corrected. Furthermore, paragraph boundaries and sentence boundaries were also marked. The noises fell into the categories defined in Table 1.

Table 4 shows the statistics in the data sets. From the table, we can see that a large number of noises (41,407) exist in the emails. We can also see that the major noise types are extra line breaks, extra spaces, casing errors, and unnecessary tokens.

In the experiments, we conducted evaluations in terms of precision, recall, F1-measure, and accuracy (for definitions of the measures, see for example (van Rijsbergen, 1979; Lita et al., 2003)).

Implementation of Baseline Methods

We used the cascaded approach and the independent approach as baselines.

For the baseline methods, we defined several basic prediction subtasks: extra line break detection, extra space detection, extra punctuation mark detection, sentence boundary detection, unnecessary token detection, and case restoration. We compared the performances of our method with those of the baseline methods on the subtasks.

Data Set	Number of Email	Number of Noises	Extra Line Break	Extra Space	Extra Punc.	Missing Space	Missing Punc.	Casing Error	Spelling Error	Misused Punc.	Unnecessary Token	Number of Paragraph Boundary	Number of Sentence Boundary
DC	100	702	476	31	8	3	24	53	14	2	91	457	291

Table 4. Statistics on data sets

For the case restoration subtask (processing on token sequence), we employed the TrueCasing method (Lita et al., 2003). The method estimates a tri-gram language model using a large data corpus with correctly cased words and then makes use of the model in case restoration. We also employed Conditional Random Fields to perform case restoration, for comparison purposes. The CRF based casing method estimates a conditional probabilistic model using the same data and the same tags defined in TrueCasing.

For unnecessary token deletion, we used rules as follows. If a token consists of non-ASCII characters or consecutive duplicate characters, such as '===', then we identify it as an unnecessary token.

For each of the other subtasks, we exploited the classification approach. For example, in extra line break detection, we made use of a classification model to identify whether or not a line break is a paragraph ending. We employed Support Vector Machines (SVM) as the classification model (Vapnik, 1998). In the classification model we utilized the same features as those in our unified model (see Table 3 for details).

In the cascaded approach, the prediction tasks are performed in sequence, where the output of each task becomes the input of each immediately following task. The order of the prediction tasks is: (1) Extra line break detection: Is a line break a paragraph ending? It then separates the text into paragraphs using the remaining line breaks. (2) Extra space detection: Is a space an extra space? (3) Extra punctuation mark detection: Is a punctuation mark a noise? (4) Sentence boundary detection: Is a punctuation mark a sentence boundary? (5) Unnecessary token deletion: Is a token an unnecessary token? (6) Case restoration. Each of steps (1) to (4) uses a classification model (SVM), step (5) uses rules, whereas step (6) uses either a language model (TrueCasing) or a CRF model (CRF).

In the independent approach, we perform the prediction tasks independently. When there is a conflict between the outcomes of two classifiers, we adopt the result of the latter classifier, as determined by the order of classifiers in the cascaded approach.

To test how dependencies between different types of noises affect the performance of normalization, we also conducted experiments using the unified model by removing the transition features.

Implementation of Our Method

In the implementation of our method, we used the tool CRF++, available at http://chasen.org/~taku/software/CRF++/. We made use of all the default settings of the tool in the experiments.

5.2 Text Normalization Experiments

Results

We evaluated the performances of our method (Unified) and the baseline methods (Cascaded and Independent) on the 12 data sets. Table 5 shows the five-fold cross-validation results. Our method outperforms the two baseline methods.

Table 6 shows the overall performances of text normalization by our method and the two baseline methods. We see that our method outperforms the two baseline methods. It can also be seen that the performance of the unified method decreases when removing the transition features (Unified w/o Transition Features).

We conducted sign tests for each subtask on the results, which indicate that all the improvements of Unified over Cascaded and Independent are statistically significant ($p << 0.01$).

Detection Task		Prec.	Rec.	F1	Acc.
Extra Line Break	Independent	95.16	91.52	93.30	93.81

Discussions

Our method outperforms the independent method and the cascaded method in all the subtasks, especially in the subtasks that have strong dependencies with each other, for example, sentence boundary detection, extra punctuation mark detection, and case restoration.

The cascaded method suffered from ignorance of the dependencies between the subtasks. For example, there were 3,314 cases in which sentence boundary detection needs to use the results of extra line break detection, extra punctuation mark detection, and case restoration. However, in the cascaded method, sentence boundary detection is conducted after extra punctuation mark detection and before case restoration, and thus it cannot leverage the results of case restoration. Furthermore, errors of extra punctuation mark detection can lead to errors in sentence boundary detection.

The independent method also cannot make use of dependencies across different subtasks, because it conducts all the subtasks from the raw input data. This is why for detection of extra space, extra punctuation mark, and casing error, the independent method cannot perform as well as our method.

Our method benefits from the ability of modeling dependencies between subtasks. We see from Table 6 that by leveraging the dependencies, our method can outperform the method without using dependencies (Unified w/o Transition Features) by 0.62% in terms of F1-measure.

Here we use the example in Figure 1 to show the advantage of our method compared with the independent and the cascaded methods. With normalization by the independent method, we obtain:

I'm thinking about buying a pocket PC device for my wife this Christmas, The worry that I have is that she won't be able to sync it to her outlook express contacts.//

With normalization by the cascaded method, we obtain:

I'm thinking about buying a pocket PC device for my wife this Christmas, the worry that I have is that she won't be able to sync it to her outlook express contacts.//

With normalization by our method, we obtain:

I'm thinking about buying a Pocket PC device for my wife this Christmas.// The worry that I have is that she won't be able to sync it to her Outlook Express contacts.//

The independent method can correctly deal with some of the errors. For instance, it can capitalize the first word in the first and the third line, remove extra periods in the fifth line, and remove the four extra line breaks. However, it mistakenly removes the period in the second line and it cannot restore the cases of some words, for example 'pocket' and 'outlook express'.

In the cascaded method, each process carries out cleaning/normalization from the output of the previous process and thus can make use of the cleaned/normalized results from the previous process. However, errors in the previous processes will also propagate to the later processes. For example, the cascaded method mistakenly removes the period in the second line. The error allows case restoration to make the error of keeping the word 'the' in lower case.

TrueCasing-based methods for case restoration suffer from low precision (27.32% by Independent and 28.04% by Cascaded), although their recalls are high (87.44% and 88.21% respectively). There are two reasons: 1) About 10% of the errors in Cascaded are due to errors of sentence boundary detection and extra line break detection in previous steps; 2) The two baselines tend to restore cases of words to the forms having higher probabilities in the data set and cannot take advantage of the dependencies with the other normalization subtasks. For example, 'outlook' was restored to first letter capitalized in both 'Outlook Express' and 'a pleasant outlook'. Our method can take advantage of the dependencies with other subtasks and thus correct 85.01% of the errors that the two baseline methods cannot handle. Cascaded and Independent methods employing CRF for case restoration improve the accuracies somewhat. However, they are still inferior to our method.

Although we have conducted error analysis on the results given by our method, we omit the details here due to space limitation and will report them in a future expanded version of this paper.

We also compared the speed of our method with those of the independent and cascaded methods. We tested the three methods on a computer with two 2.8G Dual-Core CPUs and three Gigabyte memory. On average, it needs about 5 hours for training the normalization models using our method and 25 seconds for tagging in the cross-validation experiments. The independent and the cascaded methods (with TrueCasing) require less time for training (about 2 minutes and 3 minutes respectively) and for tagging (several seconds). This indicates that the efficiency of our method still needs improvement.

6 Conclusion

In this paper, we have investigated the problem of text normalization, an important issue for natural language processing. We have first defined the problem as a task consisting of noise elimination and boundary detection subtasks. We have then proposed a unified tagging approach to perform the task, specifically to treat text normalization as assigning tags representing deletion, preservation, or replacement of the tokens in the text. Experiments show that our approach significantly outperforms the two baseline methods for text normalization.

Sparse Information Extraction: Unsupervised Language Models to the Rescue

Doug Downey, Stefan Schoenmackers, and Oren Etzioni

Abstract

Even in a massive corpus such as the Web, a substantial fraction of extractions appear infrequently. This paper shows how to assess the correctness of *sparse* extractions by utilizing unsupervised language models. The REALM system, which combines HMM-based and n-gram-based language models, ranks candidate extractions by the likelihood that they are correct. Our experiments show that REALM reduces extraction error by 39%, on average, when compared with previous work.

Because REALM pre-computes language models based on its corpus and does not require *any* hand-tagged seeds, it is far more scalable than approaches that learn models for each individual relation from hand-tagged data. Thus, REALM is ideally suited for open information extraction where the relations of interest are not specified in advance and their number is potentially vast.

1 Introduction

Information Extraction (IE) from text is far from infallible. In response, researchers have begun to exploit the redundancy in massive corpora such as the Web in order to assess the veracity of extractions (*e.g.*, (Downey et al., 2005; Etzioni et al., 2005; Feldman et al., 2006)). In essence, such methods utilize *extraction patterns* to generate candidate extractions (*e.g.*, "Istanbul") and then assess each candidate by computing co-occurrence statistics between the extraction and words or phrases indicative of class membership (*e.g.*, "cities such as").

However, Zipf's Law governs the distribution of extractions. Thus, even the Web has limited redundancy for less prominent instances of relations. Indeed, 50% of the extractions in the data sets employed by (Downey et al., 2005) appeared only once. As a result, Downey *et al.*'s model, and related methods, had no way of assessing which extraction is more likely to be correct for fully half of the extractions. This problem is particularly acute when moving beyond unary relations. We refer to this challenge as the task of *assessing sparse extractions*.

This paper introduces the idea that *language modeling* techniques such as n-gram statistics (Manning and Schütze, 1999) and HMMs (Rabiner, 1989) can be used to effectively assess sparse extractions. The paper introduces the REALM system, and highlights its unique properties. Notably, REALM does not require *any* hand-tagged seeds, which enables it to scale to *Open IE*—extraction where the relations of interest are not specified in advance, and their number is potentially vast (Banko et al., 2007).

REALM is based on two key hypotheses. The *KnowItAll hypothesis* is that extractions that occur more frequently in distinct sentences in the corpus are more likely to be correct. For example, the hypothesis suggests that the argument pair (`Giuliani`, `New York`) is relatively likely to be appropriate for the `Mayor` relation, simply because this pair is extracted for the `Mayor` relation relatively frequently. Second, we employ an instance of the *distributional hypothesis* (Harris, 1985), which

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 696–703,
Prague, Czech Republic, June 2007.

can be phrased as follows: different instances of the same semantic relation tend to appear in similar textual contexts. We assess sparse extractions by comparing the contexts in which they appear to those of more common extractions. Sparse extractions whose contexts are more similar to those of common extractions are judged more likely to be correct based on the conjunction of the KnowItAll and the distributional hypotheses.

The contributions of the paper are as follows:

- The paper introduces the insight that the subfield of language modeling provides unsupervised methods that can be leveraged to assess sparse extractions. These methods are more scalable than previous assessment techniques, and require no hand tagging whatsoever.
- The paper introduces an HMM-based technique for checking whether two arguments are of the proper type for a relation.
- The paper introduces a *relational* n-gram model for the purpose of determining whether a sentence that mentions multiple arguments actually expresses a particular relationship between them.
- The paper introduces a novel language-modeling system called REALM that combines both HMM-based models and relational n-gram models, and shows that REALM reduces error by an average of 39% over previous methods, when applied to sparse extraction data.

The remainder of the paper is organized as follows. Section 2 introduces the IE assessment task, and describes the REALM system in detail. Section 3 reports on our experimental results followed by a discussion of related work in Section 4. Finally, we conclude with a discussion of scalability and with directions for future work.

2 IE Assessment

This section formalizes the *IE assessment* task and describes the REALM system for solving it. An IE assessor takes as input a list of candidate extractions meant to denote instances of a relation, and outputs a *ranking* of the extractions with the goal that correct extractions rank higher than incorrect ones. A *correct* extraction is defined to be a true instance of the relation mentioned in the input text.

More formally, the list of candidate extractions for a relation R is denoted as $E_R = \{(a_1, b_1), \ldots, (a_m, b_m)\}$. An extraction ($a_i$, b_i) is an ordered pair of strings. The extraction is *correct* if and only if the relation R holds between the arguments named by a_i and b_i. For example, for $R =$ `Headquartered`, a pair (a_i, b_i) is correct *iff* there exists an organization a_i that is in fact headquartered in the location b_i.[1]

E_R is generated by applying an extraction mechanism, typically a set of extraction "patterns", to each sentence in a corpus, and recording the results. Thus, many elements of E_R are identical extractions derived from different sentences in the corpus.

This task definition is notable for the minimal inputs required—IE assessment does not require knowing the relation name nor does it require hand-tagged seed examples of the relation. Thus, an IE Assessor is applicable to Open IE.

2.1 System Overview

In this section, we describe the REALM system, which utilizes language modeling techniques to perform IE Assessment.

REALM takes as input a set of extractions E_R, and outputs a ranking of those extractions. The algorithm REALM follows is outlined in Figure 1. REALM begins by automatically selecting from E_R a set of *bootstrapped seeds* S_R intended to serve as correct examples of the relation R. REALM utilizes the KnowItAll hypothesis, setting S_R equal to the h elements in E_R extracted most frequently from the underlying corpus. This results in a noisy set of seeds, but the methods that use these seeds are noise tolerant.

REALM then proceeds to rank the remaining (non-seed) extractions by utilizing two language-modeling components. An *n-gram language model* is a probability distribution $P(w_1, ..., w_n)$ over consecutive word sequences of length n in a corpus. Formally, if we assume a seed (s_1, s_2) is a correct extraction of a relation R, the distributional hypothesis states that the *context distribution* around the seed extraction, $P(w_1, ..., w_n | w_i = s_1, w_j = s_2)$ for $1 \leq i, j \leq n$ tends to be "more similar" to

[1] For clarity, our discussion focuses on relations between pairs of arguments. However, the methods we propose can be extended to relations of any arity.

$P(w_1, ..., w_n | w_i = e_1, w_j = e_2)$ when the extraction (e_1, e_2) is correct. Naively comparing context distributions is problematic, however, because the arguments to a relation often appear separated by several intervening words. In our experiments, we found that when relation arguments appear together in a sentence, 75% of the time the arguments are separated by at least three words. This implies that n must be large, and for sparse argument pairs it is not possible to estimate such a large language model accurately, because the number of modeling parameters is proportional to the vocabulary size raised to the nth power. To mitigate sparsity, REALM utilizes smaller language models in its two components as a means of "backing-off' from estimating context distributions explicitly, as described below.

First, REALM utilizes an HMM to estimate whether each extraction has arguments of the proper type for the relation. Each relation R has a set of types for its arguments. For example, the relation `AuthorOf(a, b)` requires that its first argument be an author, and that its second be some kind of written work. Knowing whether extracted arguments are of the proper type for a relation can be quite informative for assessing extractions. The challenge is, however, that this type information is *not* given to the system since the relations (and the types of the arguments) are not known in advance. REALM solves this problem by comparing the distributions of the seed arguments and extraction arguments. Type checking mitigates data sparsity by leveraging *every* occurrence of the individual extraction arguments in the corpus, rather than only those cases in which argument pairs occur near each other.

Although argument type checking is invaluable for extraction assessment, it is not sufficient for extracting relationships between arguments. For example, an IE system using only type information might determine that `Intel` is a corporation and that `Seattle` is a city, and therefore erroneously conclude that `Headquartered(Intel, Seattle)` is correct. Thus, REALM's second step is to employ an n-gram-based language model to assess whether the extracted arguments share the appropriate relation. Again, this information is not given to the system, so REALM compares the context distributions of the extractions to those of the seeds. As described in Section 2.3, REALM employs a relational n-gram language model in order to accurately compare context distributions when extractions are sparse.

REALM(*Extractions* $E_R = \{e_1, ..., e_m\}$)
  S_R = the h most frequent extractions in E_R
  U_R = E_R - S_R
  $TypeRankings(U_R) \leftarrow$ HMM-T(S_R, U_R)
  $RelationRankings(U_R) \leftarrow$ REL-GRAMS(S_R, U_R)
  return a ranking of E_R with the elements of S_R at the top (ranked by frequency) followed by the elements of $U_R = \{u_1, ..., u_{m-h}\}$ ranked in ascending order of $TypeRanking(u_i) * RelationRanking(u_i)$.

Figure 1: Pseudocode for REALM at run-time. The language models used by the HMM-T and REL-GRAMS components are constructed in a preprocessing step.

REALM executes the type checking and relation assessment components separately; each component takes the seed and non-seed extractions as arguments and returns a ranking of the non-seeds. REALM then combines the two components' assessments into a single ranking. Although several such combinations are possible, REALM simply ranks the extractions in ascending order of the product of the ranks assigned by the two components. The following subsections describe REALM's two components in detail.

We identify the proper nouns in our corpus using the LEX method (Downey et al., 2007). In addition to locating the proper nouns in the corpus, LEX also concatenates each multi-token proper noun (*e.g.*,`Los Angeles`) together into a single token. Both of REALM's components construct language models from this tokenized corpus.

2.2 Type Checking with HMM-T

In this section, we describe our type-checking component, which takes the form of a Hidden Markov Model and is referred to as HMM-T. HMM-T ranks the set U_R of non-seed extractions, with a goal of ranking those extractions with arguments of proper type for R above extractions containing type errors. Formally, let U_{Ri} denote the set of the ith arguments of the extractions in U_R. Let S_{Ri} be defined similarly for the seed set S_R.

Our type checking technique exploits the distributional hypothesis—in this case, the intuition that

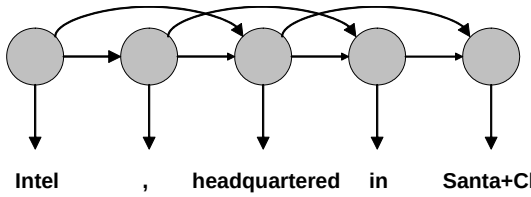

Figure 2: Graphical model employed by HMM-T. Shown is the case in which k = 2. Corpus pre-processing results in the proper noun `Santa Clara` being concatenated into a single token.

extraction arguments in U_{Ri} of the proper type will likely appear in contexts similar to those in which the seed arguments S_{Ri} appear. In order to identify terms that are distributionally similar, we train a probabilistic generative Hidden Markov Model (HMM), which treats each token in the corpus as generated by a single hidden state variable. Here, the hidden states take integral values from $\{1, \ldots, T\}$, and each hidden state variable is itself generated by some number k of previous hidden states.[2] Formally, the joint distribution of the corpus, represented as a vector of tokens $\mathbf{w}$, given a corresponding vector of states $\mathbf{t}$ is:

$$P(\mathbf{w}|\mathbf{t}) = \prod_i P(w_i|t_i)P(t_i|t_{i-1}, \ldots, t_{i-k}) \quad (1)$$

The distributions on the right side of Equation 1 can be learned from a corpus in an unsupervised manner, such that words which are distributed similarly in the corpus tend to be generated by similar hidden states (Rabiner, 1989). The generative model is depicted as a Bayesian network in Figure 2. The figure also illustrates the one way in which our implementation is distinct from a standard HMM, namely that proper nouns are detected *a priori* and modeled as single tokens (*e.g.*, `Santa Clara` is generated by a single hidden state). This allows the type checker to compare the state distributions of different proper nouns directly, even when the proper nouns contain differing numbers of words.

To generate a ranking of U_R using the learned HMM parameters, we rank the arguments e_i according to how similar their *state distributions* $P(t|e_i)$ are to those of the seed arguments.[3] Specifically, we define a function:

$$f(e) = \sum_{e_i \in e} KL(\frac{\sum_{w' \in S_{Ri}} P(t|w')}{|S_{Ri}|}, P(t|e_i)) \quad (2)$$

where KL represents KL divergence, and the outer sum is taken over the arguments e_i of the extraction e. We rank the elements of U_R in ascending order of $f(e)$.

HMM-T has two advantages over a more traditional type checking approach of simply counting the number of times in the corpus that each extraction appears in a context in which a seed also appears (*cf.* (Ravichandran et al., 2005)). The first advantage of HMM-T is efficiency, as the traditional approach involves a computationally expensive step of retrieving the potentially large set of contexts in which the extractions and seeds appear. In our experiments, using HMM-T instead of a context-based approach results in a 10-50x reduction in the amount of data that is retrieved to perform type checking. Secondly, on sparse data HMM-T has the potential to improve type checking accuracy. For example, consider comparing `Pickerington`, a sparse candidate argument of the type `City`, to the seed argument `Chicago`, for which the following two phrases appear in the corpus:

(i) "Pickerington, Ohio"
(ii) "Chicago, Illinois"

In these phrases, the textual contexts surrounding `Chicago` and `Pickerington` are not identical, so to the traditional approach these contexts offer no evidence that `Pickerington` and `Chicago` are of the same type. For a sparse token like `Pickerington`, this is problematic because the token may *never* occur in a context that precisely matches that of a seed. In contrast, in the HMM, the non-sparse tokens `Ohio` and `Illinois` are likely to have similar state distributions, as they are both the names of U.S. States. Thus, in the state space employed by the HMM, the contexts in phrases (i) and (ii) are in fact quite similar, allowing HMM-T to detect that `Pickerington` and `Chicago` are likely of the same type. Our experiments quantify the performance improvements that HMM-T of-

[2] Our implementation makes the simplifying assumption that each sentence in the corpus is generated independently.

[3] The distribution $P(t|e_i)$ for any e_i can be obtained from the HMM parameters using Bayes Rule.

fers over the traditional approach for type checking sparse data.

The time required to learn HMM-T's parameters scales proportional to T^{k+1} times the corpus size. Thus, for tractability, HMM-T uses a relatively small state space of $T = 20$ states and a limited k value of 3. While these settings are sufficient for type checking (*e.g.*, determining that `Santa Clara` is a city) they are too coarse-grained to assess relations between arguments (*e.g.*, determining that `Santa Clara` is the particular city in which `Intel` is headquartered). We now turn to the REL-GRAMS component, which performs the latter task.

2.3 Relation Assessment with REL-GRAMS

REALM's relation assessment component, called REL-GRAMS, tests whether the extracted arguments have a desired relationship, but given REALM's minimal input it has no *a priori* information about the relationship. REL-GRAMS relies instead on the distributional hypothesis to test each extraction.

As argued in Section 2.1, it is intractable to build an accurate language model for context distributions surrounding sparse argument pairs. To overcome this problem, we introduce *relational* n-gram models. Rather than simply modeling the context distribution around a given argument, a relational n-gram model specifies separate context distributions for an arguments *conditioned on* each of the other arguments with which it appears. The relational n-gram model allows us to estimate context distributions for pairs of arguments, even when the arguments do not appear together within a fixed window of n words. Further, by considering only consecutive argument pairs, the number of distinct argument pairs in the model grows at most linearly with the number of sentences in the corpus. Thus, the relational n-gram model can scale.

Formally, for a pair of arguments (e_1, e_2), a relational n-gram model estimates the distributions $P(w_1, ..., w_n | w_i = e_1, e_1 \leftrightarrow e_2)$ for each $1 \leq i \leq n$, where the notation $e_1 \leftrightarrow e_2$ indicates the event that e_2 is the next argument to either the right or the left of e_1 in the corpus.

REL-GRAMS begins by building a relational n-gram model of the arguments in the corpus. For notational convenience, we represent the model's distributions in terms of "context vectors" for each pair of arguments. Formally, for a given sentence containing arguments e_1 and e_2 consecutively, we define a *context* of the ordered pair (e_1, e_2) to be any window of n tokens around e_1. Let $C = \{c_1, c_2, ..., c_{|C|}\}$ be the set of all contexts of all argument pairs found in the corpus.[4] For a pair of arguments (e_j, e_k), we model their relationship using a $|C|$ dimensional context vector $v_{(e_j,e_k)}$, whose i-th dimension corresponds to the number of times context c_i occurred with the pair (e_j, e_k) in the corpus. These context vectors are similar to document vectors from Information Retrieval (IR), and we leverage IR research to compare them, as described below.

To assess each extraction, we determine how similar its context vector is to a canonical seed vector (created by summing the context vectors of the seeds). While there are many potential methods for determining similarity, in this work we rank extractions by decreasing values of the BM25 distance metric. BM25 is a TF-IDF variant introduced in TREC-3(Robertson et al., 1992), which outperformed both the standard cosine distance and a smoothed KL divergence on our data.

3 Experimental Results

This section describes our experiments on IE assessment for sparse data. We start by describing our experimental methodology, and then present our results. The first experiment tests the hypothesis that HMM-T outperforms an n-gram-based method on the task of type checking. The second experiment tests the hypothesis that REALM outperforms multiple approaches from previous work, and also outperforms each of its HMM-T and REL-GRAMS components taken in isolation.

3.1 Experimental Methodology

The corpus used for our experiments consisted of a sample of sentences taken from Web pages. From an initial crawl of nine million Web pages, we selected sentences containing relations between proper nouns. The resulting text corpus consisted of about

[4] Pre-computing the set C requires identifying in advance the potential relation arguments in the corpus. We consider the proper nouns identified by the LEX method (see Section 2.1) to be the potential arguments.

three million sentences, and was tokenized as described in Section 2. For tractability, before and after performing tokenization, we replaced each token occurring fewer than five times in the corpus with one of two "unknown word" markers (one for capitalized words, and one for uncapitalized words). This preprocessing resulted in a corpus containing about sixty-five million total tokens, and 214,787 unique tokens.

We evaluated performance on four relations: `Conquered`, `Founded`, `Headquartered`, and `Merged`. These four relations were chosen because they typically take proper nouns as arguments, and included a large number of sparse extractions. For each relation R, the candidate extraction list E_R was obtained using TEXTRUNNER (Banko et al., 2007). TEXTRUNNER is an IE system that computes an index of all extracted relationships it recognizes, in the form of (object, predicate, object) triples. For each of our target relations, we executed a single query to the TEXTRUNNER index for extractions whose predicate contained a phrase indicative of the relation (*e.g.*, "founded by", "headquartered in"), and the results formed our extraction list. For each relation, the 10 most frequent extractions served as bootstrapped seeds. All of the non-seed extractions were sparse (no argument pairs were extracted more than twice for a given relation). These test sets contained a total of 361 extractions.

3.2 Type Checking Experiments

As discussed in Section 2.2, on sparse data HMM-T has the potential to outperform type checking methods that rely on textual similarities of context vectors. To evaluate this claim, we tested the HMM-T system against an N-GRAMS type checking method on the task of type-checking the arguments to a relation. The N-GRAMS method compares the context vectors of extractions in the same way as the REL-GRAMS method described in Section 2.3, but is not relational (N-GRAMS considers the distribution of each extraction argument independently, similar to HMM-T). We tagged an extraction as type correct *iff* both arguments were valid for the relation, ignoring whether the relation held between the arguments.

The results of our type checking experiments are shown in Table 1. For all types, HMM-T outperforms N-GRAMS, and HMM-T reduces error (measured in missing area under the precision/recall curve) by 46%. The performance difference on each relation is statistically significant ($p < 0.01$, two-sampled t-test), using the methodology for measuring the standard deviation of area under the precision/recall curve given in (Richardson and Domingos, 2006). N-GRAMS, like REL-GRAMS, employs the BM-25 metric to measure distributional similarity between extractions and seeds. Replacing BM-25 with cosine distance cuts HMM-T's advantage over N-GRAMS, but HMM-T's error rate is still 23% lower on average.

Type	HMM-T	N-GRAMS
`Conquered`	**0.917**	0.767
`Founded`	**0.827**	0.636
`Headquartered`	**0.734**	0.589
`Merged`	**0.920**	0.854
Average	**0.849**	0.712

Table 1: Type Checking Performance. Listed is area under the precision/recall curve. HMM-T outperforms N-GRAMS for all relations, and reduces the error in terms of missing area under the curve by 46% on average.

3.3 Experiments with REALM

The REALM system combines the type checking and relation assessment components to assess extractions. Here, we test the ability of REALM to improve the ranking of a state of the art IE system, TEXTRUNNER. For these experiments, we evaluate REALM against the TEXTRUNNER frequency-based ordering, a pattern-learning approach, and the HMM-T and REL-GRAMS components taken in isolation. The TEXTRUNNER frequency-based ordering ranks extractions in decreasing order of their extraction frequency, and importantly, for our task this ordering is essentially equivalent to that produced by the "Urns" (Downey et al., 2005) and Pointwise Mutual Information (Etzioni et al., 2005) approaches employed in previous work.

The pattern-learning approach, denoted as PL, is modeled after Snowball (Agichtein, 2006). The algorithm and parameter settings for PL were those manually tuned for the `Headquartered` relation in previous work (Agichtein, 2005). A sensitivity analysis of these parameters indicated that the re-

	Conquered	Founded	Headquartered	Merged	Average
Avg. Prec.	0.698	0.578	0.400	0.742	0.605
TEXTRUNNER	0.738	0.699	0.710	0.784	0.733
PL	0.885	0.633	0.651	0.852	0.785
PL+ HMM-T	0.883	0.722	0.727	0.900	0.808
HMM-T	0.830	0.776	0.678	0.864	0.787
REL-GRAMS	**0.929 (39%)**	0.713	0.758	0.886	0.822
REALM	0.907 (19%)	**0.781 (27%)**	**0.810 (35%)**	**0.908 (38%)**	**0.851 (39%)**

Table 2: Performance of REALM for assessment of sparse extractions. Listed is area under the precision/recall curve for each method. In parentheses is the percentage reduction in error over the strongest baseline method (TEXTRUNNER or PL) for each relation. "Avg. Prec." denotes the fraction of correct examples in the test set for each relation. REALM outperforms its REL-GRAMS and HMM-T components taken in isolation, as well as the TEXTRUNNER and PL systems from previous work.

sults are sensitive to the parameter settings. However, we found no parameter settings that performed significantly better, and many settings performed significantly worse. As such, we believe our results reasonably reflect the performance of a pattern learning system on this task. Because PL performs relation assessment, we also attempted combining PL with HMM-T in a hybrid method (PL+ HMM-T) analogous to REALM.

The results of these experiments are shown in Table 2. REALM outperforms the TEXTRUNNER and PL baselines for all relations, and reduces the missing area under the curve by an average of 39% relative to the strongest baseline. The performance differences between REALM and TEXTRUNNER are statistically significant for all relations, as are differences between REALM and PL for all relations except Conquered ($p < 0.01$, two-sampled t-test). The hybrid REALM system also outperforms each of its components in isolation.

4 Related Work

To our knowledge, REALM is the first system to use language modeling techniques for IE Assessment.

Redundancy-based approaches to pattern-based IE assessment (Downey et al., 2005; Etzioni et al., 2005) require that extractions appear relatively frequently with a limited set of patterns. In contrast, REALM utilizes *all* contexts to build a model of extractions, rather than a limited set of patterns. Our experiments demonstrate that REALM outperforms these approaches on sparse data.

Type checking using *named-entity taggers* has been previously shown to improve the precision of pattern-based IE systems (Agichtein, 2005; Feldman et al., 2006), but the HMM-T type-checking component we develop differs from this work in important ways. Named-entity taggers are limited in that they typically recognize only small set of types (*e.g.*, ORGANIZATION, LOCATION, PERSON), and they require hand-tagged training data for each type. HMM-T, by contrast, performs type checking for *any* type. Finally, HMM-T does not require hand-tagged training data.

Pattern learning is a common technique for extracting and assessing sparse data (*e.g.* (Agichtein, 2005; Riloff and Jones, 1999; Paşca et al., 2006)). Our experiments demonstrate that REALM outperforms a pattern learning system closely modeled after (Agichtein, 2005). REALM is inspired by pattern learning techniques (in particular, both use the distributional hypothesis to assess sparse data) but is distinct in important ways. Pattern learning techniques require substantial processing of the corpus after the relations they assess have been specified. Because of this, pattern learning systems are unsuited to Open IE. Unlike these techniques, REALM pre-computes language models which allow it to assess extractions for arbitrary relations at run-time. In essence, pattern-learning methods run in time linear in the number of relations whereas REALM's run time is constant in the number of relations. Thus, REALM scales readily to large numbers of relations whereas pattern-learning methods do not.

A second distinction of REALM is that its type checker, unlike the named entity taggers employed in pattern learning systems (*e.g.*, Snowball), can be used to identify arbitrary types. A final distinction is that the language models REALM employs require fewer parameters and heuristics than pattern learning techniques.

Similar distinctions exist between REALM and a recent system designed to assess sparse extractions by bootstrapping a *classifier* for each target relation (Feldman et al., 2006). As in pattern learning, constructing the classifiers requires substantial processing after the target relations have been specified, and a set of hand-tagged examples per relation, making it unsuitable for Open IE.

5 Conclusions

This paper demonstrated that unsupervised language models, as embodied in the REALM system, are an effective means of assessing sparse extractions.

Another attractive feature of REALM is its scalability. Scalability is a particularly important concern for *Open Information Extraction*, the task of extracting large numbers of relations that are not specified in advance. Because HMM-T and REL-GRAMS both pre-compute language models, REALM can be queried efficiently to perform IE Assessment. Further, the language models are constructed independently of the target relations, allowing REALM to perform IE Assessment even when relations are not specified in advance.

In future work, we plan to develop a probabilistic model of the information computed by REALM. We also plan to evaluate the use of non-local context for IE Assessment by integrating document-level modeling techniques (*e.g.*, Latent Dirichlet Allocation).

Abstract

In this paper, we propose forest-to-string rules to enhance the expressive power of tree-to-string translation models. A forest-to-string rule is capable of capturing non-syntactic phrase pairs by describing the correspondence between multiple parse trees and one string. To integrate these rules into tree-to-string translation models, auxiliary rules are introduced to provide a generalization level. Experimental results show that, on the NIST 2005 Chinese-English test set, the tree-to-string model augmented with forest-to-string rules achieves a relative improvement of 4.3% in terms of BLEU score over the original model which allows tree-to-string rules only.

1 Introduction

The past two years have witnessed the rapid development of linguistically syntax-based translation models (Quirk et al., 2005; Galley et al., 2006; Marcu et al., 2006; Liu et al., 2006), which induce tree-to-string translation rules from parallel texts with linguistic annotations. They demonstrated very promising results when compared with the state of the art phrase-based system (Och and Ney, 2004) in the NIST 2006 machine translation evaluation [1]. While Galley et al. (2006) and Marcu et al. (2006) put emphasis on target language analysis, Quirk et al. (2005) and Liu et al. (2006) show benefits from modeling the syntax of source language.

One major problem with linguistically syntax-based models, however, is that tree-to-string rules fail to syntactify non-syntactic phrase pairs because they require a syntax tree fragment over the phrase to be syntactified. Here, we distinguish between *syntactic* and *non-syntactic* phrase pairs. By "syntactic" we mean that the phrase pair is subsumed by some syntax tree fragment. The phrase pairs without trees over them are non-syntactic. Marcu et al. (2006) report that approximately 28% of bilingual phrases are non-syntactic on their English-Chinese corpus.

We believe that it is important to make available to syntax-based models all the bilingual phrases that are typically available to phrase-based models. On one hand, phrases have been proven to be a simple and powerful mechanism for machine translation. They excel at capturing translations of short idioms, providing local re-ordering decisions, and incorporating context information straightforwardly. Chiang (2005) shows significant improvement by keeping the strengths of phrases while incorporating syntax into statistical translation. On the other hand, the performance of linguistically syntax-based models can be hindered by making use of only syntactic phrase pairs. Studies reveal that linguistically syntax-based models are sensitive to syntactic analysis (Quirk and Corston-Oliver, 2006), which is still not reliable enough to handle real-world texts due to limited size and domain of training data.

Various solutions are proposed to tackle the problem. Galley et al. (2004) handle non-constituent phrasal translation by traversing the tree upwards until reaches a node that subsumes the phrase. Marcu et al. (2006) argue that this choice is inap-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 704–711,
Prague, Czech Republic, June 2007.

propriate because large applicability contexts are required.

For a non-syntactic phrase pair, Marcu et al. (2006) create a xRS rule headed by a pseudo, non-syntactic nonterminal symbol that subsumes the phrase and corresponding multi-headed syntactic structure; and one sibling xRS rule that explains how the non-syntactic nonterminal symbol can be combined with other genuine nonterminals so as to obtain genuine parse trees. The name of the pseudo nonterminal is designed to reflect how the corresponding rule can be fully realized. However, they neglect alignment consistency when creating sibling rules. In addition, it is hard for the naming mechanism to deal with more complex phenomena.

Liu et al. (2006) treat bilingual phrases as lexicalized TATs (Tree-to-string Alignment Template). A bilingual phrase can be used in decoding if the source phrase is subsumed by the input parse tree. Although this solution does help, only syntactic bilingual phrases are available to the TAT-based model. Moreover, it is problematic to combine the translation probabilities of bilingual phrases and TATs, which are estimated independently.

In this paper, we propose forest-to-string rules which describe the correspondence between multiple parse trees and a string. They can not only capture non-syntactic phrase pairs but also have the capability of generalization. To integrate these rules into tree-to-string translation models, auxiliary rules are introduced to provide a generalization level. As there is no pseudo node or naming mechanism, the integration of forest-to-string rules is flexible, relying only on their root nodes. The forest-to-string and auxiliary rules enable tree-to-string models to derive in a more general way, while the strengths of conventional tree-to-string rules still remain.

2 Forest-to-String Translation Rules

We define a tree-to-string rule r as a triple $\langle \tilde{T}, \tilde{S}, \tilde{A} \rangle$, which describes the alignment $\tilde{A}$ between a source parse tree $\tilde{T} = T(f_1^{J'})$ and a target string $\tilde{S} = e_1^{I'}$. A source string $f_1^{J'}$, which is the sequence of leaf nodes of $T(f_1^{J'})$, consists of both terminals (source words) and nonterminals (phrasal categories). A target string $e_1^{I'}$ is also composed of both terminals (target words) and nonterminals (placeholders). An alignment $\tilde{A}$ is defined as a subset of the Cartesian product of source and target symbol positions:

$$\tilde{A} \subseteq \{(j, i) : j = 1, \ldots, J'; i = 1, \ldots, I'\}$$

A derivation $\theta = r_1 \circ r_2 \circ \ldots \circ r_n$ is a left-most composition of translation rules that explains how a source parse tree $T = T(f_1^J)$, a target sentence $S = e_1^I$, and the word alignment A are synchronously generated. For example, Table 1 demonstrates a derivation composed of only tree-to-string rules for the $\langle T, S, A \rangle$ tuple in Figure 1 [2].

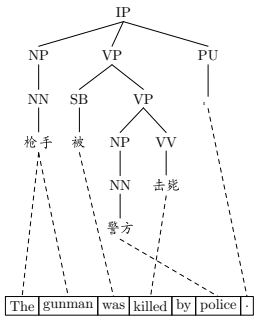

Figure 1: An English sentence aligned with a Chinese parse tree.

As we mentioned before, tree-to-string rules can not syntactify phrase pairs that are not subsumed by any syntax tree fragments. For example, for the phrase pair $\langle$"枪手 被", "*The gunman was*"$\rangle$ in Figure 1, it is impossible to extract an equivalent tree-to-string rule that subsumes the same phrase pair because valid tree-to-string rules can not be multi-headed.

To address this problem, we propose *forest-to-string rules*[3] to subsume the non-syntactic phrase pairs. A forest-to-string rule r [4] is a triple $\langle \tilde{F}, \tilde{S}, \tilde{A} \rangle$, which describes the alignment $\tilde{A}$ between K source parse trees $\tilde{F} = \tilde{T}_1^K$ and a target string $\tilde{S}$. The source string $f_1^{J'}$ is therefore the sequence of leaf nodes of $\tilde{F}$.

Auxiliary rules are introduced to integrate forest-to-string rules into tree-to-string translation models. An auxiliary rule is a special unlexicalized tree-to-string rule that allows multiple source nonterminals

[2] We use "X" to denote a nonterminal in the target string. If there are more than one nonterminals, they are indexed.

[3] The term "forest" refers to an ordered and finite set of trees.

[4] We still use "r" to represent a forest-to-string rule to reduce notational overhead.

No.	Rule		
(1)	(IP (NP) (VP) (PU))	$X_1\ X_2\ X_3$	1:1 2:2 3:3
(2)	(NP (NN 枪手))	The gunman	1:1 1:2
(3)	(VP (SB 被) (VP (NP (NN)) (VV 击毙)))	was killed by X	1:1 2:4 3:2
(4)	(NN 警方)	police	1:1
(5)	(PU 。)	.	1:1

Table 1: A derivation composed of only tree-to-string rules for Figure 1.

No.	Rule

(2)	(NP (NN 枪手)) (SB 被)	The gunman was	1:1 1:2 2:3
(3)	(VP (NP) (VV 击毙)) (PU 。)	killed by X .	1:3 2:1 3:4
(4)	(NP (NN 警方))	police	1:1

Table 2: A derivation composed of tree-to-string, forest-to-string, and auxiliary rules for Figure 1.

to correspond to one target nonterminal, suggesting that the forest-to-string rules that are rooted at such source nonterminals can be integrated.

For example, Table 2 shows a derivation composed of tree-to-string, forest-to-string, and auxiliary rules for the $\langle T, S, A\rangle$ tuple in Figure 1. r_1 is an auxiliary rule, r_2 and r_3 are forest-to-string rules, and r_4 is a conventional tree-to-string rule.

Following Marcu et al. (2006), we define the probability of a tuple $\langle T, S, A\rangle$ as the sum over all derivations $\theta_i \in \Theta$ that are consistent with the tuple, $c(\Theta) = \langle T, S, A\rangle$. The probability of each derivation θ_i is given by the product of the probabilities of all the rules $p(r_j)$ in the derivation.

$$Pr(T, S, A) = \sum_{\theta_i \in \Theta, c(\Theta)=\langle T,S,A\rangle} \prod_{r_j \in \theta_i} p(r_j) \quad (1)$$

3 Training

We obtain tree-to-string and forest-to-string rules from word-aligned, source side parsed bilingual corpus. The extraction algorithm is shown in Figure 2. Note that T' denotes either a tree or a forest.

For each span, the ⟨tree/forest, string, alignment⟩ triples are identified first. If a triple is consistent with the alignment, the *skeleton* of the triple is computed then. A skeleton s is a rule satisfying the following:

1. $s \in \mathcal{R}(t)$, s is induced from t.
2. $node(T(s)) \geq 2$, the tree/forest of s contains two or more nodes.
3. $\forall r \in \mathcal{R}(t) \wedge node(T(r)) \geq 2, T(s) \subseteq T(r)$, the tree/forest of s is the subgraph of that of any r containing two or more nodes.

Input: a source tree $T = T(f_1^J)$, a target string $S = e_1^I$, and word alignment A between them
$\mathcal{R} := \emptyset$
for $u := 0$ to $J - 1$ **do**
  for $v := 1$ to $J - u$ **do**
    identify the triple set $\mathcal{T}$ corresponding to span $(v, v + u)$
    for each triple $t = \langle T', S', A'\rangle \in \mathcal{T}$ **do**
      if $\langle T', S'\rangle$ is not consistent with A **then**
        continue
      end if
      if $u = 0 \wedge node(T') = 1$ **then**
        add t to $\mathcal{R}$
        add $\langle root(T'), \text{“}X\text{”}, 1{:}1\rangle$ to $\mathcal{R}$
      else
        compute the skeleton s of the triple t
        register rules that are built on s using rules extracted from the sub-triples of t: $\mathcal{R} := \mathcal{R} \cup build(s, \mathcal{R})$
      end if
    end for
  end for
end for
Output: rule set $\mathcal{R}$

Figure 2: Rule extraction algorithm.

Given the skeleton and rules extracted from the sub-triples, the rules for the triple can be acquired.

For example, the algorithm identifies the following triple for span $(1, 2)$ in Figure 1:

⟨(NP (NN 枪手)) (SB 被),“The gunman was”, 1:1 1:2 2:3⟩

The skeleton of the triple is:

⟨(NP) (SB),“$X_1\ X_2$”, 1:1 2:2⟩

As the algorithm proceeds bottom-up, five rules have already been extracted from the sub-triples, rooted at “NP” and “SB” respectively:

⟨(NP),“X”, 1:1⟩
⟨(NP (NN)),“X”, 1:1⟩
⟨(NP (NN 枪手)),“The gunman”, 1:1 1:2⟩

⟨(SB),“X”, 1:1⟩
⟨(SB 被),“was”, 1:1⟩

Hence, we can obtain new rules by replacing the source and target symbols of the skeleton with corresponding rules and also by modifying the alignment information. For the above triple, the combination of the five rules produces $2 \times 3 = 6$ new rules:

⟨(NP) (SB),“X_1 X_2”, 1:1 2:2⟩
⟨(NP) (SB 被),“X was”, 1:1 2:2⟩
⟨((NP (NN)) (SB),“X_1 X_2”, 1:1 2:2⟩
⟨((NP (NN)) (SB 被),“X was”, 1:1 2:2⟩
⟨(NP (NN 枪手)) (SB),“The gunman X”, 1:1 1:2⟩
⟨(NP (NN 枪手)) (SB 被),“The gunman was”, 1:1 1:2 2:3⟩

Since we need only to check the alignment consistency, in principle all phrase pairs can be captured by tree-to-string and forest-to-string rules. To lower the complexity for both training and decoding, we impose four restrictions:

1. Both the first and the last symbols in the target string must be aligned to some source symbols.
2. The height of a tree or forest is no greater than h.
3. The number of direct descendants of a node is no greater than c.
4. The number of leaf nodes is no greater than l.

Although possible, it is infeasible to learn auxiliary rules from training data. To extract an auxiliary rule which integrates at least one forest-to-string rule, one need traverse the parse tree upwards until one reaches a node that subsumes the entire forest without violating the alignment consistency. This usually results in very complex auxiliary rules, especially on real-world training data, making both training and decoding very slow. As a result, we construct auxiliary rules in decoding instead.

4 Decoding

Given a source parse tree $T(f_1^J)$, our decoder finds the target yield of the single best derivation that has source yield of $T(f_1^J)$:

$$\begin{aligned}\hat{S} &= \operatorname*{argmax}_{S,A} Pr(T,S,A) \\ &= \operatorname*{argmax}_{S,A} \sum_{\theta_i \in \Theta, c(\Theta)=\langle T,S,A\rangle} \prod_{r_j \in \theta_i} p(r_j) \\ &\approx \operatorname*{argmax}_{S,A,\theta} \prod_{r_j \in \theta, c(\theta)=\langle T,S,A\rangle} p(r_j) \qquad (2)\end{aligned}$$

Input: a source parse tree $T = T(f_1^J)$
for $u := 0$ to $J-1$ **do**
  for $v := 1$ to $J-u$ **do**
    for each T' spanning from v to $v+u$ **do**
      if T' is a tree **then**
        for each usable tree-to-string rule r **do**
          for each derivation θ inferred from r and derivations in *matrix* **do**
            add θ to *matrix*$[v, v+u, root(T')]$
          end for
        end for
        search subcell divisions $\mathcal{D}[v, v+u]$
        for each subcell division $d \in \mathcal{D}[v, v+u]$ **do**
          if d contains at least one forest cell **then**
            construct auxiliary rule r_a
            for each derivation θ inferred from r_a and derivations in *matrix* **do**
              add θ to *matrix*$[v, v+u, root(T')]$
            end for
          end if
        end for
      else
        for each usable forest-to-string rule r **do**
          for each derivation θ inferred from r and derivations in *matrix* **do**
            add θ to *matrix*$[v, v+u, \text{“”}]$
          end for
        end for
        search subcell divisions $\mathcal{D}[v, v+u]$
      end if
    end for
  end for
end for
find the best derivation $\hat{\theta}$ in *matrix*$[1, J, root(T)]$ and get the best translation $\hat{S} = e(\hat{\theta})$
Output: a target string $\hat{S}$

Figure 3: Decoding algorithm.

Figure 3 demonstrates the decoding algorithm. It organizes the derivations into an array *matrix* whose cells *matrix*$[j_1, j_2, X]$ are sets of derivations. $[j_1, j_2, X]$ represents a tree/forest rooted at X spanning from j_1 to j_2. We use the empty string “” to denote the pseudo root of a forest.

Next, we will explain how to infer derivations for a tree/forest provided a usable rule. If $T(r) = T'$, there is only one derivation which contains only the rule r. This usually happens for leaf nodes. If $T(r) \subset T'$, the rule r resorts to derivations from subcells to infer new derivations. Suppose that the decoder is to translate the source tree in Figure 1 and finds a usable rule for $[1, 5, \text{“IP”}]$:

⟨(IP (NP) (VP) (PU)),“X_1 X_2 X_3”, 1:1 2:2 3:3⟩

Subcell Division	Auxiliary Rule		
$[1,1][2,2][3,5]$	(IP (NP) (VP (SB) (VP)) (PU))	$X_1\ X_2\ X_3$	1:1 2:2 3:3 4:3
$[1,2][3,4][5,5]$	(IP (NP) (VP (SB) (VP)) (PU))	$X_1\ X_2\ X_3$	1:1 2:1 3:2 4:3
$[1,3][4,5]$	(IP (NP) (VP (SB) (VP (NP) (VV))) (PU))	$X_1\ X_2$	1:1 2:1 3:1 4:2 5:2
$[1,1][2,5]$	(IP (NP) (VP) (PU))	$X_1\ X_2$	1:1 2:2 3:2

Table 3: Subcell divisions and corresponding auxiliary rules for the source tree in Figure 1

Since the decoding algorithm proceeds in a bottom-up fashion, the uncovered portions have already been translated.

For $[1, 1, \text{“NP”}]$, suppose that we can find a derivation in *matrix*:

⟨(NP (NN 枪手)),“The gunman”, 1:1 1:2⟩

For $[2, 4, \text{“VP”}]$, we find a derivation in *matrix*:

⟨(VP (SB 被) (VP (NP (NN)) (VV 击毙))),
“was killed by X”, 1:1 2:4 3:2⟩
⟨(NN 警察),“police”, 1:1⟩

For $[5, 5, \text{“PU”}]$, we find a derivation in *matrix*:

⟨(PU 。),“.”, 1:1⟩

Henceforth, we get a derivation for $[1, 5, \text{“IP”}]$, shown in Table 1.

A translation rule r is said to be *usable* to an input tree/forest T' if and only if:

1. $T(r) \subseteq T'$, the tree/forest of r is the subgraph of T'.

2. $root(T(r)) = root(T')$, the root sequence of $T(r)$ is identical to that of T'.

For example, the following rules are usable to the tree “(NP (NR 中国) (NN 经济))”:

⟨(NP (NR) (NN)),“$X_1\ X_2$”, 1:2 2:1⟩
⟨(NP (NR 中国) (NN)),“China X”, 1:1 2:2⟩
⟨(NP (NR 中国) (NN 经济)),“China economy”, 1:1 2:2⟩

Similarly, the forest-to-string rule

⟨((NP (NR) (NN)) (VP)),“$X_1\ X_2\ X_3$”, 1:2 2:1 3:3⟩

is usable to the forest

(NP (NR 布什) (NN 总统)) (VP (VV 发表)(NN 演讲))

As we mentioned before, auxiliary rules are special unlexicalized tree-to-string rules that are built in decoding rather than learnt from real-world data. To get an auxiliary rule for a cell, we need first identify its *subcell division*.

A cell sequence $c_1, c_2, \ldots, c_n$ is referred to as a subcell division of a cell c if and only if:

1. $c_1.begin = c.begin$

2. $c_n.end = c.end$

3. $c_j.end + 1 = c_{j+1}.begin, 1 \leq j < n$

Given a subcell division, it is easy to construct the auxiliary rule for a cell. For each subcell, one need transverse the parse tree upwards until one reaches nodes that subsume it. All descendants of these nodes are dropped. The target string consists of only nonterminals, the number of which is identical to that of subcells. To limit the search space, we assume that the alignment between the source tree and the target string is monotone.

Table 3 shows some subcell divisions and corresponding auxiliary rules constructed for the source tree in Figure 1. For simplicity, we ignore the root node label.

There are 2^{n-1} subcell divisions for a cell which has a length of n. We need only consider the sub-

```
Input: a cell [j1, j2], the derivation array matrix,
  the subcell division array D
if j1 = j2 then
    p̂ := 0
    for each derivation θ in matrix[j1, j2, ·] do
        p̂ := max(p(θ), p̂)
    end for
    add {[j1, j2]} : p̂ to D[j1, j2]
else
    if [j1, j2] is a forest cell then
        p̂ := 0
        for each derivation θ in matrix[j1, j2, ·] do
            p̂ := max(p(θ), p̂)
        end for
        add {[j1, j2]} : p̂ to D[j1, j2]
    end if
    for j := j1 to j2 − 1 do
        for each division d1 ∈ D[j1, j] do
            for each division d2 ∈ D[j + 1, j2] do
                create a new division: d := d1 ⊕ d2
                add d to D[j1, j2]
            end for
        end for
    end for
end if
Output: subcell divisions D[j1, j2]
```

Figure 4: Subcell division search algorithm.

cell divisions which contain at least one forest cell because tree-to-string rules have already explored those contain only tree cells.

The actual search algorithm for subcell divisions is shown in Figure 4. We use *matrix*$[j_1, j_2, \cdot]$ to denote all trees or forests spanning from j_1 to j_2. The subcell divisions and their associated probabilities are stored in an array $\mathcal{D}$. We define an operator $\oplus$ between two divisions: their cell sequences are concatenated and the probabilities are accumulated.

As sometimes there are no usable rules available, we introduce *default* rules to ensure that we can always get a translation for any input parse tree. A default rule is a tree-to-string rule [5], built in two ways:

1. If the input tree contains only one node, the target string of the default rule is equal to the source string.

2. If the height of the input tree is greater than one, the tree of the default rule contains only the root node and its direct descendants of the input tree, the string contains only nonterminals, and the alignment is monotone.

To speed up the decoder, we limit the search space by reducing the number of rules used for each cell. There are two ways to limit the rule table size: by a fixed limit a of how many rules are retrieved for each cell, and by a probability threshold α that specify that the rule probability has to be above some value. Also, instead of keeping the full list of derivations for a cell, we store a top-scoring subset of the derivations. This can also be done by a fixed limit b or a threshold β. The subcell division array $\mathcal{D}$, in which divisions containing forest cells have priority over those composed of only tree cells, is pruned by keeping only a-best divisions.

Following Och and Ney (2002), we base our model on log-linear framework and adopt the seven feature functions described in (Liu et al., 2006). It is very important to balance the preference between conventional tree-to-string rules and the newly-introduced forest-to-string and auxiliary rules. As the probabilities of auxiliary rules are not learnt from training data, we add a feature that sums up the node count of auxiliary rules of a derivation to penalize the use of forest-to-string and auxiliary rules.

[5] There are no default rules for forests because only tree-to-string rules are essential to tree-to-string translation models.

5 Experiments

In this section, we report on experiments with Chinese-to-English translation. The training corpus consists of $31,149$ sentence pairs with $843,256$ Chinese words and $949,583$ English words. For the language model, we used SRI Language Modeling Toolkit (Stolcke, 2002) to train a trigram model with modified Kneser-Ney smoothing (Chen and Goodman, 1998) on the $31,149$ English sentences. We selected 571 short sentences from the 2002 NIST MT Evaluation test set as our development corpus, and used the 2005 NIST MT Evaluation test set as our test corpus. Our evaluation metric is BLEU-4 (Papineni et al., 2002), as calculated by the script mteval-v11b.pl with its default setting except that we used case-sensitive matching of n-grams. To perform minimum error rate training (Och, 2003) to tune the feature weights to maximize the system's BLEU score on development set, we used the script optimizeV5IBMBLEU.m (Venugopal and Vogel, 2005).

We ran GIZA++ (Och and Ney, 2000) on the training corpus in both directions using its default setting, and then applied the refinement rule "diag-and" described in (Koehn et al., 2003) to obtain a single many-to-many word alignment for each sentence pair. Next, we employed a Chinese parser written by Deyi Xiong (Xiong et al., 2005) to parse all the $31,149$ Chinese sentences. The parser was trained on articles 1-270 of Penn Chinese Treebank version 1.0 and achieved 79.4% in terms of F1 measure.

Given the word-aligned, source side parsed bilingual corpus, we obtained bilingual phrases using the training toolkits publicly released by Philipp Koehn with its default setting. Then, we applied extraction algorithm described in Figure 2 to extract both tree-to-string and forest-to-string rules by restricting $h = 3$, $c = 5$, and $l = 7$. All the rules, including bilingual phrases, tree-to-string rules, and forest-to-string rules, are filtered for the development and test sets.

According to different levels of lexicalization, we divide translation rules into three categories:

Rule	L	P	U	Total
BP	251,173	0	0	251,173
TR	56,983	41,027	3,529	101,539
FR	16,609	254,346	25,051	296,006

Table 4: Number of rules used in experiments (BP: bilingual phrase, TR: tree-to-string rule, FR: forest-to-string rule; L: lexicalized, P: partial lexicalized, U: unlexicalized).

System	Rule Set	BLEU4
Pharaoh	BP	0.2182 ± 0.0089
Lynx	BP	0.2059 ± 0.0083
	TR	0.2302 ± 0.0089
	TR + BP	0.2346 ± 0.0088
	TR + FR + AR	0.2402 ± 0.0087

Table 5: Comparison of Pharaoh and Lynx with different rule sets.

1. *lexicalized*: all symbols in both the source and target strings are terminals
2. *unlexicalized*: all symbols in both the source and target strings are nonterminals
3. *partial lexicalized*: otherwise

Table 4 shows the statistics of rules used in our experiments. We find that even though forest-to-string rules are introduced the total number (i.e. $73,592$) of lexicalized tree-to-string and forest-to-string rules is still far less than that (i.e. $251,173$) of bilingual phrases. This difference results from the restriction we impose in training that both the first and last symbols in the target string must be aligned to some source symbols. For the forest-to-string rules, partial lexicalized ones are in the majority.

We compared our system Lynx against a freely available phrase-based decoder Pharaoh (Koehn et al., 2003). For Pharaoh, we set $a = 20$, $\alpha = 0$, $b = 100$, $\beta = 10^{-5}$, and distortion limit $dl = 4$. For Lynx, we set $a = 20$, $\alpha = 0$, $b = 100$, and $\beta = 0$. Two postprocessing procedures ran to improve the outputs of both systems: OOVs removal and recapitalization.

Table 5 shows results on test set using Pharaoh and Lynx with different rule sets. Note that Lynx is capable of using only bilingual phrases plus default rules to perform monotone search. The 95% confidence intervals were computed using Zhang's significance tester (Zhang et al., 2004). We modified it to conform to NIST's current definition of the BLEU brevity penalty. We find that Lynx outperforms Pharaoh significantly. The integration of forest-to-string rules achieves an absolute improvement of 1.0% (4.3% relative) over using tree-to-string rules only. This difference is statistically significant ($p < 0.01$). It also achieves better result than treating bilingual phrases as lexicalized tree-to-string rules. To produce the best result of 0.2402, Lynx made use of $26,082$ tree-to-string rules, $9,219$ default rules, $5,432$ forest-to-string rules, and $2,919$ auxiliary rules. This suggests that tree-to-string rules still play a central role, although the integration of forest-to-string and auxiliary rules is really beneficial.

Forest-to-String Rule Set	BLEU4
None	0.2225 ± 0.0085
L	0.2297 ± 0.0081
P	0.2279 ± 0.0083
U	0.2270 ± 0.0087
L + P + U	0.2312 ± 0.0082

Table 6: Effect of lexicalized, partial lexicalized, and unlexicalized forest-to-string rules.

Table 6 demonstrates the effect of forest-to-string rules with different lexicalization levels. We set $a = 3$, $\alpha = 0$, $b = 10$, and $\beta = 0$. The second row "None" shows the result of using only tree-to-string rules. "L" denotes using tree-to-string rules and lexicalized forest-to-string rules. Similarly, "L+P+U" denotes using tree-to-string rules and all forest-to-string rules. We find that lexicalized forest-to-string rules are more useful.

6 Conclusion

In this paper, we introduce forest-to-string rules to capture non-syntactic phrase pairs that are usually unaccessible to traditional tree-to-string translation models. With the help of auxiliary rules, forest-to-string rules can be integrated into tree-to-string models to offer more general derivations. Experiment results show that the tree-to-string model augmented with forest-to-string rules significantly outperforms

the original model which allows tree-to-string rules only.

Our current rule extraction algorithm attaches the unaligned target words to the nearest ascendants that subsume them. This constraint hampers the expressive power of our model. We will try a more general way as suggested in (Galley et al., 2006), making no a priori assumption about assignment and using EM training to learn the probability distribution. We will also conduct experiments on large scale training data to further examine our design philosophy.

Abstract

This paper presents a Function Word centered, Syntax-based (FWS) solution to address phrase ordering in the context of statistical machine translation (SMT). Motivated by the observation that function words often encode grammatical relationship among phrases within a sentence, we propose a probabilistic synchronous grammar to model the ordering of function words and their left and right arguments. We improve phrase ordering performance by lexicalizing the resulting rules in a small number of cases corresponding to function words. The experiments show that the FWS approach consistently outperforms the baseline system in ordering function words' arguments and improving translation quality in both perfect and noisy word alignment scenarios.

1 Introduction

The focus of this paper is on function words, a class of words with little intrinsic meaning but is vital in expressing grammatical relationships among words within a sentence. Such encoded grammatical information, often implicit, makes function words pivotal in modeling structural divergences, as projecting them in different languages often result in long-range structural changes to the realized sentences.

Just as a foreign language learner often makes mistakes in using function words, we observe that current machine translation (MT) systems often perform poorly in ordering function words' arguments; lexically correct translations often end up reordered incorrectly. Thus, we are interested in modeling the structural divergence encoded by such function words. A key finding of our work is that modeling the ordering of the dependent arguments of function words results in better translation quality.

Most current systems use statistical knowledge obtained from corpora in favor of rich natural language knowledge. Instead of using syntactic knowledge to determine function words, we approximate this by equating the most frequent words as function words. By explicitly modeling phrase ordering around these frequent words, we aim to capture the most important and prevalent ordering productions.

2 Related Work

A good translation should be both faithful with adequate lexical choice to the source language and fluent in its word ordering to the target language. In pursuit of better translation, phrase-based models (Och and Ney, 2004) have significantly improved the quality over classical word-based models (Brown et al., 1993). These multiword phrasal units contribute to fluency by inherently capturing intra-phrase reordering. However, despite this progress, inter-phrase reordering (especially long distance ones) still poses a great challenge to statistical machine translation (SMT).

The basic phrase reordering model is a simple unlexicalized, context-insensitive distortion penalty model (Koehn et al., 2003). This model assumes little or no structural divergence between language pairs, preferring the original, translated order by penalizing reordering. This simple model works well when properly coupled with a well-trained language

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 712–719,
Prague, Czech Republic, June 2007.

model, but is otherwise impoverished without any lexical evidence to characterize the reordering.

To address this, lexicalized context-sensitive models incorporate contextual evidence. The local prediction model (Tillmann and Zhang, 2005) models structural divergence as the relative position between the translation of two neighboring phrases. Other further generalizations of orientation include the global prediction model (Nagata et al., 2006) and distortion model (Al-Onaizan and Papineni, 2006).

However, these models are often fully lexicalized and sensitive to individual phrases. As a result, they are not robust to unseen phrases. A careful approximation is vital to avoid data sparseness. Proposals to alleviate this problem include utilizing bilingual phrase cluster or words at the phrase boundary (Nagata et al., 2006) as the phrase identity.

The benefit of introducing lexical evidence without being fully lexicalized has been demonstrated by a recent state-of-the-art *formally* syntax-based model[1], Hiero (Chiang, 2005). Hiero performs phrase ordering by using linked non-terminal symbols in its synchronous CFG production rules coupled with lexical evidence. However, since it is difficult to specify a well-defined rule, Hiero has to rely on weak heuristics (i.e., length-based thresholds) to extract rules. As a result, Hiero produces grammars of enormous size. Watanabe et al. (2006) further reduces the grammar's size by enforcing all rules to comply with Greibach Normal Form.

Taking the lexicalization an intuitive a step forward, we propose a novel, finer-grained solution which models the content and context information encoded by function words - approximated by high frequency words. Inspired by the success of syntax-based approaches, we propose a synchronous grammar that accommodates gapping production rules, while focusing on the statistical modeling in relation to function words. We refer to our approach as the Function Word-centered Syntax-based approach (FWS). Our FWS approach is different from Hiero in two key aspects. First, we use only a small set of high frequency lexical items to lexicalize non-terminals in the grammar. This results in a much smaller set of rules compared to Hiero,

[1]Chiang (2005) used the term "formal" to indicate the use of synchronous grammar but without linguistic commitment

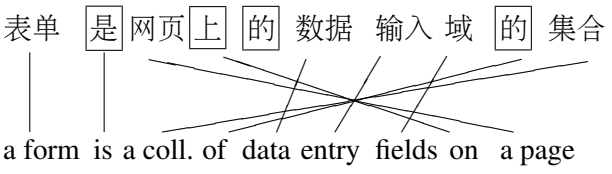

Figure 1: A Chinese-English sentence pair.

greatly reducing the computational overhead that arises when moving from phrase-based to syntax-based approach. Furthermore, by modeling only high frequency words, we are able to obtain reliable statistics even in small datasets. Second, as opposed to Hiero, where phrase ordering is done implicitly alongside phrase translation and lexical weighting, we directly model the reordering process using orientation statistics.

The FWS approach is also akin to (Xiong et al., 2006) in using a synchronous grammar as a reordering constraint. Instead of using Inversion Transduction Grammar (ITG) (Wu, 1997) directly, we will discuss an ITG extension to accommodate gapping.

3 Phrase Ordering around Function Words

We use the following Chinese (c) to English (e) translation in Fig.1 as an illustration to conduct an inquiry to the problem. Note that the sentence translation requires some translations of English words to be ordered far from their original position in Chinese. Recovering the correct English ordering requires the inversion of the Chinese postpositional phrase, followed by the inversion of the first smaller noun phrase, and finally the inversion of the second larger noun phrase. Nevertheless, the correct ordering can be recovered if the position and the semantic roles of the arguments of the boxed function words were known. Such a function word centered approach also hinges on knowing the correct phrase boundaries for the function words' arguments and which reorderings are given precedence, in case of conflicts.

We propose modeling these sources of knowledge using a statistical formalism. It includes 1) a model to capture bilingual orientations of the left and right arguments of these function words; 2) a model to approximate correct reordering sequence; and 3) a model for finding constituent boundaries of

the left and right arguments. Assuming that the most frequent words in a language are function words, we can apply orientation statistics associated with these words to reorder their adjacent left and right neighbors. We follow the notation in (Nagata et al., 2006) and define the following bilingual orientation values given two neighboring source (Chinese) phrases: Monotone-Adjacent (MA); Reverse-Adjacent (RA); Monotone-Gap (MG); and Reverse-Gap (RG). The first clause (monotone, reverse) indicates whether the target language translation order follows the source order; the second (adjacent, gap) indicates whether the source phrases are adjacent or separated by an intervening phrase on the target side.

Table 1 shows the orientation statistics for several function words. Note that we separate the statistics for left and right arguments to account for differences in argument structures: some function words take a single argument (e.g., prepositions), while others take two or more (e.g., copulas). To handle other reordering decisions not explicitly encoded (i.e., lexicalized) in our FWS model, we introduce a universal token $\mathcal{U}$, to be used as a backoff statistic when function words are absent.

For example, orientation statistics for 是 (to be) overwhelmingly suggests that the English translation of its surrounding phrases is identical to its Chinese ordering. This reflects the fact that the arguments of copulas in both languages are realized in the same order. The orientation statistics for postposition 上 (on) suggests inversion which captures the divergence between Chinese postposition to the English preposition. Similarly, the dominant orientation for particle 的 (of) suggests the noun-phrase shift from modified-modifier to modifier-modified, which is common when translating Chinese noun phrases to English.

Taking all parts of the model, which we detail later, together with the knowledge in Table 1, we demonstrate the steps taken to translate the example in Fig. 2. We highlight the function words with boxed characters and encapsulate content words as indexed symbols. As shown, orientation statistics from function words alone are adequate to recover the English ordering - in practice, content words also influence the reordering through a language model. One can think of the FWS approach as a foreign language learner with limited knowledge about Chinese grammar but fairly knowledgable about the role of Chinese function words.

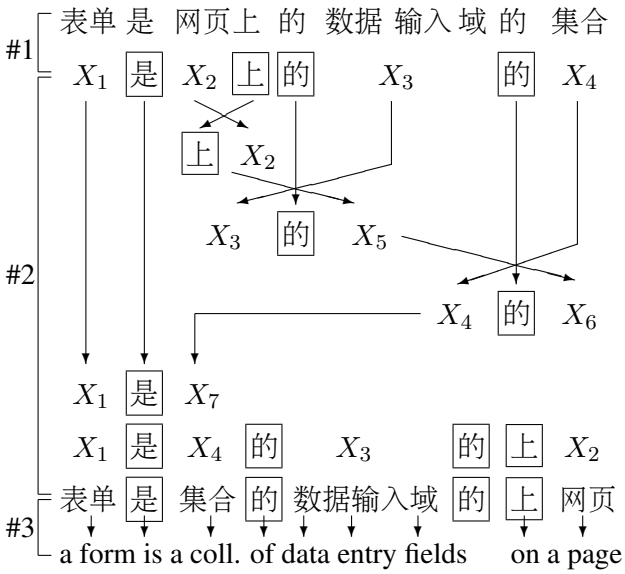

Figure 2: In Step 1, function words (boxed characters) and content words (indexed symbols) are identified. Step 2 reorders phrases according to knowledge embedded in function words. A new indexed symbol is introduced to indicate previously reordered phrases for conciseness. Step 3 finally maps Chinese phrases to their English translation.

4 The FWS Model

We first discuss the extension of standard ITG to accommodate gapping and then detail the statistical components of the model later.

4.1 Single Gap ITG (SG-ITG)

The FWS model employs a synchronous grammar to describe the admissible orderings.

The utility of ITG as a reordering constraint for most language pairs, is well-known both empirically (Zens and Ney, 2003) and analytically (Wu, 1997), however ITG's *straight* (monotone) and *inverted* (reverse) rules exhibit strong cohesiveness, which is inadequate to express orientations that require gaps. We propose SG-ITG that follows Wellington et al. (2006)'s suggestion to model at most one gap.

We show the rules for SG-ITG below. Rules 1-3 are identical to those defined in standard ITG, in which monotone and reverse orderings are represented by square and angle brackets, respectively.

Rank	Word	unigram	MA_L	RA_L	MG_L	RG_L	MA_R	RA_R	MG_R	RG_R

-	$\mathcal{U}$	0.0002	**0.76**	0.14	0.06	0.05	**0.74**	0.13	0.07	0.06

Table 1: Orientation statistics and unigram probability of selected frequent Chinese words in the HIT corpus. Subscripts L/R refers to lexical unit's orientation with respect to its left/right neighbor. $\mathcal{U}$ is the universal token used in back-off for $N = 128$. Dominant orientations of each word are in **bold**.

(1) $X \rightarrow c/e$
(2) $X \rightarrow [XX]$ (3) $X \rightarrow \langle XX \rangle$
(4) $X^{\diamond} \rightarrow [X \diamond X]$ (5) $X^{\diamond} \rightarrow \langle X \diamond X \rangle$
(6) $X \rightarrow [X * X]$ (7) $X \rightarrow \langle X * X \rangle$

SG-ITG introduces two new sets of rules: gapping (Rules 4-5) and dovetailing (Rules 6-7) that deal specifically with gaps. On the RHS of the gapping rules, a diamond symbol ($\diamond$) indicates a gap, while on the LHS, it emits a superscripted symbol $X^{\diamond}$ to indicate a gapped phrase (plain Xs without superscripts are thus contiguous phrases). Gaps in $X^{\diamond}$ are eventually filled by actual phrases via dovetailing (marked with an $*$ on the RHS).

Fig.3 illustrates gapping and dovetailing rules using an example where two Chinese adjectival phrases are translated into a single English subordinate clause. SG-ITG can generate the correct ordering by employing gapping followed by dovetailing, as shown in the following simplified trace:

$X_1^{\diamond}$ $\rightarrow$ ⟨ 1997 的 第一版, **V.1** $\diamond$ **1997** ⟩
$X_2^{\diamond}$ $\rightarrow$ ⟨ 1998 的 第二版, **V.2** $\diamond$ **1998** ⟩
X_3 $\rightarrow$ $[X_1 * X_2]$
$\rightarrow$ [1997 的 第一版 和 1998 的 第二版,
V.1 $\diamond$ **1997** $*$ **V.2** $\diamond$ **1998**]
$\rightarrow$ 1997 的第一版和1998 的第二版,
V.1 and **V.2** that were released in **1997** and **1998**

where $X_1^{\diamond}$ and $X_2^{\diamond}$ each generate the translation of their respective Chinese noun phrase using gapping and X_3 generates the English subclause by dovetailing the two gapped phrases together.

Thus far, the grammar is unlexicalized, and does not incorporate any lexical evidence. Now we modify the grammar to introduce lexicalized function words to SG-ITG. In practice, we introduce a new set of lexicalized non-terminal symbols Y_i, $i \in \{1...N\}$, to represent the top N most-frequent words in the vocabulary; the existing unlexicalized X is now reserved for content words. This difference does not inherently affect the structure of the grammar, but rather lexicalizes the statistical model.

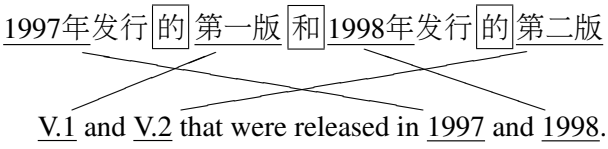

Figure 3: An example of an alignment that can be generated only by allowing gaps.

In this way, although different Y_is follow the same production rules, they are associated with different statistics. This is reflected in Rules 8-9. Rule 8 emits the function word; Rule 9 reorders the arguments around the function word, resembling our orientation model (see Section 4.2) where a function word influences the orientation of its left and right arguments. For clarity, we omit notation that denotes which rules have been applied (monotone, reverse; gapping, dovetailing).

(8) $Y_i \rightarrow c/e$ (9) $X \rightarrow XY_iX$

In practice, we replace Rule 9 with its equivalent 2-normal form set of rules (Rules 10-13). Finally, we introduce rules to handle back-off (Rules 14-16) and upgrade (Rule 17). These allow SG-ITG to re-

vert function words to normal words and vice versa.

(10) $R \rightarrow Y_i X$ (11) $L \rightarrow X Y_i$
(12) $X \rightarrow L X$ (13) $X \rightarrow X R$
(14) $Y_i \rightarrow X$ (15) $R \rightarrow X$
(16) $L \rightarrow X$ (17) $X \rightarrow Y_{\mathcal{U}}$

Back-off rules are needed when the grammar has to reorder two adjacent function words, where one set of orientation statistics must take precedence over the other. The example in Fig.1 illustrates such a case where the orientation of 上 (on) and 的 (of) compete for influence. In this case, the grammar chooses to use 的 (of) and reverts the function word 上 (on) to the unlexicalized form.

The upgrade rule is used for cases where there are two adjacent phrases, both of which are not function words. Upgrading allows either phrase to act as a function word, making use of the universal word's orientation statistics to reorder its neighbor.

4.2 Statistical model

We now formulate the FWS model as a statistical framework. We replace the deterministic rules in our SG-ITG grammar with probabilistic ones, elevating it to a stochastic grammar. In particular, we develop the three sub models (see Section 3) which influence the choice of production rules for ordering decision. These models operate on the 2-norm rules, where the RHS contains one function word and its argument (except in the case of the phrase boundary model). We provide the intuition for these models next, but their actual form will be discussed in the next section on training.

1) Orientation Model *ori(o|H,Y_i)***:** This model captures the preference of a function word Y_i to a particular orientation $o \in \{MA, RA, MG, RG\}$ in reordering its $H \in \{left, right\}$ argument X. The parameter H determines which set of Y_i's statistics to use (left or right); the model consults Y_i's left orientation statistic for Rules 11 and 13 where X precedes Y_i, otherwise Y_i's right orientation statistic is used for Rules 10 and 12.

2) Preference Model *pref(Y_i)***:** This model arbitrates reordering in the cases where two function words are adjacent and the backoff rules have to decide which function word takes precedence, reverting the other to the unlexicalized X form. This model prefers the function word with higher unigram probability to take the precedence.

3) Phrase Boundary Model *pb(X)***:** This model is a penalty-based model, favoring the resulting alignment that conforms to the source constituent boundary. It penalizes Rule 1 if the terminal rule X emits a Chinese phrase that violates the boundary ($pb = e^{-1}$), otherwise it is inactive ($pb = 1$).

These three sub models act as features alongside seven other standard SMT features in a log-linear model, resulting in the following set of features $\{f_1, \ldots, f_{10}\}$: f_1) orientation $ori(o|H, Y_i)$; f_2) preference $pref(Y_i)$; f_3) phrase boundary $pb(X)$; f_4) language model $lm(e)$; $f_5 - f_6$) phrase translation score $\phi(e|c)$ and its inverse $\phi(c|e)$; $f_7 - f_8$) lexical weight $lex(e|c)$ and its inverse $lex(c|e)$; f_9) word penalty wp; and f_{10}) phrase penalty pp.

The translation is then obtained from the most probable derivation of the stochastic SG-ITG. The formula for a single derivation is shown in Eq. (18), where $X_1, X_2, ..., X_L$ is a sequence of rules with $w(X_l)$ being the weight of each particular rule X_l. $w(X_l)$ is estimated through a log-linear model, as in Eq. (19), with all the abovementioned features where λ_j reflects the contribution of each feature f_j.

$$(18) \quad P(X_1, ..., X_L) = \prod_{l=1}^{L} w(X_l)$$

$$(19) \quad w(X_l) = \prod_{j=1}^{10} f_j(X_l)^{\lambda_j}$$

5 Training

We train the orientation and preference models from statistics of a training corpus. To this end, we first derive the event counts and then compute the relative frequency of each event. The remaining phrase boundary model can be modeled by the output of a standard text chunker, as in practice it is simply a constituent boundary detection mechanism together with a penalty scheme.

The events of interest to the orientation model are (Y_i, o) tuples, where $o \in \{MA, RA, MG, RG\}$ is an orientation value of a particular function word Y_i. Note that these tuples are not directly observable from training data. Hence, we need an algorithm to derive (Y_i, o) tuples from a parallel corpus. Since both left and right statistics share identical training steps, thus we omit references to them.

The algorithm to derive (Y_i, o) involves several steps. First, we estimate the bi-directional alignment

by running GIZA++ and applying the "grow-diag-final" heuristic. Then, the algorithm enumerates all Y_i and determines its orientation o with respect to its argument X to derive (Y_i, o). To determine o, the algorithm inspects the monotonicity (monotone or reverse) and adjacency (adjacent or gap) between Y_i's and X's alignments.

Monotonicity can be determined by looking at the Y_i's alignment with respect to the most fine-grained level of X (i.e., word level alignment). However, such a heuristic may inaccurately suggest gap orientation. Figure 1 illustrates this problem when deriving the orientation for the second 的 (of). Looking only at the word alignment of its left argument 域 (fields) incorrectly suggests a gapped orientation, where the alignment of 数据输入 (data entry) intervened. It is desirable to look at the alignment of 数据输入域 (data entry fields) at the phrase level, which suggests the correct adjacent orientation instead.

To address this issue, the algorithm uses gapping conservatively by utilizing the consistency constraint (Och and Ney, 2004) to suggest phrase level alignment of X. The algorithm exhaustively grows consistent blocks containing the most fine-grained level of X not including Y_i. Subsequently, it merges each hypothetical argument with the Y_i's alignment. The algorithm decides that Y_i has a gapped orientation only if all merged blocks violate the consistency constraint, concluding an adjacent orientation otherwise.

With the event counts $C(Y_i, o)$ of tuple (Y_i, o), we estimate the orientation model for Y_i and $\mathcal{U}$ using Eqs. (20) and (21). We also estimate the preference model with word unigram counts $C(Y_i)$ using Eqs. (22) and (23), where V indicates the vocabulary size.

$$(20)\ ori(o|Y_i) = C(Y_i, o)/C(Y_i, \cdot), i \leqslant N$$

$$(21)\ ori(o|\mathcal{U}) = \sum_{i>N} C(Y_i, o) / \sum_{i>N} C(Y_i, \cdot)$$

$$(22)\ pref(Y_i) = C(Y_i)/C(\cdot), i \leqslant N$$

$$(23)\ pref(\mathcal{U}) = 1/(V-N) \sum_{i>N} C(Y_i)/C(\cdot)$$

Samples of these statistics are found in Table 1 and have been used in the running examples. For instance, the statistic $ori(RA_L|的) = 0.52$, which is the dominant one, suggests that the grammar inversely order 的(of)'s left argument; while in our illustration of backoff rules in Fig.1, the grammar chooses 的(of) to take precedence since $pref(的) > pref(上)$.

6 Decoding

We employ a bottom-up CKY parser with a beam to find the derivation of a Chinese sentence which maximizes Eq. (18). The English translation is then obtained by post-processing the best parse.

We set the beam size to 30 in our experiment and further constrain reordering to occur within a window of 10 words. Our decoder also prunes entries that violate the following constraints: 1) each entry contains at most one gap; 2) any gapped entries must be dovetailed at the next level higher; 3) an entry spanning the whole sentence must not contain gaps.

The score of each newly-created entry is derived from the scores of its parts accordingly. When scoring entries, we treat gapped entries as contiguous phrases by ignoring the gap symbol and rely on the orientation model to penalize such entries. This allows a fair score comparison between gapped and contiguous entries.

7 Experiments

We would like to study how the FWS model affects 1) the ordering of phrases around function words; 2) the overall translation quality. We achieve this by evaluating the FWS model against a baseline system using two metrics, namely, orientation accuracy and BLEU respectively.

We define the orientation accuracy of a (function) word as the accuracy of assigning correct orientation values to both its left and right arguments. We report the aggregate for the top 1024 most frequent words; these words cover 90% of the test set.

We devise a series of experiments and run it in two scenarios - manual and automatic alignment - to assess the effects of using perfect or real-world input. We utilize the HIT bilingual computer manual corpus, which has been manually aligned, to perform Chinese-to-English translation (see Table 2). Manual alignment is essential as we need to measure orientation accuracy with respect to a gold standard.

		Chinese	English
train	words	145,731	135,032
(7K sentences)	vocabulary	5,267	8,064
dev	words	13,986	14,638
(1K sentences)	untranslatable	486 (3.47%)	
test	words	27,732	28,490
(2K sentences)	untranslatable	935 (3.37%)	

Table 2: Statistics for the HIT corpus.

A language model is trained using the SRILM-Toolkit, and a text chunker (Chen et al., 2006) is applied to the Chinese sentences in the test and dev sets to extract the constituent boundaries necessary for the phrase boundary model. We run minimum error rate training on dev set using Chiang's toolkit to find a set of parameters that optimizes BLEU score.

7.1 Perfect Lexical Choice

Here, the task is simplified to recovering the correct order of the English sentence from the scrambled Chinese order. We trained the orientation model using manual alignment as input. The aforementioned decoder is used with phrase translation, lexical mapping and penalty features turned off.

Table 4 compares orientation accuracy and BLEU between our FWS model and the baseline. The baseline (lm+d) employs a language model and distortion penalty features, emulating the standard Pharaoh model. We study the behavior of the FWS model with different numbers of lexicalized items N. We start with the language model alone (N=0) and incrementally add the orientation (+ori), preference (+ori+pref) and phrase boundary models (+ori+pref+pb).

As shown, the language model alone is relatively weak, assigning the correct orientation in only 62.28% of the cases. A closer inspection reveals that the lm component aggressively promotes reverse reorderings. Including a distortion penalty model (the baseline) improves the accuracy to 72.55%. This trend is also apparent for the BLEU score.

When we incorporate the FSW model, including just the most frequent word (Y_1=的), we see improvement. This model promotes non-monotone reordering conservatively around Y_1 (where the dominant statistic suggests reverse ordering). Increasing the value of N leads to greater improvement. The most effective improvement is obtained by increasing N to 128. Additional (marginal) improvement is obtained at the expense of modeling an additional 900+ lexical items. We see these results as validating our claim that modeling the top few most frequent words captures most important and prevalent ordering productions.

pharaoh (dl=5)	22.44 ± 0.94
+ori	23.80 ± 0.98
+ori+pref	23.85 ± 1.00
+ori+pref+pb	23.86 ± 1.08

Table 3: BLEU score with the 95% confidence intervals based on (Zhang and Vogel, 2004). All improvement over the baseline (row 1) are statistically significant under paired bootstrap resampling.

Lastly, we study the effect of the pref and pb features. The inclusion of both sub models has little affect on orientation accuracy, but it improves BLEU consistently (although not significantly). This suggests that both models correct the mistakes made by the ori model while preserving the gain. They are not as effective as the addition of the basic orientation model as they only play a role when two lexicalized entries are adjacent.

7.2 Full SMT experiments

Here, all knowledge is automatically trained on the train set, and as a result, the input word alignment is noisy. As a baseline, we use the state-of-the-art phrase-based Pharaoh decoder. For a fair comparison, we run minimum error rate training for different distortion limits from 0 to 10 and report the best parameter (dl=5) as the baseline.

We use the phrase translation table from the baseline and perform an identical set of experiments as the perfect lexical choice scenario, except that we only report the result for N=128, due to space constraint. Table 3 reports the resulting BLEU scores.

As shown, the FWS model improves BLEU score significantly over the baseline. We observe the same trend as the one in perfect lexical choice scenario where top 128 most frequent words provides the majority of improvement. However, the pb features yields no noticeable improvement unlike in prefect lexical choice scenario; this is similar to the findings in (Koehn et al., 2003).

		N=0	N=1	N=4	N=16	N=64	N=128	N=256	N=1024
Orientation Acc. (%)	lm+d	72.55							
	+ori	62.28	76.52	76.58	77.38	77.54	**78.17**	77.76	*78.38*
	+ori+pref		76.66	76.82	77.57	77.74	**78.13**	77.94	*78.54*
	+ori+pref+pb		76.70	76.85	77.58	77.70	**78.20**	77.94	*78.56*
BLEU	lm+d	75.13							
	+ori	66.54	77.54	77.57	78.22	78.48	**78.76**	78.58	*79.20*
	+ori+pref		77.60	77.70	78.29	78.65	**78.77**	78.70	*79.30*
	+ori+pref+pb		77.69	77.80	78.34	78.65	**78.93**	78.79	*79.30*

Table 4: Results using perfect aligned input. Here, (lm+d) is the baseline; (+ori), (+ori+pref) and (+ori+pref+pb) are different FWS configurations. The results of the model (where N is varied) that features the largest gain are **bold**, whereas the highest score is *italicized*.

8 Conclusion

In this paper, we present a statistical model to capture the grammatical information encoded in function words. Formally, we develop the Function Word Syntax-based (FWS) model, a probabilistic synchronous grammar, to encode the orientation statistics of arguments to function words. Our experimental results shows that the FWS model significantly improves the state-of-the-art phrase-based model.

We have touched only the surface benefits of modeling function words. In particular, our proposal is limited to modeling function words in the source language. We believe that conditioning on both source and target pair would result in more fine-grained, accurate orientation statistics.

From our error analysis, we observe that 1) reordering may span several levels and the preference model does not handle this phenomena well; 2) correctly reordered phrases with incorrect boundaries severely affects BLEU score and the phrase boundary model is inadequate to correct the boundaries especially for cases of long phrase. In future, we hope to address these issues while maintaining the benefits offered by modeling function words.

Abstract

Inspired by previous preprocessing approaches to SMT, this paper proposes a novel, probabilistic approach to reordering which combines the merits of syntax and phrase-based SMT. Given a source sentence and its parse tree, our method generates, by tree operations, an n-best list of reordered inputs, which are then fed to standard phrase-based decoder to produce the optimal translation. Experiments show that, for the NIST MT-05 task of Chinese-to-English translation, the proposal leads to BLEU improvement of 1.56%.

1 Introduction

The phrase-based approach has been considered the default strategy to Statistical Machine Translation (SMT) in recent years. It is widely known that the phrase-based approach is powerful in local lexical choice and word reordering within short distance. However, long-distance reordering is problematic in phrase-based SMT. For example, the distance-based reordering model (Koehn et al., 2003) allows a decoder to translate in non-monotonous order, under the constraint that the distance between two phrases translated consecutively does not exceed a limit known as *distortion limit*. In theory the distortion limit can be assigned a very large value so that all possible reorderings are allowed, yet in practise it is observed that too high a distortion limit not only harms efficiency but also translation performance (Koehn et al., 2005). In our own experiment setting, the best distortion limit for Chinese-English translation is 4. However, some ideal translations exhibit reorderings longer than such distortion limit. Consider the sentence pair in NIST MT-2005 test set shown in figure 1(a): after translating the word "修补/*mend*", the decoder should 'jump' across six words and translate the last phrase "关系 裂缝/*fissures in the relationship*". Therefore, while short-distance reordering is under the scope of the distance-based model, long-distance reordering is simply out of the question.

A terminological remark: In the rest of the paper, we will use the terms *global reordering* and *local reordering* in place of long-distance reordering and short-distance reordering respectively. The distinction between long and short distance reordering is solely defined by distortion limit.

Syntax[1] is certainly a potential solution to global reordering. For example, for the last two Chinese phrases in figure 1(a), simply swapping the two children of the NP node will produce the correct word order on the English side. However, there are also reorderings which do not agree with syntactic analysis. Figure 1(b) shows how our phrase-based decoder[2] obtains a good English translation by reordering two blocks. It should be noted that the second Chinese block "结束 时" and its English counterpart "*at the end of*" are not constituents at all.

In this paper, our interest is the value of syntax in reordering, and the major statement is that syntactic information is useful in handling global reordering

[1] Here by syntax it is meant linguistic syntax rather than formal syntax.

[2] The decoder is introduced in section 6.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 720–727,
Prague, Czech Republic, June 2007.

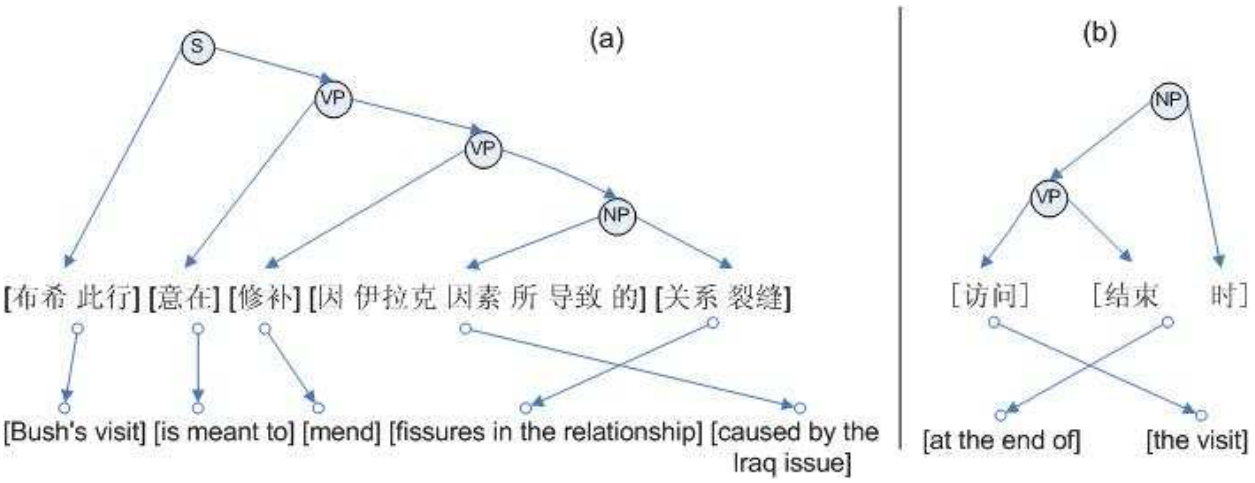

Figure 1: Examples on how syntax (a) helps and (b) harms reordering in Chinese-to-English translation
The lines and nodes on the top half of the figures show the phrase structure of the Chinese sentences, while the links on the bottom half of the figures show the alignments between Chinese and English phrases. Square brackets indicate the boundaries of blocks found by our decoder.

and it achieves better MT performance on the basis of the standard phrase-based model. To prove it, we developed a hybrid approach which preserves the strength of phrase-based SMT in local reordering as well as the strength of syntax in global reordering.

Our method is inspired by previous *preprocessing* approaches like (Xia and McCord, 2004), (Collins et al., 2005), and (Costa-jussà and Fonollosa, 2006), which split translation into two stages:

$$S \rightarrow S' \rightarrow T \quad (1)$$

where a sentence of the source language (SL), S, is first reordered with respect to the word order of the target language (TL), and then the reordered SL sentence S' is translated as a TL sentence T by monotonous translation.

Our first contribution is a new translation model as represented by formula 2:

$$S \rightarrow n \times S' \rightarrow n \times T \rightarrow \hat{T} \quad (2)$$

where an n-best list of S', instead of only one S', is generated. The reason of such change will be given in section 2. Note also that the translation process $S' \rightarrow T$ is not monotonous, since the distance-based model is needed for local reordering. Our second contribution is our definition of the best translation:

$$\arg\max_{T} \exp(\lambda_r \log Pr(S \rightarrow S') + \sum_i \lambda_i F_i(S' \rightarrow T))$$

where F_i are the features in the standard phrase-based model and $Pr(S \rightarrow S')$ is our new feature, viz. the probability of reordering S as S'. The details of this model are elaborated in sections 3 to 6. The settings and results of experiments on this new model are given in section 7.

2 Related Work

There have been various attempts to syntax-based SMT, such as (Yamada and Knight, 2001) and (Quirk et al., 2005). We do not adopt these models since a lot of subtle issues would then be introduced due to the complexity of syntax-based decoder, and the impact of syntax on reordering will be difficult to single out.

There have been many reordering strategies under the phrase-based camp. A notable approach is lexicalized reordering (Koehn et al., 2005) and (Tillmann, 2004). It should be noted that this approach achieves the best result within certain distortion limit and is therefore not a good model for global reordering.

There are a few attempts to the preprocessing approach to reordering. The most notable ones are (Xia and McCord, 2004) and (Collins et al., 2005), both of which make use of linguistic syntax in the preprocessing stage. (Collins et al., 2005) analyze German clause structure and propose six types

of rules for transforming German parse trees with respect to English word order. Instead of relying on manual rules, (Xia and McCord, 2004) propose a method in learning patterns of rewriting SL sentences. This method parses training data and uses some heuristics to align SL phrases with TL ones. From such alignment it can extract rewriting patterns, of which the units are words and POSs. The learned rewriting rules are then applied to rewrite SL sentences before monotonous translation.

Despite the encouraging results reported in these papers, the two attempts share the same shortcoming that their reordering is deterministic. As pointed out in (Al-Onaizan and Papineni, 2006), these strategies make hard decisions in reordering which cannot be undone during decoding. That is, the choice of reordering is independent from other translation factors, and once a reordering mistake is made, it cannot be corrected by the subsequent decoding.

To overcome this weakness, we suggest a method to 'soften' the hard decisions in preprocessing. The essence is that our preprocessing module generates n-best S's rather than merely one S'. A variety of reordered SL sentences are fed to the decoder so that the decoder can consider, to certain extent, the interaction between reordering and other factors of translation. The entire process can be depicted by formula 2, recapitulated as follows:

$$S \rightarrow n \times S' \rightarrow n \times T \rightarrow \hat{T}.$$

Apart from their deterministic nature, the two previous preprocessing approaches have their own weaknesses. (Collins et al., 2005) count on manual rules and it is suspicious if reordering rules for other language pairs can be easily made. (Xia and McCord, 2004) propose a way to learn rewriting patterns, nevertheless the units of such patterns are words and their POSs. Although there is no limit to the length of rewriting patterns, due to data sparseness most patterns being applied would be short ones. Many instances of global reordering are therefore left unhandled.

3 The Acquisition of Reordering Knowledge

To avoid this problem, we give up using rewriting patterns and design a form of reordering knowledge which can be directly applied to parse tree nodes. Given a node N on the parse tree of an SL sentence, the required reordering knowledge should enable the preprocessing module to determine how probable the children of N are reordered.[3] For simplicity, let us first consider the case of binary nodes only. Let N_1 and N_2, which yield phrases p_1 and p_2 respectively, be the child nodes of N. We want to determine the order of p_1 and p_2 with respect to their TL counterparts, $T(p_1)$ and $T(p_2)$. The knowledge for making such a decision can be learned from a word-aligned parallel corpus. There are two questions involved in obtaining training instances:

- How to define $T(p_i)$?
- How to define the order of $T(p_i)$s?

For the first question, we adopt a similar method as in (Fox, 2002): given an SL phrase $p_s = s_1 \dots s_i \dots s_n$ and a word alignment matrix A, we can enumerate the set of TL words $\{t_i : t_i \epsilon A(s_i)\}$, and then arrange the words in the order as they appear in the TL sentence. Let $\mathit{first}(t)$ be the first word in this sorted set and $\mathit{last}(t)$ be the last word. $T(p_s)$ is defined as the phrase $\mathit{first}(t) \dots \mathit{last}(t)$ in the TL sentence. Note that $T(p_s)$ may contain words not in the set $\{t_i\}$.

The question of the order of two TL phrases is not a trivial one. Since a word alignment matrix usually contains a lot of noises as well as one-to-many and many-to-many alignments, two TL phrases may overlap with each other. For the sake of the quality of reordering knowledge, if $T(p_1)$ and $T(p_2)$ overlap, then the node N with children N_1 and N_2 is not taken as a training instance. Obviously it will greatly reduce the amount of training input. To remedy data sparseness, less probable alignment points are removed so as to minimize overlapping phrases, since, after removing some alignment point, one of the TL phrases may become shorter and the two phrases may no longer overlap. The implementation is similar to the idea of *lexical weight* in (Koehn et al., 2003): all points in the alignment matrices of the entire training corpus are collected to calculate the probabilistic distribution, $P(t|s)$, of some TL word

[3] Some readers may prefer the expression *the subtree rooted at node N* to *node N*. The latter term is used in this paper for simplicity.

t given some SL word s. Any pair of overlapping $T(p_i)$s will be redefined by iteratively removing less probable word alignments until they no longer overlap. If they still overlap after all one/many-to-many alignments have been removed, then the refinement will stop and N, which covers p_is, is no longer taken as a training instance.

In sum, given a bilingual training corpus, a parser for the SL, and a word alignment tool, we can collect all binary parse tree nodes, each of which may be an instance of the required reordering knowledge. The next question is what kind of reordering knowledge can be formed out of these training instances. Two forms of reordering knowledge are investigated:

1. Reordering Rules, which have the form

$$Z:\ X\ Y \Rightarrow \begin{cases} X\ Y & Pr(\text{IN-ORDER}) \\ Y\ X & Pr(\text{INVERTED}) \end{cases}$$

   where Z is the phrase label of a binary node and X and Y are the phrase labels of Z's children, and $Pr(\text{INVERTED})$ and $Pr(\text{IN-ORDER})$ are the probability that X and Y are inverted on TL side and that not inverted, respectively. The probability figures are estimated by Maximum Likelihood Estimation.

2. Maximum Entropy (ME) Model, which does the binary classification whether a binary node's children are inverted or not, based on a set of features over the SL phrases corresponding to the two children nodes. The features that we investigated include the leftmost, rightmost, head, and context words[4], and their POSs, of the SL phrases, as well as the phrase labels of the SL phrases and their parent.

4 The Application of Reordering Knowledge

After learning reordering knowledge, the preprocessing module can apply it to the parse tree, t_S, of an SL sentence S and obtain the n-best list of S'. Since a ranking of S' is needed, we need some way to score each S'. Here probability is used as the scoring metric. In this section it is explained how the n-best reorderings of S and their associated scores/probabilites are computed.

Let us first look into the scoring of a particular reordering. Let $Pr(p \rightarrow p')$ be the probability of reordering a phrase p into p'. For a phrase q yielded by a non-binary node, there is only one 'reordering' of q, viz. q itself, thus $Pr(q \rightarrow q) = 1$. For a phrase p yielded by a binary node N, whose left child N_1 has reorderings p_1^i and right child N_2 has the reorderings p_2^j $(1 \leq i, j \leq n)$, p' has the form $p_1^i p_2^j$ or $p_2^j p_1^i$. Therefore, $Pr(p \rightarrow p') =$

$$\begin{cases} Pr(\text{IN-ORDER}) \times Pr(p_1^i \rightarrow p_1^{i'}) \times Pr(p_2^j \rightarrow p_2^{j'}) \\ Pr(\text{INVERTED}) \times Pr(p_2^j \rightarrow p_2^{j'}) \times Pr(p_1^i \rightarrow p_1^{i'}) \end{cases}$$

The figures $Pr(\text{IN-ORDER})$ and $Pr(\text{INVERTED})$ are obtained from the learned reordering knowledge. If reordering knowledge is represented as rules, then the required probability is the probability associated with the rule that can apply to N. If reordering knowledge is represented as an ME model, then the required probability is:

$$P(r|N) = \frac{\exp(\sum_i \lambda_i f_i(N, r))}{\sum_{r'} \exp(\sum_i \lambda_i f_i(N, r'))}$$

where $r \epsilon \{\text{IN-ORDER}, \text{INVERTED}\}$, and f_i's are features used in the ME model.

Let us turn to the computation of the n-best reordering list. Let $R(N)$ be the number of reorderings of the phrase yielded by N, then:

$$R(N) = \begin{cases} 2R(N_1)R(N_2) & \text{if } N \text{ has children } N_1, N_2 \\ 1 & \text{otherwise} \end{cases}$$

It is easily seen that the number of S's increases exponentially. Fortunately, what we need is merely an n-best list rather than a full list of reorderings. Starting from the leaves of t_S, for each node N covering phrase p, we only keep track of the n p's that have the highest reordering probability. Thus $R(N) \leq n$. There are at most $2n^2$ reorderings for any node and only the top-scored n reorderings are recorded. The n-best reorderings of S, i.e. the n-best reorderings of the yield of the root node of t_S, can be obtained by this efficient bottom-up method.

5 The Generalization of Reordering Knowledge

In the last two sections reordering knowledge is learned from and applied to binary parse tree nodes

[4]The context words of the SL phrases are the word to the left of the left phrase and the word to the right of the right phrase.

only. It is not difficult to generalize the theory of reordering knowledge to nodes of other branching factors. The case of binary nodes is simple as there are only two possible reorderings. The case of 3-ary nodes is a bit more complicated as there are six.[5] In general, an n-ary node has $n!$ possible reorderings of its children. The maximum entropy model has the same form as in the binary case, except that there are more classes of reordering patterns as n increases. The form of reordering rules, and the calculation of reordering probability for a particular node, can also be generalized easily.[6] The only problem for the generalized reordering knowledge is that, as there are more classes, data sparseness becomes more severe.

6 The Decoder

The last three sections explain how the $S \rightarrow n \times S'$ part of formula 2 is done. The $S' \rightarrow T$ part is simply done by our re-implementation of PHARAOH (Koehn, 2004). Note that non-monotonous translation is used here since the distance-based model is needed for local reordering. For the $n \times T \rightarrow \hat{T}$ part, the factors in consideration include the score of T returned by the decoder, and the reordering probability $Pr(S \rightarrow S')$. In order to conform to the log-linear model used in the decoder, we integrate the two factors by defining the total score of T as formula 3:

$$\exp(\lambda_r \log Pr(S \rightarrow S') + \sum_i \lambda_i F_i(S' \rightarrow T)) \quad (3)$$

The first term corresponds to the contribution of syntax-based reordering, while the second term that of the features F_i used in the decoder. All the feature weights (λs) were trained using our implementation of Minimum Error Rate Training (Och, 2003). The final translation $\hat{T}$ is the T with the highest total score.

[5] Namely, $N_1N_2N_3$, $N_1N_3N_2$, $N_2N_1N_3$, $N_2N_3N_1$, $N_3N_1N_2$, and $N_3N_2N_1$, if the child nodes in the original order are N_1, N_2, and N_3.

[6] For example, the reordering probability of a phrase $p = p_1p_2p_3$ generated by a 3-ary node N is

$$Pr(r) \times Pr(p_1^i) \times Pr(p_2^j) \times Pr(p_3^k)$$

where r is one of the six reordering patterns for 3-ary nodes.

It is observed in pilot experiments that, for a lot of long sentences containing several clauses, only one of the clauses is reordered. That is, our greedy reordering algorithm (c.f. section 4) has a tendency to focus only on a particular clause of a long sentence.

The problem was remedied by modifying our decoder such that it no longer translates a sentence at once; instead the new decoder does:

1. split an input sentence S into clauses $\{C_i\}$;
2. obtain the reorderings among $\{C_i\}$, $\{S_j\}$;
3. for each S_j, do
   (a) for each clause C_i in S_j, do
      i. reorder C_i into n-best C_i's,
      ii. translate each C_i' into $T(C_i')$,
      iii. select $\hat{T}(C_i')$;
   (b) concatenate $\{\hat{T}(C_i')\}$ into T_j;
4. select $\hat{T}_j$.

Step 1 is done by checking the parse tree if there are any IP or CP nodes[7] immediately under the root node. If yes, then all these IPs, CPs, and the remaining segments are treated as clauses. If no, then the entire input is treated as one single clause. Step 2 and step 3(a)(i) still follow the algorithm in section 4. Step 3(a)(ii) is trivial, but there is a subtle point about the calculation of language model score: the language model score of a translated clause is not independent from other clauses; it should take into account the last few words of the previous translated clause. The best translated clause $\hat{T}(C_i')$ is selected in step 3(a)(iii) by equation 3. In step 4 the best translation $\hat{T}_j$ is

$$\arg\max_{T_j} \exp(\lambda_r \log Pr(S \rightarrow S_j) + \sum_i score(T(C_i'))).$$

7 Experiments

7.1 Corpora

Our experiments are about Chinese-to-English translation. The NIST MT-2005 test data set is used for evaluation. (Case-sensitive) BLEU-4 (Papineni et al., 2002) is used as the evaluation metric. The

[7] IP stands for *inflectional phrase* and CP for *complementizer phrase*. These two types of phrases are *clauses* in terms of the Government and Binding Theory.

test set and development set of NIST MT-2002 are merged to form our development set. The training data for both reordering knowledge and translation table is the one for NIST MT-2005. The GIGAWORD corpus is used for training language model. The Chinese side of all corpora are segmented into words by our implementation of (Gao et al., 2003).

7.2 The Preprocessing Module

As mentioned in section 3, the preprocessing module for reordering needs a parser of the SL, a word alignment tool, and a Maximum Entropy training tool. We use the Stanford parser (Klein and Manning, 2003) with its default Chinese grammar, the GIZA++ (Och and Ney, 2000) alignment package with its default settings, and the ME tool developed by (Zhang, 2004).

Section 5 mentions that our reordering model can apply to nodes of any branching factor. It is interesting to know how many branching factors should be included. The distribution of parse tree nodes as shown in table 1 is based on the result of parsing the Chinese side of NIST MT-2002 test set by the Stanford parser. It is easily seen that the majority of parse tree nodes are binary ones. Nodes with more than 3 children seem to be negligible. The 3-ary nodes occupy a certain proportion of the distribution, and their impact on translation performance will be shown in our experiments.

7.3 The decoder

The data needed by our Pharaoh-like decoder are translation table and language model. Our 5-gram language model is trained by the SRI language modeling toolkit (Stolcke, 2002). The translation table is obtained as described in (Koehn et al., 2003), i.e. the alignment tool GIZA++ is run over the training data in both translation directions, and the two alignment matrices are integrated by the GROW-DIAG-FINAL method into one matrix, from which phrase translation probabilities and lexical weights of both directions are obtained.

5	ME ((3)+phrase label)	30.12	30.30
6	ME ((4)+context)	30.24	30.76

Table 3: Tests on Various Reordering Models
The 3rd column comprises the BLEU scores obtained by reordering binary nodes only, the 4th column the scores by reordering both binary and 3-ary nodes. The features used in the ME models are explained in section 3.

The most important system parameter is, of course, distortion limit. Pilot experiments using the standard phrase-based model show that the optimal distortion limit is 4, which was therefore selected for all our experiments.

7.4 Experiment Results and Analysis

The baseline of our experiments is the standard phrase-based model, which achieves, as shown by table 2, the BLEU score of 29.22. From the same table we can also see that the clause splitting mechanism introduced in section 6 does not significantly affect translation performance.

Two sets of experiments were run. The first set, of which the results are shown in table 3, tests the effect of different forms of reordering knowledge. In all these tests only the top 10 reorderings of each clause are generated. The contrast between tests 1 and 2 shows that ME modeling of reordering outperforms reordering rules. Tests 3 and 4 show that phrase labels can achieve as good performance as the lexical features of mere leftmost and rightmost words. However, when more lexical features

Table 5: Tests on Various Constraints

are added (tests 4 and 6), phrase labels can no longer compete with lexical features. Surprisingly, test 5 shows that the combination of phrase labels and lexical features is even worse than using either phrase labels or lexical features only.

Apart from quantitative evaluation, let us consider the translation example of test 6 shown in table 4. To generate the correct translation, a phrase-based decoder should, after translating the word "增加" as "*increase*", jump to the last word "投资(investment)". This is obviously out of the capability of the baseline model, and our approach can accomplish the desired reordering as expected.

By and large, the experiment results show that no matter what kind of reordering knowledge is used, the preprocessing of syntax-based reordering does greatly improve translation performance, and that the reordering of 3-ary nodes is crucial.

The second set of experiments test the effect of some constraints. The basic setting is the same as that of test 6 in the first experiment set, and reordering is applied to both binary and 3-ary nodes. The results are shown in table 5.

In test (a), the constraint is that the module does not consider any reordering of a node if the yield of this node contains not more than four words. The underlying rationale is that reordering within distortion limit should be left to the distance-based model during decoding, and syntax-based reordering should focus on global reordering only. The result shows that this hypothesis does not hold. In practice syntax-based reordering also helps local reordering. Consider the translation example of test (a) shown in table 6. Both the baseline model and our model translate in the same way up to the word "围绕" (which is incorrectly translated as "*and*"). From this point, the proposed preprocessing model correctly jump to the last phrase "进行 了 讨论/*discussed*", while the baseline model fail to do so for the best translation. It should be noted, however, that there are only four words between "围绕" and the last phrase, and the desired order of decoding is within the capability of the baseline system. With the feature of syntax-based global reordering, a phrase-based decoder performs better even with respect to local reordering. It is because syntax-based reordering adds more weight to a hypothesis that moves words across longer distance, which is penalized by the distance-based model.

In test (b) distortion limit is set as 0; i.e. reordering is done merely by syntax-based preprocessing. The worse result is not surprising since, after all, preprocessing discards many possibilities and thus reduce the search space of the decoder. Some local reordering model is still needed during decoding.

Finally, test (c) shows that translation performance does not improve significantly by raising the number of reorderings. This implies that our approach is very efficient in that only a small value of n is capable of capturing the most important global reordering patterns.

8 Conclusion and Future Work

This paper proposes a novel, probabilistic approach to reordering which combines the merits of syntax and phrase-based SMT. On the one hand, global reordering, which cannot be accomplished by the

phrase-based model, is enabled by the tree operations in preprocessing. On the other hand, local reordering is preserved and even strengthened in our approach. Experiments show that, for the NIST MT-05 task of Chinese-to-English translation, the proposal leads to BLEU improvement of 1.56%.

Despite the encouraging experiment results, it is still not very clear how the syntax-based and distance-based models complement each other in improving word reordering. In future we need to investigate their interaction and identify the contribution of each component. Moreover, it is observed that the parse trees returned by a full parser like the Stanford parser contain too many nodes which seem not be involved in desired reorderings. Shallow parsers should be tried to see if they improve the quality of reordering knowledge.

Machine Translation by Triangulation: Making Effective Use of Multi-Parallel Corpora

Trevor Cohn and **Mirella Lapata**
Human Computer Research Centre, School of Informatics
University of Edinburgh
{tcohn,mlap}@inf.ed.ac.uk

Abstract

Current phrase-based SMT systems perform poorly when using small training sets. This is a consequence of unreliable translation estimates and low coverage over source and target phrases. This paper presents a method which alleviates this problem by exploiting multiple translations of the same source phrase. Central to our approach is *triangulation*, the process of translating from a source to a target language via an intermediate third language. This allows the use of a much wider range of parallel corpora for training, and can be combined with a standard phrase-table using conventional smoothing methods. Experimental results demonstrate BLEU improvements for triangulated models over a standard phrase-based system.

1 Introduction

Statistical machine translation (Brown et al., 1993) has seen many improvements in recent years, most notably the transition from word- to phrase-based models (Koehn et al., 2003). Modern SMT systems are capable of producing high quality translations when provided with large quantities of training data. With only a small training sample, the translation output is often inferior to the output from using larger corpora because the translation algorithm must rely on more sparse estimates of phrase frequencies and must also 'back-off' to smaller sized phrases. This often leads to poor choices of target phrases and reduces the coherence of the output. Unfortunately, parallel corpora are not readily available in large quantities, except for a small subset of the world's languages (see Resnik and Smith (2003) for discussion), therefore limiting the potential use of current SMT systems.

In this paper we provide a means for obtaining more reliable translation frequency estimates from small datasets. We make use of *multi-parallel* corpora (sentence aligned parallel texts over three or more languages). Such corpora are often created by international organisations, the United Nations (UN) being a prime example. They present a challenge for current SMT systems due to their relatively moderate size and domain variability (examples of UN texts include policy documents, proceedings of meetings, letters, *etc.*). Our method translates each target phrase, $\mathbf{t}$, first to an intermediate language, $\mathbf{i}$, and then into the source language, $\mathbf{s}$. We call this two-stage translation process *triangulation* (Kay, 1997). We present a probabilistic formulation through which we can estimate the desired phrase translation distribution (phrase-table) by marginalisation, $p(\mathbf{s}|\mathbf{t}) = \sum_{\mathbf{i}} p(\mathbf{s}, \mathbf{i}|\mathbf{t})$.

As with conventional smoothing methods (Koehn et al., 2003; Foster et al., 2006), triangulation increases the robustness of phrase translation estimates. In contrast to smoothing, our method alleviates data sparseness by exploring additional multi-parallel data rather than adjusting the probabilities of existing data. Importantly, triangulation provides us with separately estimated phrase-tables which could be further smoothed to provide more reliable distributions. Moreover, the triangulated phrase-tables can be easily combined with the standard source-target phrase-table, thereby improving the coverage over unseen source phrases.

As an example, consider Figure 1 which shows the coverage of unigrams and larger n-gram phrases when using a standard source target phrase-table, a triangulated phrase-table with one (*it*) and nine languages (*all*), and a combination of standard and triangulated phrase-tables (*all+standard*). The phrases were harvested from a small French-English bitext

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 728–735,
Prague, Czech Republic, June 2007.

and evaluated against a test set. Although very few small phrases are unknown, the majority of larger phrases are unseen. The *Italian* and *all* results show that triangulation alone can provide similar or improved coverage compared to the standard source-target model; further improvement is achieved by combining the triangulated and standard models (*all+standard*). These models and datasets will be described in detail in Section 3.

We also demonstrate that triangulation can be used on its own, that is *without a source-target distribution*, and still yield acceptable translation output. This is particularly heartening, as it provides a means of translating between the many "low density" language pairs for which we don't yet have a source-target bitext. This allows SMT to be applied to a much larger set of language pairs than was previously possible.

In the following section we provide an overview of related work. Section 3 introduces a generative formulation of triangulation. We present our evaluation framework in Section 4 and results in Section 5.

2 Related Work

The idea of using multiple source languages for improving the translation quality of the target language dates back at least to Kay (1997), who observed that ambiguities in translating from one language onto another may be resolved if a translation into some third language is available. Systems which have used this notion of triangulation typically create several candidate sentential target translations for source sentences via different languages. A single translation is then selected by finding the candidate that yields the best overall score (Och and Ney, 2001; Utiyama and Isahara, 2007) or by co-training (Callison-Burch and Osborne, 2003). This ties in with recent work on ensemble combinations of SMT systems, which have used alignment techniques (Matusov et al., 2006) or simple heuristics (Eisele, 2005) to guide target sentence selection and generation. Beyond SMT, the use of an intermediate language as a translation aid has also found application in cross-lingual information retrieval (Gollins and Sanderson, 2001).

Callison-Burch et al. (2006) propose the use of paraphrases as a means of dealing with unseen source phrases. Their method acquires paraphrases by identifying candidate phrases in the source language, translating them into multiple target languages, and then back to the source. Unknown source phrases are substituted by the back-translated paraphrases and translation proceeds on the paraphrases.

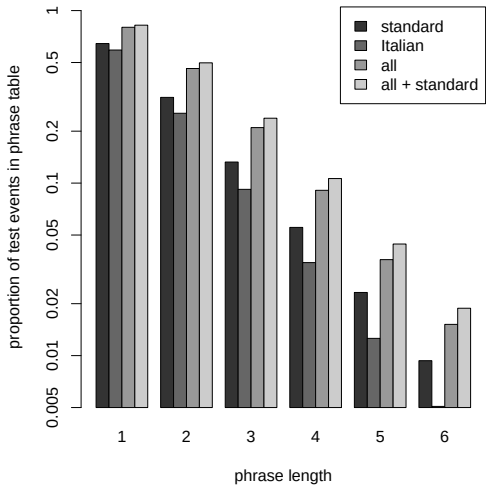

Figure 1: Coverage of *fr* → *en* test phrases using a 10,000 sentence bitext. The standard model is shown alongside triangulated models using one (Italian) or nine other languages (all).

In line with previous work, we exploit multiple source corpora to alleviate data sparseness and increase translation coverage. However, we differ in several important respects. Our method operates over phrases rather than sentences. We propose a generative formulation which treats triangulation not as a post-processing step but as part of the translation model itself. The induced phrase-table entries are fed directly into the decoder, thus avoiding the additional inefficiencies of merging the output of several translation systems.

Although related to Callison-Burch et al. (2006) our method is conceptually simpler and more general. Phrase-table entries are created via multiple source languages without the intermediate step of paraphrase extraction, thereby reducing the exposure to compounding errors. Our phrase-tables may well contain paraphrases but these are naturally induced as part of our model, without extra processing effort. Furthermore, we improve the translation estimates for both seen and unseen phrase-table entries, whereas Callison-Burch et al. concentrate solely on unknown phrases. In contrast to Utiyama and Isahara (2007), we employ a large number of intermediate languages and demonstrate how triangulated phrase-tables can be combined with standard phrase-tables to improve translation output.

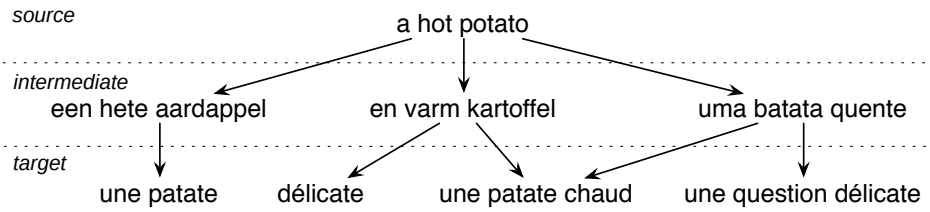

Figure 2: Triangulation between English (source) and French (target), showing three phrases in Dutch, Danish and Portuguese, respectively. Arrows denote phrases aligned in a language pair and also the generative translation process.

3 Triangulation

We start with a motivating example before formalising the mechanics of triangulation. Consider translating the English phrase *a hot potato*[1] into French, as shown in Figure 2. In our corpus this English phrase occurs only three times. Due to errors in the word alignment the phrase was not included in the English-French phrase-table. Triangulation first translates *hot potato* into a set of intermediate languages (Dutch, Danish and Portuguese are shown in the figure), and then these phrases are further translated into the target language (French). In the example, four different target phrases are obtained, all of which are useful phrase-table entries. We argue that the redundancy introduced by a large suite of other languages can correct for errors in the word alignments and also provide greater generalisation, since the translation distribution is estimated from a richer set of data-points. For example, instances of the Danish *en varm kartoffel* may be used to translate several English phrases, not only *a hot potato*.

In general we expect that a wider range of possible translations are found for any source phrase, simply due to the extra layer of indirection. So, if a source phrase tends to align with two different target phrases, then we would also expect it to align with two phrases in the 'intermediate' language. These intermediate phrases should then each align with two target phrases, yielding up to four target phrases. Consequently, triangulation will often produce more varied translation distributions than the standard source-target approach.

3.1 Formalisation

We now formalise triangulation as a generative probabilistic process operating independently on phrase pairs. We start with the conditional distribution over three languages, $p(\mathbf{s}, \mathbf{i}|\mathbf{t})$, where the arguments denote phrases in the source, intermediate and target language, respectively. From this distribution, we can find the desired conditional over the source-target pair by marginalising out the intermediate phrases:[2]

$$p(\mathbf{s}|\mathbf{t}) = \sum_{\mathbf{i}} p(\mathbf{s}|\mathbf{i}, \mathbf{t}) p(\mathbf{i}|\mathbf{t}) \approx \sum_{\mathbf{i}} p(\mathbf{s}|\mathbf{i}) p(\mathbf{i}|\mathbf{t}) \quad (1)$$

where (1) imposes a simplifying conditional independence assumption: the intermediate phrase fully represents the information (semantics, syntax, *etc.*) in the source phrase, rendering the target phrase redundant in $p(\mathbf{s}|\mathbf{i}, \mathbf{t})$.

Equation (1) requires that all phrases in the intermediate-target bitext must also be found in the source-intermediate bitext, such that $p(\mathbf{s}|\mathbf{i})$ is defined. Clearly this will often not be the case. In these situations we could back-off to another distribution (by discarding part, or all, of the conditioning context), however we take a more pragmatic approach and ignore the missing phrases. This problem of missing contexts is uncommon in multi-parallel corpora, but is more common when the two bitexts are drawn from different sources.

While triangulation is intuitively appealing, it may suffer from a few problems. Firstly, as with any SMT approach, the translation estimates are based on noisy automatic word alignments. This leads to many errors and omissions in the phrase-table. With a standard source-target phrase-table these errors are only encountered once, however with triangulation they are encountered twice, and therefore the errors will compound. This leads to more noisy estimates than in the source-target phrase-table.

Secondly, the increased exposure to noise means that triangulation will omit a greater proportion of large or rare phrases than the standard method. An

[1] An idiom meaning a situation for which no one wants to claim responsibility.

[2] Equation (1) is used with the source and target arguments reversed to give $p(\mathbf{t}|\mathbf{s})$.

alignment error in either of the source-intermediate or intermediate-target bitexts can prevent the extraction of a source-target phrase pair. This effect can be seen in Figure 1, where the coverage of the Italian triangulated phrase-table is worse than the standard source-target model, despite the two models using the same sized bitexts. As we explain in the next section, these problems can be ameliorated by using the triangulated phrase-table in conjunction with a standard phrase-table.

Finally, another potential problem stems from the independence assumption in (1), which may be an oversimplification and lead to a loss of information. The experiments in Section 5 show that this effect is only mild.

3.2 Merging the phrase-tables

Once induced, the triangulated phrase-table can be usefully combined with the standard source-target phrase-table. The simplest approach is to use linear interpolation to combine the two (or more) distributions, as follows:

$$p(\mathbf{s}, \mathbf{t}) = \sum_j \lambda_j p_j(\mathbf{s}, \mathbf{t}) \quad (2)$$

where each joint distribution, p_j, has a non-negative weight, λ_j, and the weights sum to one. The joint distribution for triangulated phrase-tables is defined in an analogous way to Equation (1). We expect that the standard phrase-table should be allocated a higher weight than triangulated phrase-tables, as it will be less noisy. The joint distribution is now conditionalised to yield $p(\mathbf{s}|\mathbf{t})$ and $p(\mathbf{t}|\mathbf{s})$, which are both used as features in the decoder. Note that the resulting conditional distribution will be drawn solely from one input distribution when the conditioning context is unseen in the remaining distributions. This may lead to an over-reliance on unreliable distributions, which can be ameliorated by smoothing (e.g., Foster et al. (2006)).

As an alternative to linear interpolation, we also employ a weighted product for phrase-table combination:

$$p(\mathbf{s}|\mathbf{t}) \propto \prod_j p_j(\mathbf{s}|\mathbf{t})^{\lambda_j} \quad (3)$$

This has the same form used for log-linear training of SMT decoders (Och, 2003), which allows us to treat each distribution as a feature, and learn the mixing weights automatically. Note that we must individually smooth the component distributions in (3) to stop zeros from propagating. For this we use Simple Good-Turing smoothing (Gale and Sampson, 1995) for each distribution, which provides estimates for zero count events.

4 Experimental Design

Corpora We used the Europarl corpus (Koehn, 2005) for experimentation. This corpus consists of about 700,000 sentences of parliamentary proceedings from the European Union in eleven European languages. We present results on the full corpus for a range of language pairs. In addition, we have created smaller parallel corpora by sub-sampling 10,000 sentence bitexts for each language pair. These corpora are likely to have minimal overlap — about 1.5% of the sentences will be shared between each pair. However, the phrasal overlap is much greater (10 to 20%), which allows for triangulation using these common phrases. This training setting was chosen to simulate translating to or from a "low density" language, where only a few small independently sourced parallel corpora are available. These bitexts were used for direct translation and triangulation. All experimental results were evaluated on the ACL/WMT 2005[3] set of 2,000 sentences, and are reported in BLEU percentage-points.

Decoding Pharaoh (Koehn, 2003), a beam-search decoder, was used to maximise:

$$\mathbf{T}^* = \arg\max_{\mathbf{T}} \prod_j f_j(\mathbf{T}, \mathbf{S})^{\lambda_j} \quad (4)$$

where $\mathbf{T}$ and $\mathbf{S}$ denote a target and source sentence respectively. The parameters, λ_j, were trained using minimum error rate training (Och, 2003) to maximise the BLEU score (Papineni et al., 2002) on a 150 sentence development set. We used a standard set of features, comprising a 4-gram language model, distance based distortion model, forward and backward translation probabilities, forward and backward lexical translation scores and the phrase- and word-counts. The translation models and lexical scores were estimated on the training corpus which was automatically aligned using Giza++ (Och et al., 1999) in both directions between source and target and symmetrised using the growing heuristic (Koehn et al., 2003).

[3]For details see `http://www.statmt.org/wpt05/mt-shared-task`.

Lexical weights The lexical translation score is used for smoothing the phrase-table translation estimate. This represents the translation probability of a phrase when it is decomposed into a series of independent word-for-word translation steps (Koehn et al., 2003), and has proven a very effective feature (Zens and Ney, 2004; Foster et al., 2006). Pharaoh's lexical weights require access to word-alignments; calculating these alignments between the source and target words in a phrase would prove difficult for a triangulated model. Therefore we use a modified lexical score, corresponding to the maximum IBM model 1 score for the phrase pair:

$$lex(\mathbf{t}|\mathbf{s}) = \frac{1}{Z} \max_{\mathbf{a}} \prod_{k} p(t_k|s_{a_k}) \qquad (5)$$

where the maximisation[4] ranges over all one-to-many alignments and Z normalises the score by the number of possible alignments.

The lexical probability is obtained by interpolating a relative frequency estimate on the source-target bitext with estimates from triangulation, in the same manner used for phrase translations in (1) and (2). The addition of the lexical probability feature yielded a substantial gain of up to two BLEU points over a basic feature set.

5 Experimental Results

The evaluation of our method was motivated by three questions: (1) How do different training requirements affect the performance of the triangulated models presented in this paper? We expect performance gains with triangulation on small and moderate datasets. (2) Is machine translation output influenced by the choice of the intermediate language/s? Here, we would like to evaluate whether the number and choice of intermediate languages matters. (3) What is the quality of the triangulated phrase-table? In particular, we are interested in the resulting distribution and whether it is sufficiently distinct from the standard phrase-table.

5.1 Training requirements

Before reporting our results, we briefly discuss the specific choice of model for our experiments. As mentioned in Section 3, our method combines the triangulated phrase-table with the standard source-target one. This is desired in order to compensate for the noise incurred by the triangulation process. We used two combination methods, namely linear interpolation (see (2)) and a weighted geometric mean (see (3)).

	standard	interp	+indic	separate
en → *de*	12.03	12.66	12.95	12.25
fr → *en*	23.02	24.63	23.86	23.43

Table 1: Different feature sets used with the 10K training corpora, using a single language (*es*) for triangulation. The columns refer to standard, uniform interpolation, interpolation with 0-1 indicator features, and separate phrase-tables, respectively.

Table 1 reports the results for two translation tasks when triangulating with a single language (*es*) using three different feature sets, each with different translation features. The *interpolation* model uses uniform linear interpolation to merge the standard and triangulated phrase-tables. Non-uniform mixtures did not provide consistent gains, although, as expected, biasing towards the standard phrase-table was more effective than against. The *indicator* model uses the same interpolated distribution along with a series of 0-1 indicator features to identify the source of each event, *i.e.*, if each $(\mathbf{s}, \mathbf{t})$ pair is present in phrase-table j. We also tried per-context features with similar results. The *separate* model has a separate feature for each phrase-table.

All three feature sets improve over the standard source-target system, while the interpolated features provided the best overall performance. The relatively poorer performance of the separate model is perhaps surprising, as it is able to differentially weight the component distributions; this is probably due to MERT not properly handling the larger feature sets. In all subsequent experiments we report results using linear interpolation.

As a proof of concept, we first assessed the effect of triangulation on corpora consisting of 10,000 sentence bitexts. We expect triangulation to deliver performance gains on small corpora, since a large number of phrase-table entries will be unseen. In Table 2 each entry shows the BLEU score when using the standard phrase-table and the absolute improvement when using triangulation. Here we have used three languages for triangulation ($it \cup \{de, en, es, fr\} \setminus \{s, t\}$). The source-target languages were chosen so as to mirror the evaluation setup of NAACL/WMT. The translation tasks range

[4]The maximisation in (5) can be replaced with a sum with similar experimental results.

s ↓ t →	*de*	*en*	*es*	*fr*
de	-	17.58	16.84	18.06
	-	+1.20	+1.99	+1.94
en	12.45	-	23.83	24.05
	+1.22	-	+1.04	+1.48
es	12.31	23.83	-	32.69
	+2.24	+1.35	-	+0.85
fr	11.76	23.02	31.22	-
	+2.41	+2.24	+1.30	-

Table 2: BLEU improvements over the standard phrase-table (top) when interpolating with three triangulated phrase-tables (bottom) on the small training sample.

from easy (*es* → *fr*) to very hard (*de* → *en*). In all cases triangulation resulted in an improvement in translation quality, with the highest gains observed for the most difficult tasks (to and from German). For these tasks the standard systems have poor coverage (due in part to the sizeable vocabulary of German phrases) and therefore the gain can be largely explained by the additional coverage afforded by the triangulated phrase-tables.

To test whether triangulation can also improve performance of larger corpora we ran six separate translation tasks on the full Europarl corpus. The results are presented in Table 3, for a single triangulation language used alone (*triang*) or uniformly interpolated with the standard phrase-table (*interp*). These results show that triangulation can produce high quality translations on its own, which is noteworthy, as it allows for SMT between a much larger set of language pairs. Using triangulation in conjunction with the standard phrase-table improved over the standard system in most instances, and only degraded performance once. The improvement is largest for the German tasks which can be explained by triangulation providing better robustness to noisy alignments (which are often quite poor for German) and better estimates of low-count events. The difficulty of aligning German with the other languages is apparent from the Giza++ perplexity: the final Model 4 perplexities for German are quite high, as much as double the perplexity for more easily aligned language pairs (*e.g.*, Spanish-French).

Figure 3 shows the effect of triangulation on different sized corpora for the language pair *fr* → *en*. It presents learning curves for the standard system and a triangulated system using one language (*es*). As can be seen, gains from triangulation only diminish slightly for larger training corpora, and that

task	standard	interm	triang	interp
de → *en*	23.85	*es*	23.48	**24.36**
en → *de*	17.24	*es*	16.28	**17.42**
es → *en*	30.48	*fr*	29.06	**30.52**
en → *es*	**29.09**	*fr*	28.19	**29.09**
fr → *en*	29.66	*es*	29.59	**30.36**
en → *fr*	**30.07**	*es*	28.94	29.62

Table 3: Results on the full training set showing triangulation with a single language, both alone (triang) and alongside a standard model (interp).

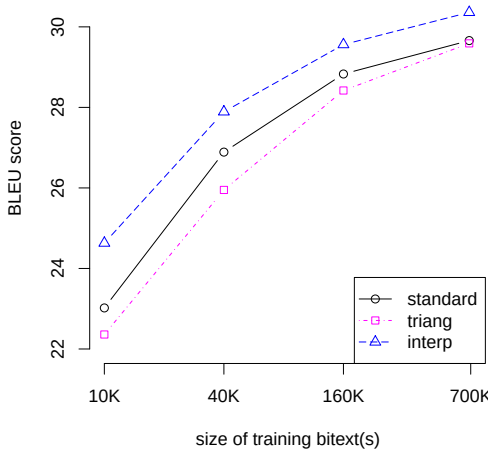

Figure 3: Learning curve for *fr* → *en* translation for the standard source-target model and a triangulated model using Spanish as an intermediate language.

the purely triangulated models have very competitive performance. The gain from interpolation with a triangulated model is roughly equivalent to having twice as much training data.

Finally, notice that triangulation may benefit when the sentences in each bitext are drawn from the same source, in that there are no unseen 'intermediate' phrases, and therefore (1) can be easily evaluated. We investigate this by examining the robustness of our method in the face of disjoint bitexts. The concepts contained in each bitext will be more varied, potentially leading to better coverage of the target language. In lieu of a study on different domain bitexts which we plan for the future, we bisected the Europarl corpus for *fr* → *en*, triangulating with Spanish. The triangulated models were presented with *fr-es* and *es-en* bitexts drawn from either the same half of the corpus or from different halves, resulting in scores of 28.37 and 28.13, respectively.[5] These results indicate that triangulation is effective

[5]The baseline source-target system on one half has a score of 28.85.

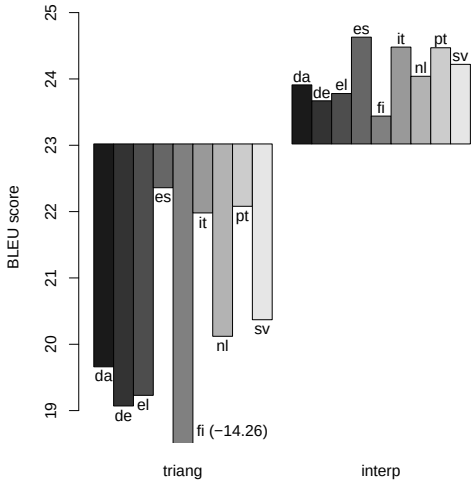

Figure 4: Comparison of different triangulation languages for *fr* → *en* translation, relative to the standard model (10K training sample). The bar for *fi* has been truncated to fit on the graph.

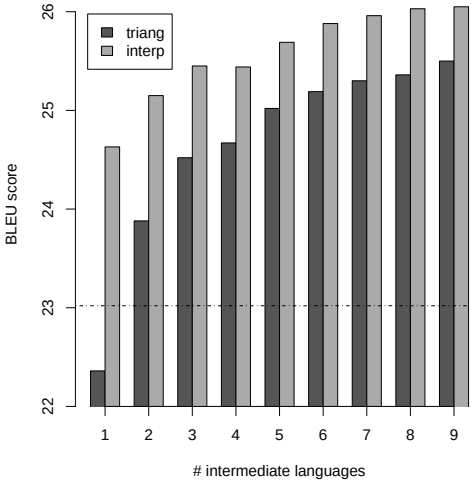

Figure 5: Increasing the number of intermediate languages used for triangulation increases performance for *fr* → *en* (10K training sample). The dashed line shows the BLEU score for the standard phrase-table.

for disjoint bitexts, although ideally we would test this with independently sourced parallel texts.

5.2 The choice of intermediate languages

The previous experiments used an ad-hoc choice of 'intermediate' language/s for triangulation, and we now examine which languages are most effective. Figure 4 shows the efficacy of the remaining nine languages when translating *fr* → *en*. Minimum error-rate training was not used for this experiment, or the next shown in Figure 5, in order to highlight the effect of the changing translation estimates. Romance languages (*es, it, pt*) give the best results, both on their own and when used together with the standard phrase-table (using uniform interpolation); Germanic languages (*de, nl, da, sv*) are a distant second, with the less related Greek and Finnish the least useful. Interpolation yields an improvement for all 'intermediate' languages, even Finnish, which has a very low score when used alone.

The same experiment was repeated for *en* → *de* translation with similar trends, except that the Germanic languages out-scored the Romance languages. These findings suggest that 'intermediate' languages which exhibit a high degree of similarity with the source or target language are desirable. We conjecture that this is a consequence of better automatic word alignments and a generally easier translation task, as well as a better preservation of information between aligned phrases.

Using a single language for triangulation clearly improves performance, but can we realise further improvements by using additional languages? Figure 5 shows the performance profile for *fr* → *en* when adding languages in a fixed order. The languages were ordered by family, with Romance before Germanic before Greek and Finnish. Each addition results in an increase in performance, even for the final languages, from which we expect little information. The purely triangulated (triang) and interpolated scores (interp) are converging, suggesting that the source-target bitext is redundant given sufficient triangulated data. We obtained similar results for *en* → *de*.

5.3 Evaluating the quality of the phrase-table

Our experimental results so far have shown that triangulation is not a mere approximation of the source-target phrase-table, but that it extracts additional useful translation information. We now assess the phrase-table quality more directly. Comparative statistics of a standard and a triangulated phrase-table are given in Table 4. The coverage over source and target phrases is much higher in the standard table than the triangulated tables, which reflects the reduced ability of triangulation to extract large phrases — despite the large increase in the number of events. The table also shows the overlapping probability mass which measures the sum of probability in one table for which the events are present in the other. This shows that the majority of mass is shared by both tables (as joint distributions), although there are significant differences. The Jensen-Shannon divergence is perhaps more appropriate for the comparison, giving a relatively high divergence

	standard	triang
source phrases (M)	8	2.5
target phrases (M)	7	2.5
events (M)	12	70
overlapping mass	0.646	0.750

Table 4: Comparative statistics of the standard triangulated table on *fr* → *en* using the full training set and Spanish as an intermediate language.

of 0.3937. This augurs well for the combination of standard and triangulated phrase-tables, where diversity is valued. The decoding results (shown in Table 3 for $fr \rightarrow en$) indicate that the two methods have similar efficacy, and that their interpolated combination provides the best overall performance.

6 Conclusion

In this paper we have presented a novel method for obtaining more reliable translation estimates from small datasets. The key premise of our work is that multi-parallel data can be usefully exploited for improving the coverage and quality of phrase-based SMT. Our triangulation method translates from a source to a target via one or many intermediate languages. We present a generative formulation of this process and show how it can be used together with the entries of a standard source-target phrase-table.

We observe large performance gains when translating with triangulated models trained on small datasets. Furthermore, when combined with a standard phrase-table, our models also yield performance improvements on larger datasets. Our experiments revealed that triangulation benefits from a large set of intermediate languages and that performance is increased when languages of the same family to the source or target are used as intermediates.

We have just scratched the surface of the possibilities for the framework discussed here. Important future directions lie in combining triangulation with richer means of conventional smoothing and using triangulation to translate between low-density language pairs.

A Maximum Expected Utility Framework for Binary Sequence Labeling

Martin Jansche*
jansche@acm.org

Abstract

We consider the problem of predictive inference for probabilistic binary sequence labeling models under F-score as utility. For a simple class of models, we show that the number of hypotheses whose expected F-score needs to be evaluated is linear in the sequence length and present a framework for efficiently evaluating the expectation of many common loss/utility functions, including the F-score. This framework includes both exact and faster inexact calculation methods.

1 Introduction

1.1 Motivation and Scope

The weighted F-score (van Rijsbergen, 1974) plays an important role in the evaluation of binary classifiers, as it neatly summarizes a classifier's ability to identify the positive class. A variety of methods exists for training classifiers that optimize the F-score, or some similar trade-off between false positives and false negatives, precision and recall, sensitivity and specificity, type I error and type II error rate, etc. Among the most general methods are those of Mozer et al. (2001), whose constrained optimization technique is similar to those in (Gao et al., 2006; Jansche, 2005). More specialized methods also exist, for example for support vector machines (Musicant et al., 2003) and for conditional random fields (Gross et al., 2007; Suzuki et al., 2006).

All of these methods are about classifier training. In this paper we focus primarily on the related, but orthogonal, issue of predictive inference with a fully trained probabilistic classifier. Using the weighted F-score as our utility function, predictive inference amounts to choosing an optimal hypothesis which maximizes the expected utility. We refer to this as the prediction or decoding task. In general, decoding can be a hard computational problem (Casacuberta and de la Higuera, 2000; Knight, 1999). In this paper we show that the maximum expected F-score decoding problem can be solved in polynomial time under certain assumptions about the underlying probability model. One key ingredient in our solution is a very general framework for evaluating the expected F-score, and indeed many other utility functions, of a fixed hypothesis.[1] This framework can also be applied to discriminative classifier training.

1.2 Background and Notation

We formulate our approach in terms of sequence labeling, although it has applications beyond that. This is motivated by the fact that our framework for evaluating expected utility is indeed applicable to general sequence labeling tasks, while our decoding method is more restricted. Another reason is that the F-score is only meaningful for comparing two (multi)sets or two binary sequences, but the notation for multisets is slightly more awkward.

All tasks considered here involve strings of binary labels. We write the length of a given string $y \in \{0,1\}^n$ as $|y| = n$. It is convenient to view such strings as real vectors – whose components happen to be 0 or 1 – with the dot product defined as usual. Then $y \cdot y$ is the number of ones that occur in the string y. For two strings x, y of the same length $|x| = |y|$ the number of ones that occur at corresponding indices is $x \cdot y$.

Given a hypothesis z and a gold standard label sequence y, we define the following quantities:

1. $T = y \cdot y$, the genuine positives;
2. $P = z \cdot z$, the predicted positives;
3. $A = z \cdot y$, the true positives (predicted positives that are genuinely positive);

Prague, Czech Republic, June 2007.

4. $Recl = A/T$, recall (a.k.a. sensitivity or power);
5. $Prec = A/P$, precision.

The β-weighted F-score is then defined as the weighted harmonic mean of recall and precision. This simplifies to

$$F_\beta = \frac{(\beta+1)A}{P+\beta T} \qquad (\beta > 0) \tag{1}$$

where we assume for convenience that $0/0 \stackrel{\text{def}}{=} 1$ to avoid explicitly dealing with the special case of the denominator being zero. We will write the weighted F-score from now on as $F(z,y)$ to emphasize that it is a function of z and y.

1.3 Expected *F*-Score

In Section 3 we will develop a method for evaluating the expectation of the F-score, which can also be used as a smooth approximation of the raw F-score during classifier training: in that task (which we will not discuss further in this paper), z are the supervised labels, y is the classifier output, and the challenge is that $F(z,y)$ does not depend smoothly on the parameters of the classifier. Gradient-based optimization techniques are not applicable unless some of the quantities defined above are replaced by approximations that depend smoothly on the classifier's parameters. For example, the constrained optimization method of (Mozer et al., 2001) relies on approximations of sensitivity (which they call *CA*) and specificity[2] (their *CR*); related techniques (Gao et al., 2006; Jansche, 2005) rely on approximations of true positives, false positives, and false negatives, and, indirectly, recall and precision. Unlike these methods we compute the expected F-score exactly, without relying on *ad hoc* approximations of the true positives, etc.

Being able to efficiently compute the expected F-score is a prerequisite for maximizing it during decoding. More precisely, we compute the expectation of the function

$$y \mapsto F(z,y), \tag{2}$$

which is a unary function obtained by holding the first argument of the binary function F fixed. It will henceforth be abbreviated as $F(z,\cdot)$, and we will denote its expected value by

$$\mathrm{E}[F(z,\cdot)] = \sum_{y \in \{0,1\}^{|z|}} F(z,y)\ \Pr(y). \tag{3}$$

[2] Defined as $[(\vec{1}-z)\cdot(\vec{1}-y)]/[(\vec{1}-y)\cdot(\vec{1}-y)]$.

This expectation is taken with respect to a probability model over binary label sequences, written as $\Pr(y)$ for simplicity. This probability model may be conditional, that is, in general it will depend on covariates x and parameters θ. We have suppressed both in our notation, since x is fixed during training and decoding, and we assume that the model is fully identified during decoding. This is for clarity only and does not limit the class of models, though we will introduce additional, limiting assumptions shortly. We are now ready to tackle the inference task formally.

2 Maximum Expected *F*-Score Inference

2.1 Problem Statement

Optimal predictive inference under F-score utility requires us to find an hypothesis $\hat{z}$ of length n which maximizes the expected F-score relative to a given probabilistic sequence labeling model:

$$\hat{z} = \operatorname*{argmax}_{z \in \{0,1\}^n} \mathrm{E}[F(z,\cdot)] = \operatorname*{argmax}_{z \in \{0,1\}^n} \sum_y F(z,y)\ \Pr(y). \tag{4}$$

We require the probability model to factor into independent Bernoulli components (Markov order zero):

$$\Pr(y = (y_1,\ldots,y_n)) = \prod_{i=1}^{n} p_i^{y_i}\,(1-p_i)^{1-y_i}. \tag{5}$$

In practical applications we might choose the overall probability distribution to be the product of independent logistic regression models, for example. Ordinary classification arises as a special case when the y_i are i.i.d., that is, a single probabilistic classifier is used to find $\Pr(y_i = 1 \mid x_i)$. For our present purposes it is sufficient to assume that the inference algorithm takes as its input the vector $(p_1,\ldots,p_n)$, where p_i is the probability that $y_i = 1$.

The discrete maximization problem (4) cannot be solved naively, since the number of hypotheses that would need to be evaluated in a brute-force search for an optimal hypothesis $\hat{z}$ is exponential in the sequence length n. We show below that in fact only a few hypotheses ($n+1$ instead of 2^n) need to be examined in order to find an optimal one.

The inference algorithm is the intuitive one, analogous to the following simple observation: Start with the hypothesis $z = 00\ldots0$ and evaluate its raw F-score $F(z,y)$ relative to a fixed but unknown binary

string y. Then z will have perfect precision (no positive labels means no chance to make mistakes), and zero recall (unless $y = z$). Switch on any bit of z that is currently off. Then precision will decrease or remain equal, while recall will increase or remain equal. Repeat until $z = 11\ldots1$ is reached, in which case recall will be perfect and precision at its minimum. The inference algorithm for expected F-score follows the same strategy, and in particular it switches on the bits of z in order of non-increasing probability: start with $00\ldots0$, then switch on the bit $i_1 = \operatorname{argmax}_i p_i$, etc. until $11\ldots1$ is reached. We now show that this intuitive strategy is indeed admissible.

2.2 Outer and Inner Maximization

In general, maximization can be carried out piecewise, since

$$\operatorname*{argmax}_{x\in X} f(x) = \operatorname*{argmax}_{x\in\{\operatorname{argmax}_{y\in Y} f(y)\mid Y\in\pi(X)\}} f(x),$$

where $\pi(X)$ is any family $(Y_1, Y_2, \ldots)$ of nonempty subsets of X whose union $\bigcup_i Y_i$ is equal to X. (Recursive application would lead to a divide-and-conquer algorithm.) Duplication of effort is avoided if $\pi(X)$ is a partition of X.

Here we partition the set $\{0,1\}^n$ into equivalence classes based on the number of ones in a string (viewed as a real vector). Define S_m to be the set

$$S_m = \{s \in \{0,1\}^n \mid s \cdot s = m\}$$

consisting of all binary strings of fixed length n that contain exactly m ones. Then the maximization problem (4) can be transformed into an inner maximization

$$\hat{s}^{(m)} = \operatorname*{argmax}_{s\in S_m} \mathrm{E}\left[F(s,\cdot)\right], \tag{6}$$

followed by an outer maximization

$$\hat{z} = \operatorname*{argmax}_{z\in\{\hat{s}^{(0)},\ldots,\hat{s}^{(n)}\}} \mathrm{E}\left[F(z,\cdot)\right]. \tag{7}$$

2.3 Closed-Form Inner Maximization

The key insight is that the inner maximization problem (6) can be solved analytically. Given a vector $p = (p_1, \ldots, p_n)$ of probabilities, define $z^{(m)}$ to be the binary label sequence with exactly m ones and $n-m$ zeroes where for all indices i, k we have

$$\left[z_i^{(m)} = 1 \wedge z_k^{(m)} = 0\right] \rightarrow p_i \geq p_k.$$

Algorithm 1 Maximizing the Expected F-Score.

```
1: Input: probabilities p = (p_1, ..., p_n)
2: I ← indices of p sorted by non-increasing probability
3: z ← 0...0
4: a ← 0
5: v ← expectF(z, p)
6: for j ← 1 to n do
7:     i ← I[j]
8:     z[i] ← 1        // switch on the ith bit
9:     u ← expectF(z, p)
10:    if u > v then
11:        a ← j
12:        v ← u
13: for j ← a + 1 to n do
14:    z[I[j]] ← 0
15: return (z, v)
```

In other words, the most probable m bits (according to p) in $z^{(m)}$ are set and the least probable $n-m$ bits are off. We rely on the following result, whose proof is deferred to Appendix A:

Theorem 1. $(\forall s \in S_m)\ \mathrm{E}\left[F(z^{(m)},\cdot)\right] \geq \mathrm{E}\left[F(s,\cdot)\right]$.

Because $z^{(m)}$ is maximal in S_m, we may equate $z^{(m)} = \operatorname{argmax}_{s\in S_m} \mathrm{E}\left[F(s,\cdot)\right] = \hat{s}^{(m)}$ (modulo ties, which can always arise with argmax).

2.4 Pedestrian Outer Maximization

With the inner maximization (6) thus solved, the outer maximization (7) can be carried out naively, since only $n+1$ hypotheses need to be evaluated. This is precisely what Algorithm 1 does, which keeps track of the maximum value in v. On termination $z = \operatorname{argmax}_s \mathrm{E}\left[F(s,\cdot)\right]$. Correctness follows directly from our results in this section.

Algorithm 1 runs in time $\mathrm{O}(n \log n + n\, f(n))$. A total of $\mathrm{O}(n \log n)$ time is required for accessing the vector p in sorted order (line 2). This dominates the $\mathrm{O}(n)$ time required to explicitly generate the optimal hypothesis (lines 13–14). The algorithm invokes a subroutine *expectF*(z, p) a total of $n+1$ times. This subroutine, which is the topic of the next section, evaluates, in time $f(n)$, the expected F-score (with respect to p) of a given hypothesis z of length n.

3 Computing the Expected F-Score

3.1 Problem Statement

We now turn to the problem of computing the expected value (3) of the F-score for a given hypothesis z relative to a fully identified probability model. The method presented here does not strictly require the

zeroth-order Markov assumption (5) instated earlier (a higher-order Markov assumption will suffice), but it shall remain in effect for simplicity.

As with the maximization problem (4), the sum in (3) is over exponentially many terms and cannot be computed naively. But observe that the F-score (1) is a (rational) function of integer counts which are bounded, so it can take on only a finite, and indeed small, number of distinct values. We shall see shortly that the function (2) whose expectation we wish to compute has a domain whose cardinality is exponential in n, but the cardinality of its range is polynomial in n. The latter is sufficient to ensure that its expectation can be computed in polynomial time. The method we are about to develop is in fact very general and applies to many other loss and utility functions besides the F-score.

3.2 Expected F-Score as an Integral

A few notions from real analysis are helpful because they highlight the importance of thinking about functions in terms of their range, level sets, and the equivalence classes they induce on their domain (the kernel of the function). A function $g : \Omega \to \mathbb{R}$ is said to be *simple* if it can be expressed as a linear combination of indicator functions (characteristic functions):

$$g(x) = \sum_{k \in K} a_k \, \chi_{B_k}(x),$$

where K is a finite index set, $a_k \in \mathbb{R}$, and $B_k \subseteq \Omega$. ($\chi_S : S \to \{0,1\}$ is the characteristic function of set S.)

Let Ω be a countable set and $\mathscr{P}$ be a probability measure on Ω. Then the expectation of g is given by the Lebesgue integral of g. In the case of a simple function g as defined above, the integral, and hence the expectation, is defined as

$$\mathrm{E}[g] = \int_\Omega g \, \mathrm{d}\mathscr{P} = \sum_{k \in K} a_k \, \mathscr{P}(B_k). \qquad (8)$$

This gives us a general recipe for evaluating $\mathrm{E}[g]$ when Ω is much larger than the range of g. Instead of computing the sum $\sum_{y \in \Omega} g(y) \, \mathscr{P}(\{y\})$ we can compute the sum in (8) above. This directly yields an efficient algorithm whenever K is sufficiently small and $\mathscr{P}(B_k)$ can be evaluated efficiently.

The expected F-score is thus the Lebesgue integral of the function (2). Looking at the definition of the F-score in (1) we see that the only expressions which depend on y are $A = z \cdot y$ and $T = y \cdot y$ ($P = z \cdot z$ is fixed because z is). But $0 \le z \cdot y \le y \cdot y \le n = |z|$. Therefore $F(z, \cdot)$ takes on at most $(n+1)(n+2)/2$, i.e. quadratically many, distinct values. It is a simple function with

$$K = \{(A,T) \in \mathbb{N}_0 \times \mathbb{N}_0 \mid A \le T \le |z|,\ A \le z \cdot z\}$$

$$a_{(A,T)} = \frac{(\beta+1)\,A}{z \cdot z + \beta\, T} \qquad \text{where } 0/0 \stackrel{\text{def}}{=} 1$$

$$B_{(A,T)} = \{y \mid z \cdot y = A,\ y \cdot y = T\}.$$

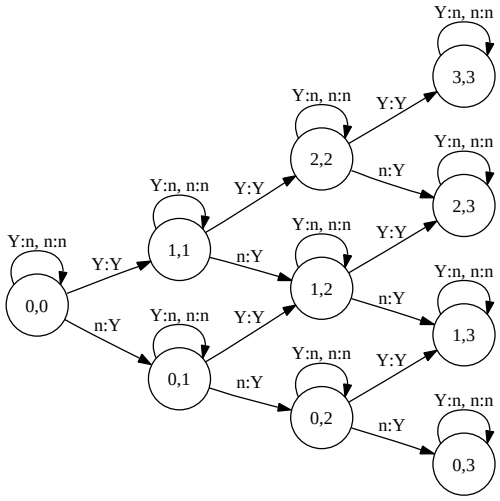

Figure 1: Finite State Classifier h'.

3.3 Computing Membership in B_k

Observe that the family of sets $\left(B_{(A,T)}\right)_{(A,T) \in K}$ is a partition (namely the kernel of $F(z,\cdot)$) of the set $\Omega = \{0,1\}^n$ of all label sequences of length n. In turn it gives rise to a function $h : \Omega \to K$ where $h(y) = k$ iff $y \in B_k$. The function h can be computed by a deterministic finite automaton, viewed as a sequence classifier: rather than assigning binary accept/reject labels, it assigns arbitrary labels from a finite set, in this case the index set K. For simplicity we show the initial portion of a slightly more general two-tape automaton h' in Figure 1. It reads the two sequences z and y on its two input tapes and counts the number of matching positive labels (represented as Y) as well as the number of positive labels on the second tape. Its behavior is therefore $h'(z,y) = (z \cdot y,\ y \cdot y)$. The function h is obtained as a special case when z (the first tape) is fixed.

Note that this only applies to the special case when

Algorithm 2 Simple Function Instance for F-Score.

```
def start():
  return (0,0)
def transition(k,z,i,y_i):
  (A,T) ← k
  if y_i = 1 then
    T ← T+1
    if z[i] = 1 then
      A ← A+1
  return (A,T)
def a(k,z):
  (A,T) ← k
  F ← (β+1)A / (z·z+βT)        // where 0/0 ≝ 1
  return F
```

Algorithm 3 Value of a Simple Function.

```
1: Input: instance g of the simple function interface, strings z
   and y of length n
2: k ← g.start()
3: for i ← 1 to n do
4:     k ← g.transition(k,z,i,y[i])
5: return g.a(k,z)
```

the family $B = (B_k)_{k \in K}$ is a partition of Ω. It is always possible to express any simple function in this way, but in general there may be an exponential increase in the size of K when the family B is required to be a partition. However for the special cases we consider here this problem does not arise.

3.4 The Simple Function Trick

In general, what we will call the *simple function trick* amounts to representing the simple function g whose expectation we want to compute by:

1. a finite index set K (perhaps implicit),
2. a deterministic finite state classifier $h : \Omega \to K$,
3. and a vector of coefficients $(a_k)_{k \in K}$.

In practice, this means instantiating an interface with three methods: the start and transition function of the transducer which computes h' (and from which h can be derived), and an accessor method for the coefficients a. Algorithm 2 shows the F-score instance.

Any simple function g expressed as an instance of this interface can then be evaluated very simply as $g(x) = a_{h(x)}$. This is shown in Algorithm 3.

Evaluating $\mathrm{E}[g]$ is also straightforward: Compose the DFA h with the probability model p and use an algebraic path algorithm to compute the total probability mass $\mathscr{P}(B_k)$ for each final state k of the resulting automaton. If p factors into independent components as required by (5), the composition is greatly simplified. If p incorporates label history (higher-order Markov assumption), nothing changes in principle, though the following algorithm assumes for simplicity that the stronger assumption is in effect.

Algorithm 4 Expectation of a Simple Function.

```
 1: Input: instance g of the simple function interface, string z
    and probability vector p of length n
 2: M ← Map()
 3: M[g.start()] ← 1
 4: for i ← 1 to n do
 5:     N ← Map()
 6:     for (k,P) ∈ M do
 7:         // transition on y_i = 0
 8:         k_0 ← g.transition(k,z,i,0)
 9:         if k_0 ∉ N then
10:             N[k_0] ← 0
11:         N[k_0] ← N[k_0] + P × (1 − p[i])
12:         // transition on y_i = 1
13:         k_1 ← g.transition(k,z,i,1)
14:         if k_1 ∉ N then
15:             N[k_1] ← 0
16:         N[k_1] ← N[k_1] + P × p[i]
17:     M ← N
18: E ← 0
19: for (k,P) ∈ M do
20:     E ← E + g.a(k,z) × P
21: return E
```

Algorithm 4 expands the following composed automaton, represented implicitly: the finite-state transducer h' specified as part of the simple function object g is composed on the left with the string z (yielding h) and on the right with the probability model p. The outer loop variable i is an index into z and hence a state in the automaton that accepts z; the variable k keeps track of the states of the automaton implemented by g; and the probability model has a single state by assumption, which does not need to be represented explicitly. Exploring the states in order of increasing i puts them in topological order, which means that the algebraic path problem can be solved in time linear in the size of the composed automaton. The maps M and N keep track of the algebraic distance from the start state to each intermediate state. On termination of the first outer loop (lines 4–17), the map M contains the final states together with their distances. The algebraic distance of a final state k is now equal to $\mathscr{P}(B_k)$, so the expected value E can be computed in the second loop (lines 18–20) as suggested by (8).

When the utility function interface g is instantiated as in Algorithm 2 to represent the F-score, the runtime of Algorithm 4 is cubic in n, with very small

constants.[3] The first main loop iterates over n. The inner loop iterates over the states expanded at iteration i, of which there are $O(i^2)$ many when dealing with the F-score. The second main loop iterates over the final states, whose number is quadratic in n in this case. The overall cubic runtime of the first loop dominates the computation.

3.5 Other Utility Functions

With other functions g the runtime of Algorithm 4 will depend on the asymptotic size of the index set K. If there are asymptotically as many intermediate states at any point as there are final states, then the general asymptotic runtime is $O(n|K|)$.

Many loss/utility functions are subsumed by the present framework. Zero–one loss is trivial: the automaton has two states (success, failure); it starts and remains in the success state as long as the symbols read on both tapes match; on the first mismatch it transitions to, and remains in, the failure state.

Hamming (1950) distance is similar to zero–one loss, but counts the number of mismatches (bounded by n), whereas zero–one loss only counts up to a threshold of one.

A more interesting case is given by the P_k-score (Beeferman et al., 1999) and its generalizations, which moves a sliding window of size k over a pair of label sequences (z, y) and counts the number of windows which contain a segment boundary on one of the sequences but not the other. To compute its expectation in our framework, all we have to do is express the sliding window mechanism as an automaton, which can be done very naturally (see the proof-of-concept implementation for further details).

4 Faster Inexact Computations

Because the exact computation of the expected F-score by Algorithm 4 requires cubic time, the overall runtime of Algorithm 1 (the decoder) is quartic.[4]

Faster decoding can be achieved by modifying Algorithm 4 to compute an approximation (in fact, a lower bound) of the expected F-score.[5] This is done by introducing an additional parameter L which limits the number of intermediate states that get expanded. Instead of iterating over all states and their associated probabilities (inner loop starting at line 6), one iterates over the top L states only. We require that $L \geq 1$ for this to be meaningful. Before entering the inner loop the entries of the map M are expanded and, using the linear time selection algorithm, the top L entries are selected. Because each state that gets expanded in the inner loop has out-degree 2, the new state map N will contain at most $2L$ states. This means that we have an additional loop invariant: the size of M is always less than or equal to $2L$. Therefore the selection algorithm runs in time $O(L)$, and so does the abridged inner loop, as well as the second outer loop. The overall runtime of this modified algorithm is therefore $O(nL)$.

If L is a constant function, the inexact computation of the expected F-score runs in linear time and the overall decoding algorithm in quadratic time. In particular if $L = 1$ the approximate expected F-score is equal to the F-score of the MAP hypothesis, and the modified inference algorithm reduces to a variant of Viterbi decoding. If L is a linear function of n, the overall decoding algorithm runs in cubic time.

We experimentally compared the exact quartic-time decoding algorithm with the approximate decoding algorithm for $L = 2n$ and for $L = 1$. We computed the absolute difference between the expected F-score of the optimal hypothesis (as found by the exact algorithm) and the expected F-score of the winning hypothesis found by the approximate decoding algorithm. For different sequence lengths $n \in \{1, \ldots, 50\}$ we performed 10 runs of the different decoding algorithms on randomly generated probability vectors p, where each p_i was randomly drawn from a continuous uniform distribution on $(0, 1)$, or, in a second experiment, from a Beta$(1/2, 1/2)$ distribution (to simulate an over-trained classifier).

For $L = 1$ there is a substantial difference of about

[3] A tight upper bound on the total number of states of the composed automaton in the worst case is $\left\lfloor \frac{1}{12}n^3 + \frac{5}{8}n^2 + \frac{17}{12}n + 1 \right\rfloor$.

[4] It is possible to speed up the decoding algorithm in absolute terms, though not asymptotically, by exploiting the fact that it explores very similar hypotheses in sequence. Algorithm 4 can be modified to store and return all of its intermediate map data-structures. This modified algorithm then requires cubic space instead of quadratic space. This additional storage cost pays off when the algorithm is called a second time, with its formal parameter z bound to a string that differs from the one of the preceding run in just one position. This means that the map data-structures only need to be recomputed from that position forward. However, this does not lead to an asymptotically faster algorithm in the worst case.

[5] For error bounds, see the proof-of-concept implementation.

0.6 between the expected F-scores of the winning hypothesis computed by the exact algorithm and by the approximate algorithm. Nevertheless the approximate decoding algorithm found the optimal hypothesis more than 99% of the time. This is presumably due to the additional regularization inherent in the discrete maximization of the decoder proper: even though the computed expected F-scores may be far from their exact values, this does not necessarily affect the behavior of the decoder very much, since it only needs to find the maximum among a small number of such scores. The error introduced by the approximation would have to be large enough to disturb the order of the hypotheses examined by the decoder in such a way that the true maximum is reordered. This generally does not seem to happen.

For $L = 2n$ the computed approximate expected F-scores were indistinguishable from their exact values. Consequently the approximate decoder found the true maximum every time.

5 Conclusion and Related Work

We have presented efficient algorithms for maximum expected F-score decoding. Our exact algorithm runs in quartic time, but an approximate cubic-time variant is indistinguishable in practice. A quadratic-time approximation makes very few mistakes and remains practically useful.

We have further described a general framework for computing the expectations of certain loss/utility functions. Our method relies on the fact that many functions are sparse, in the sense of having a finite range that is much smaller than their codomain. To evaluate their expectations, we can use the simple function trick and concentrate on their level sets: it suffices to evaluate the probability of those sets/ events. The fact that the commonly used utility functions like the F-score have only polynomially many level sets is sufficient (but not necessary) to ensure that our method is efficient. Because the coefficients a_k can be arbitrary (in fact, they can be generalized to be elements of a vector space over the reals), we can deal with functions that go beyond simple counts.

Like the methods developed by Allauzen et al. (2003) and Cortes et al. (2003) our technique incorporates finite automata, but uses a direct threshold-counting technique, rather than a nondeterministic counting technique which relies on path multiplicities. This makes it easy to formulate the simultaneous counting of two distinct quantities, such as our A and T, and to reason about the resulting automata.

The method described here is similar in spirit to those of Gao et al. (2006) and Jansche (2005), who discuss maximum expected F-score training of decision trees and logistic regression models. However, the present work is considerably more general in two ways: (1) the expected utility computations presented here are not tied in any way to particular classifiers, but can be used with large classes of probabilistic models; and (2) our framework extends beyond the computation of F-scores, which fall out as a special case, to other loss and utility functions, including the P_k score. More importantly, expected F-score computation as presented here can be exact, if desired, whereas the cited works always use an approximation to the quantities we have called A and T.

Appendix A Proof of Theorem 1

The proof of Theorem 1 employs the following lemma:

Theorem 2. *For fixed n and p, let $s,t \in S_m$ for some m with $1 \leq m < n$. Further assume that s and t differ only in two bits, i and k, in such a way that $s_i = 1$, $s_k = 0$; $t_i = 0$, $t_k = 1$; and $p_i \geq p_k$. Then $\mathrm{E}[F(s,\cdot)] \geq \mathrm{E}[F(t,\cdot)]$.*

Proof. Express the expected F-score $\mathrm{E}[F(s,\cdot)]$ as a sum and split the summation into two parts:

$$\sum_y F(s,y)\Pr(y) = \sum_{\substack{y \\ y_i = y_k}} F(s,y)\Pr(y) + \sum_{\substack{y \\ y_i \neq y_k}} F(s,y)\Pr(y).$$

If $y_i = y_k$ then $F(s,y) = F(t,y)$, for three reasons: the number of ones in s and t is the same (namely m) by assumption; y is constant; and the number of true positives is the same, that is $s \cdot y = t \cdot y$. The latter holds because s and y agree everywhere except on i and k; if $y_i = y_k = 0$, then there are no true positives at i and k; and if $y_i = y_k = 1$ then s_i is a true positive but s_k is not, and conversely t_k is but t_i is not. Therefore

$$\sum_{\substack{y \\ y_i = y_k}} F(s,y)\Pr(y) = \sum_{\substack{y \\ y_i = y_k}} F(t,y)\Pr(y). \tag{9}$$

Focus on those summands where $y_i \neq y_k$. Specifically group them into pairs (y,z) where y and z are identical except that $y_i = 1$ and $y_k = 0$, but $z_i = 0$ and $z_k = 1$. In other words, the two summations on the right-hand side of the following equality are carried out in parallel:

$$\sum_{\substack{y \\ y_i \neq y_k}} F(s,y)\Pr(y) = \sum_{\substack{y \\ y_i = 1 \\ y_k = 0}} F(s,y)\Pr(y) + \sum_{\substack{z \\ z_i = 0 \\ z_k = 1}} F(s,z)\Pr(z).$$

Then, focusing on s first:

$$\begin{aligned}
&F(s,y)\Pr(y) + F(s,z)\Pr(z) \\
&= \frac{(\beta+1)(A+1)}{m+\beta T}\Pr(y) + \frac{(\beta+1)A}{m+\beta T}\Pr(z) \\
&= \left[(A+1)p_i(1-p_k) + A(1-p_i)p_k\right]\frac{(\beta+1)}{m+\beta T}\,C \\
&= \left[p_i + (p_i + p_k - 2p_ip_k)A - p_ip_k\right]\frac{(\beta+1)}{m+\beta T}\,C \\
&= [p_i + C_0]\,C_1,
\end{aligned}$$

where $A = s \cdot z$ is the number of true positives between s and z (s and y have an additional true positive at i by construction); $T = y \cdot y = z \cdot z$ is the number of positive labels in y and z (identical by assumption); and

$$C = \frac{\Pr(y)}{p_i(1-p_k)} = \frac{\Pr(z)}{(1-p_i)p_k}$$

is the probability of y and z evaluated on all positions except for i and k. This equality holds because of the zeroth-order Markov assumption (5) imposed on $\Pr(y)$. C_0 and C_1 are constants that allow us to focus on the essential aspects.

The situation for t is similar, except for the true positives:

$$\begin{aligned}
&F(t,y)\Pr(y) + F(t,z)\Pr(z) \\
&= \frac{(\beta+1)A}{m+\beta T}\Pr(y) + \frac{(\beta+1)(A+1)}{m+\beta T}\Pr(z) \\
&= \left[A\,p_i(1-p_k) + (A+1)(1-p_i)p_k\right]\frac{(\beta+1)}{m+\beta T}\,C \\
&= \left[p_k + (p_i + p_k - 2p_ip_k)A - p_ip_k\right]\frac{(\beta+1)}{m+\beta T}\,C \\
&= [p_k + C_0]\,C_1
\end{aligned}$$

where all constants have the same values as above. But $p_i \geq p_k$ by assumption, $p_k + C_0 \geq 0$, and $C_1 \geq 0$, so we have

$$\begin{aligned}
&F(s,y)\Pr(y) + F(s,z)\Pr(z) = [p_i + C_0]\,C_1 \\
&\geq F(t,y)\Pr(y) + F(t,z)\Pr(z) = [p_k + C_0]\,C_1,
\end{aligned}$$

and therefore

$$\sum_{\substack{y \\ y_i \neq y_k}} F(s,y)\Pr(y) \geq \sum_{\substack{y \\ y_i \neq y_k}} F(t,y)\Pr(y). \tag{10}$$

The theorem follows from equality (9) and inequality (10). □

Proof of Theorem 1: $(\forall s \in S_m)\ \mathrm{E}[F(z^{(m)},\cdot)] \geq \mathrm{E}[F(s,\cdot)]$. Observe that $z^{(m)} \in S_m$ by definition (see Section 2.3). For $m = 0$ and $m = n$ the theorem holds trivially because S_m is a singleton set. In the nontrivial cases, Theorem 2 is applied repeatedly. The string $z^{(m)}$ can be transformed into any other string $s \in S_m$ by repeatedly clearing a more likely set bit and setting a less likely unset bit.

In particular this can be done as follows: First, find the indices where $z^{(m)}$ and s disagree. By construction there must be an even number of such indices; indeed there are equinumerous sets

$$\left\{ i \mid z_i^{(m)} = 1 \wedge s_i = 0 \right\} \approx \left\{ j \mid z_j^{(m)} = 0 \wedge s_j = 1 \right\}.$$

This holds because the total number of ones is fixed and identical in $z^{(m)}$ and s, and so is the total number of zeroes. Next, sort those indices by non-increasing probability and represent them as $i_1, \ldots, i_k$ and $j_1, \ldots, j_k$. Let $s_0 = z^{(m)}$. Then let s_1 be identical to s_0 except that $s_{i_1} = 0$ and $s_{j_1} = 1$. Form $s_2, \ldots, s_k$ along the same lines and observe that $s_k = s$ by construction. By definition of $z^{(m)}$ it must be the case that $p_{i_r} \geq p_{j_r}$ for all $r \in \{1, \ldots, k\}$. Therefore Theorem 2 applies at every step along the way from $z^{(m)} = s_0$ to $s_k = s$, and so the expected utility is non-increasing along that path. □

A Fully Bayesian Approach to Unsupervised Part-of-Speech Tagging*

Abstract

Unsupervised learning of linguistic structure is a difficult problem. A common approach is to define a generative model and maximize the probability of the hidden structure given the observed data. Typically, this is done using maximum-likelihood estimation (MLE) of the model parameters. We show using part-of-speech tagging that a fully Bayesian approach can greatly improve performance. Rather than estimating a single set of parameters, the Bayesian approach integrates over all possible parameter values. This difference ensures that the learned structure will have high probability over a range of possible parameters, and permits the use of priors favoring the sparse distributions that are typical of natural language. Our model has the structure of a standard trigram HMM, yet its accuracy is closer to that of a state-of-the-art discriminative model (Smith and Eisner, 2005), up to 14 percentage points better than MLE. We find improvements both when training from data alone, and using a tagging dictionary.

1 Introduction

Unsupervised learning of linguistic structure is a difficult problem. Recently, several new model-based approaches have improved performance on a variety of tasks (Klein and Manning, 2002; Smith and Eisner, 2005). Nearly all of these approaches have one aspect in common: the goal of learning is to identify the set of model parameters that maximizes some objective function. Values for the hidden variables in the model are then chosen based on the learned parameterization. Here, we propose a different approach based on Bayesian statistical principles: rather than searching for an optimal set of parameter values, we seek to directly maximize the probability of the hidden variables given the observed data, integrating over all possible parameter values. Using part-of-speech (POS) tagging as an example application, we show that the Bayesian approach provides large performance improvements over maximum-likelihood estimation (MLE) for the same model structure. Two factors can explain the improvement. First, integrating over parameter values leads to greater robustness in the choice of tag sequence, since it must have high probability over a range of parameters. Second, integration permits the use of priors favoring sparse distributions, which are typical of natural language. These kinds of priors can lead to degenerate solutions if the parameters are estimated directly.

Before describing our approach in more detail, we briefly review previous work on unsupervised POS tagging. Perhaps the most well-known is that of Merialdo (1994), who used MLE to train a trigram hidden Markov model (HMM). More recent work has shown that improvements can be made by modifying the basic HMM structure (Banko and Moore, 2004), using better smoothing techniques or added constraints (Wang and Schuurmans, 2005), or using a discriminative model rather than an HMM

Prague, Czech Republic, June 2007.

(Smith and Eisner, 2005). Non-model-based approaches have also been proposed (Brill (1995); see also discussion in Banko and Moore (2004)). All of this work is really POS *disambiguation*: learning is strongly constrained by a dictionary listing the allowable tags for each word in the text. Smith and Eisner (2005) also present results using a diluted dictionary, where infrequent words may have any tag. Haghighi and Klein (2006) use a small list of labeled prototypes and no dictionary.

A different tradition treats the identification of syntactic classes as a knowledge-free clustering problem. Distributional clustering and dimensionality reduction techniques are typically applied when linguistically meaningful classes are desired (Schütze, 1995; Clark, 2000; Finch et al., 1995); probabilistic models have been used to find classes that can improve smoothing and reduce perplexity (Brown et al., 1992; Saul and Pereira, 1997). Unfortunately, due to a lack of standard and informative evaluation techniques, it is difficult to compare the effectiveness of different clustering methods.

In this paper, we hope to unify the problems of POS disambiguation and syntactic clustering by presenting results for conditions ranging from a full tag dictionary to no dictionary at all. We introduce the use of a new information-theoretic criterion, *variation of information* (Meilă, 2002), which can be used to compare a gold standard clustering to the clustering induced from a tagger's output, regardless of the cluster labels. We also evaluate using tag accuracy when possible. Our system outperforms an HMM trained with MLE on both metrics in all circumstances tested, often by a wide margin. Its accuracy in some cases is close to that of Smith and Eisner's (2005) discriminative model. Our results show that the Bayesian approach is particularly useful when learning is less constrained, either because less evidence is available (corpus size is small) or because the dictionary contains less information.

In the following section, we discuss the motivation for a Bayesian approach and present our model and search procedure. Section 3 gives results illustrating how the parameters of the prior affect results, and Section 4 describes how to infer a good choice of parameters from unlabeled data. Section 5 presents results for a range of corpus sizes and dictionary information, and Section 6 concludes.

2 A Bayesian HMM

2.1 Motivation

In model-based approaches to unsupervised language learning, the problem is formulated in terms of identifying latent structure from data. We define a model with parameters θ, some observed variables $\mathbf{w}$ (the linguistic input), and some latent variables $\mathbf{t}$ (the hidden structure). The goal is to assign appropriate values to the latent variables. Standard approaches do so by selecting values for the model parameters, and then choosing the most probable variable assignment based on those parameters. For example, maximum-likelihood estimation (MLE) seeks parameters $\hat{\theta}$ such that

$$\hat{\theta} = \operatorname*{argmax}_{\theta} P(\mathbf{w}|\theta), \tag{1}$$

where $P(\mathbf{w}|\theta) = \sum_{\mathbf{t}} P(\mathbf{w}, \mathbf{t}|\theta)$. Sometimes, a non-uniform prior distribution over θ is introduced, in which case $\hat{\theta}$ is the *maximum a posteriori* (MAP) solution for θ:

$$\hat{\theta} = \operatorname*{argmax}_{\theta} P(\mathbf{w}|\theta)P(\theta). \tag{2}$$

The values of the latent variables are then taken to be those that maximize $P(\mathbf{t}|\mathbf{w}, \hat{\theta})$.

In contrast, the Bayesian approach we advocate in this paper seeks to identify a distribution over latent variables directly, without ever fixing particular values for the model parameters. The distribution over latent variables given the observed data is obtained by integrating over all possible values of θ:

$$P(\mathbf{t}|\mathbf{w}) = \int P(\mathbf{t}|\mathbf{w}, \theta)P(\theta|\mathbf{w})d\theta. \tag{3}$$

This distribution can be used in various ways, including choosing the MAP assignment to the latent variables, or estimating expected values for them.

To see why integrating over possible parameter values can be useful when inducing latent structure, consider the following example. We are given a coin, which may be biased ($t = 1$) or fair ($t = 0$), each with probability .5. Let θ be the probability of heads. If the coin is biased, we assume a uniform distribution over θ, otherwise $\theta = .5$. We observe $\mathbf{w}$, the outcomes of 10 coin flips, and we wish to determine whether the coin is biased (i.e. the value of

t). Assume that we have a uniform prior on θ, with $p(\theta) = 1$ for all $\theta \in [0, 1]$. First, we apply the standard methodology of finding the MAP estimate for θ and then selecting the value of t that maximizes $P(t|\mathbf{w}, \hat{\theta})$. In this case, an elementary calculation shows that the MAP estimate is $\hat{\theta} = n_H/10$, where n_H is the number of heads in $\mathbf{w}$ (likewise, n_T is the number of tails). Consequently, $P(t|\mathbf{w}, \hat{\theta})$ favors $t = 1$ for any sequence that does not contain exactly five heads, and assigns equal probability to $t = 1$ and $t = 0$ for any sequence that does contain exactly five heads — a counterintuitive result. In contrast, using some standard results in Bayesian analysis we can show that applying Equation 3 yields

$$P(t = 1|\mathbf{w}) = 1/\left(1 + \frac{11!}{n_H! n_T! 2^{10}}\right) \quad (4)$$

which is significantly less than .5 when $n_H = 5$, and only favors $t = 1$ for sequences where $n_H \geq 8$ or $n_H \leq 2$. This intuitively sensible prediction results from the fact that the Bayesian approach is sensitive to the *robustness* of a choice of t to the value of θ, as illustrated in Figure 1. Even though a sequence with $n_H = 6$ yields a MAP estimate of $\hat{\theta} = 0.6$ (Figure 1 (a)), $P(t = 1|\mathbf{w}, \theta)$ is only greater than 0.5 for a small range of θ around $\hat{\theta}$ (Figure 1 (b)), meaning that the choice of $t = 1$ is not very robust to variation in θ. In contrast, a sequence with $n_H = 8$ favors $t = 1$ for a wide range of θ around $\hat{\theta}$. By integrating over θ, Equation 3 takes into account the consequences of possible variation in θ.

Another advantage of integrating over θ is that it permits the use of linguistically appropriate priors. In many linguistic models, including HMMs, the distributions over variables are multinomial. For a multinomial with parameters $\theta = (\theta_1, \ldots, \theta_K)$, a natural choice of prior is the K-dimensional Dirichlet distribution, which is conjugate to the multinomial.[1] For simplicity, we initially assume that all K parameters (also known as *hyperparameters*) of the Dirichlet distribution are equal to β, i.e. the Dirichlet is *symmetric*. The value of β determines which parameters θ will have high probability: when $\beta = 1$, all parameter values are equally likely; when $\beta > 1$, multinomials that are closer to uniform are preferred; and when $\beta < 1$, high probability is assigned to sparse multinomials, where one or more parameters are at or near 0.

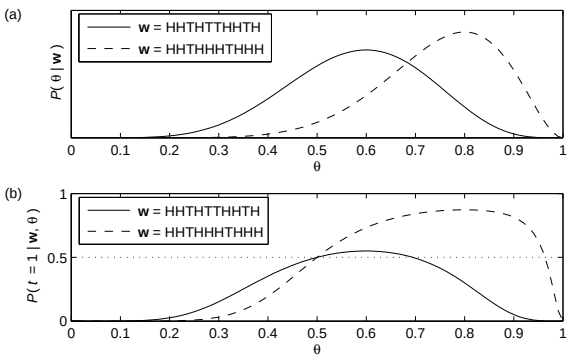

Figure 1: The Bayesian approach to estimating the value of a latent variable, t, from observed data, $\mathbf{w}$, chooses a value of t robust to uncertainty in θ. (a) Posterior distribution on θ given $\mathbf{w}$. (b) Probability that $t = 1$ given $\mathbf{w}$ and θ as a function of θ.

Typically, linguistic structures are characterized by sparse distributions (e.g., POS tags are followed with high probability by only a few other tags, and have highly skewed output distributions). Consequently, it makes sense to use a Dirichlet prior with $\beta < 1$. However, as noted by Johnson et al. (2007), this choice of β leads to difficulties with MAP estimation. For a sequence of draws $\mathbf{x} = (x_1, \ldots, x_n)$ from a multinomial distribution θ with observed counts $n_1, \ldots, n_K$, a symmetric Dirichlet(β) prior over θ yields the MAP estimate $\theta_k = \frac{n_k + \beta - 1}{n + K(\beta - 1)}$. When $\beta \geq 1$, standard MLE techniques such as EM can be used to find the MAP estimate simply by adding "pseudocounts" of size $\beta - 1$ to each of the expected counts n_k at each iteration. However, when $\beta < 1$, the values of θ that set one or more of the θ_k equal to 0 can have infinitely high posterior probability, meaning that MAP estimation can yield degenerate solutions. If, instead of estimating θ, we integrate over all possible values, we no longer encounter such difficulties. Instead, the probability that outcome x_i takes value k given previous outcomes $\mathbf{x}_{-i} = (x_1, \ldots, x_{i-1})$ is

$$\begin{aligned} P(k|\mathbf{x}_{-i}, \beta) &= \int P(k|\theta) P(\theta|\mathbf{x}_{-i}, \beta)\, d\theta \\ &= \frac{n_k + \beta}{i - 1 + K\beta} \end{aligned} \quad (5)$$

[1] A prior is *conjugate* to a distribution if the posterior has the same form as the prior.

where n_k is the number of times k occurred in $\mathbf{x}_{-i}$. See MacKay and Peto (1995) for a derivation.

2.2 Model Definition

Our model has the structure of a standard trigram HMM, with the addition of symmetric Dirichlet priors over the transition and output distributions:

$$\begin{aligned} t_i|t_{i-1}=t,t_{i-2}=t',\tau^{(t,t')} &\sim \text{Mult}(\tau^{(t,t')}) \\ w_i|t_i=t,\omega^{(t)} &\sim \text{Mult}(\omega^{(t)}) \\ \tau^{(t,t')}|\alpha &\sim \text{Dirichlet}(\alpha) \\ \omega^{(t)}|\beta &\sim \text{Dirichlet}(\beta) \end{aligned}$$

where t_i and w_i are the ith tag and word. We assume that sentence boundaries are marked with a distinguished tag. For a model with T possible tags, each of the transition distributions $\tau^{(t,t')}$ has T components, and each of the output distributions $\omega^{(t)}$ has W_t components, where W_t is the number of word types that are permissible outputs for tag t. We will use τ and ω to refer to the entire transition and output parameter sets. This model assumes that the prior over state transitions is the same for all histories, and the prior over output distributions is the same for all states. We relax the latter assumption in Section 4.

Under this model, Equation 5 gives us

$$P(t_i|\mathbf{t}_{-i},\alpha) = \frac{n_{(t_{i-2},t_{i-1},t_i)}+\alpha}{n_{(t_{i-2},t_{i-1})}+T\alpha} \quad (6)$$

$$P(w_i|t_i,\mathbf{t}_{-i},\mathbf{w}_{-i},\beta) = \frac{n_{(t_i,w_i)}+\beta}{n_{(t_i)}+W_{t_i}\beta} \quad (7)$$

where $n_{(t_{i-2},t_{i-1},t_i)}$ and $n_{(t_i,w_i)}$ are the number of occurrences of the trigram (t_{i-2},t_{i-1},t_i) and the tag-word pair (t_i,w_i) in the $i-1$ previously generated tags and words. Note that, by integrating out the parameters τ and ω, we induce dependencies between the variables in the model. The probability of generating a particular trigram tag sequence (likewise, output) depends on the number of times that sequence (output) has been generated previously. Importantly, trigrams (and outputs) remain *exchangeable*: the probability of a set of trigrams (outputs) is the same regardless of the order in which it was generated. The property of exchangeability is crucial to the inference algorithm we describe next.

2.3 Inference

To perform inference in our model, we use Gibbs sampling (Geman and Geman, 1984), a stochastic procedure that produces samples from the posterior distribution $P(\mathbf{t}|\mathbf{w},\alpha,\beta) \propto P(\mathbf{w}|\mathbf{t},\beta)P(\mathbf{t}|\alpha)$. We initialize the tags at random, then iteratively resample each tag according to its conditional distribution given the current values of all other tags. Exchangeability allows us to treat the current counts of the other tag trigrams and outputs as "previous" observations. The only complication is that resampling a tag changes the identity of three trigrams at once, and we must account for this in computing its conditional distribution. The sampling distribution for t_i is given in Figure 2.

In Bayesian statistical inference, multiple samples from the posterior are often used in order to obtain statistics such as the expected values of model variables. For POS tagging, estimates based on multiple samples might be useful if we were interested in, for example, the probability that two words have the same tag. However, computing such probabilities across all pairs of words does not necessarily lead to a consistent clustering, and the result would be difficult to evaluate. Using a single sample makes standard evaluation methods possible, but yields suboptimal results because the value for each tag is sampled from a distribution, and some tags will be assigned low-probability values. Our solution is to treat the Gibbs sampler as a stochastic search procedure with the goal of identifying the MAP tag sequence. This can be done using tempering (annealing), where a temperature of ϕ is equivalent to raising the probabilities in the sampling distribution to the power of $\frac{1}{\phi}$. As ϕ approaches 0, even a single sample will provide a good MAP estimate.

3 Fixed Hyperparameter Experiments

3.1 Method

Our initial experiments follow in the tradition begun by Merialdo (1994), using a tag dictionary to constrain the possible parts of speech allowed for each word. (This also fixes W_t, the number of possible words for tag t.) The dictionary was constructed by listing, for each word, all tags found for that word in the entire WSJ treebank. For the experiments in this section, we used a 24,000-word subset of the tree-

$$P(t_i|\mathbf{t}_{-i},\mathbf{w},\alpha,\beta) \propto \frac{n_{(t_i,w_i)}+\beta}{n_{t_i}+W_{t_i}\beta}\cdot\frac{n_{(t_{i-2},t_{i-1},t_i)}+\alpha}{n_{(t_{i-2},t_{i-1})}+T\alpha}\cdot\frac{n_{(t_{i-1},t_i,t_{i+1})}+I(t_{i-2}=t_{i-1}=t_i=t_{i+1})+\alpha}{n_{(t_{i-1},t_i)}+I(t_{i-2}=t_{i-1}=t_i)+T\alpha}$$
$$\cdot\frac{n_{(t_i,t_{i+1},t_{i+2})}+I(t_{i-2}=t_i=t_{i+2},t_{i-1}=t_{i+1})+I(t_{i-1}=t_i=t_{i+1}=t_{i+2})+\alpha}{n_{(t_i,t_{i+1})}+I(t_{i-2}=t_i,t_{i-1}=t_{i+1})+I(t_{i-1}=t_i=t_{i+1})+T\alpha}$$

Figure 2: Conditional distribution for t_i. Here, $\mathbf{t}_{-i}$ refers to the current values of all tags except for t_i, $I(.)$ is a function that takes on the value 1 when its argument is true and 0 otherwise, and all counts n_x are with respect to the tag trigrams and tag-word pairs in $(\mathbf{t}_{-i},\mathbf{w}_{-i})$.

bank as our unlabeled training corpus. 54.5% of the tokens in this corpus have at least two possible tags, with the average number of tags per token being 2.3. We varied the values of the hyperparameters α and β and evaluated overall tagging accuracy. For comparison with our Bayesian HMM (BHMM) in this and following sections, we also present results from the Viterbi decoding of an HMM trained using MLE by running EM to convergence (MLHMM). Where direct comparison is possible, we list the scores reported by Smith and Eisner (2005) for their conditional random field model trained using contrastive estimation (CRF/CE).[2]

For all experiments, we ran our Gibbs sampling algorithm for 20,000 iterations over the entire data set. The algorithm was initialized with a random tag assignment and a temperature of 2, and the temperature was gradually decreased to .08. Since our inference procedure is stochastic, our reported results are an average over 5 independent runs.

Results from our model for a range of hyperparameters are presented in Table 1. With the best choice of hyperparameters ($\alpha = .003, \beta = 1$), we achieve average tagging accuracy of 86.8%. This far surpasses the MLHMM performance of 74.5%, and is closer to the 90.1% accuracy of CRF/CE on the same data set using oracle parameter selection. The effects of α, which determines the probability of the transition distributions, are stronger than the effects of β, which determines the probability of the output distributions. The optimal value of .003 for α reflects the fact that the true transition probability matrix for this corpus is indeed sparse. As α grows larger, the model prefers more uniform transition probabilities, which causes it to perform worse. Although the true output distributions tend to be sparse as well, the level of sparseness depends on the tag (consider function words vs. content words in particular). Therefore, a value of β that accurately reflects the most probable output distributions for some tags may be a poor choice for other tags. This leads to the smaller effect of β, and suggests that performance might be improved by selecting a different β for each tag, as we do in the next section.

Value of α	Value of β .001	.003	.01	.03	.1	.3	1.0
.001	85.0	85.7	86.1	86.0	86.2	86.5	86.6
.003	85.5	85.5	85.8	86.6	86.7	86.7	**86.8**
.01	85.3	85.5	85.6	85.9	86.4	86.4	86.2
.03	85.9	85.8	86.1	86.2	86.6	86.8	86.4
.1	85.2	85.0	85.2	85.1	84.9	85.5	84.9
.3	84.4	84.4	84.6	84.4	84.5	85.7	85.3
1.0	83.1	83.0	83.2	83.3	83.5	83.7	83.9

Table 1: Percentage of words tagged correctly by BHMM as a function of the hyperparameters α and β. Results are averaged over 5 runs on the 24k corpus with full tag dictionary. Standard deviations in most cases are less than .5.

A final point worth noting is that even when $\alpha = \beta = 1$ (i.e., the Dirichlet priors exert no influence) the BHMM still performs much better than the MLHMM. This result underscores the importance of integrating over model parameters: the BHMM identifies a sequence of tags that have high proba-

[2]Results of CRF/CE depend on the set of features used and the contrast neighborhood. In all cases, we list the best score reported for any contrast neighborhood using trigram (but no spelling) features. To ensure proper comparison, all corpora used in our experiments consist of the same randomized sets of sentences used by Smith and Eisner. Note that training on sets of contiguous sentences from the beginning of the treebank consistently improves our results, often by 1-2 percentage points or more. MLHMM scores show less difference between randomized and contiguous corpora.

bility over a range of parameter values, rather than choosing tags based on the single best set of parameters. The improved results of the BHMM demonstrate that selecting a sequence that is robust to variations in the parameters leads to better performance.

4 Hyperparameter Inference

In our initial experiments, we experimented with different fixed values of the hyperparameters and reported results based on their optimal values. However, choosing hyperparameters in this way is time-consuming at best and impossible at worst, if there is no gold standard available. Luckily, the Bayesian approach allows us to automatically select values for the hyperparameters by treating them as additional variables in the model. We augment the model with priors over the hyperparameters (here, we assume an improper uniform prior), and use a single Metropolis-Hastings update (Gilks et al., 1996) to resample the value of each hyperparameter after each iteration of the Gibbs sampler. Informally, to update the value of hyperparameter α, we sample a proposed new value α' from a normal distribution with $\mu = \alpha$ and $\sigma = .1\alpha$. The probability of accepting the new value depends on the ratio between $P(\mathbf{t}|\mathbf{w}, \alpha)$ and $P(\mathbf{t}|\mathbf{w}, \alpha')$ and a term correcting for the asymmetric proposal distribution.

Performing inference on the hyperparameters allows us to relax the assumption that every tag has the same prior on its output distribution. In the experiments reported in the following section, we used two different versions of our model. The first version (BHMM1) uses a single value of β for all word classes (as above); the second version (BHMM2) uses a separate β_j for each tag class j.

5 Inferred Hyperparameter Experiments

5.1 Varying corpus size

In this set of experiments, we used the full tag dictionary (as above), but performed inference on the hyperparameters. Following Smith and Eisner (2005), we trained on four different corpora, consisting of the first 12k, 24k, 48k, and 96k words of the WSJ corpus. For all corpora, the percentage of ambiguous tokens is 54%-55% and the average number of tags per token is 2.3. Table 2 shows results for the various models and a random baseline (averaged over 5 random tag assignments). Hyperparameter inference leads to slightly lower scores than are obtained by oracle hyperparameter selection, but both versions of BHMM are still far superior to MLHMM for all corpus sizes. Not surprisingly, the advantages of BHMM are most pronounced on the smallest corpus: the effects of parameter integration and sensible priors are stronger when less evidence is available from the input. In the limit as corpus size goes to infinity, the BHMM and MLHMM will make identical predictions.

	Corpus size			
Accuracy	12k	24k	48k	96k
random	64.8	64.6	64.6	64.6
MLHMM	71.3	74.5	76.7	78.3
CRF/CE	86.2	88.6	88.4	89.4
BHMM1	85.8	85.2	83.6	85.0
BHMM2	85.8	84.4	85.7	85.8
$\sigma <$	.7	.2	.6	.2

Table 2: Percentage of words tagged correctly by the various models on different sized corpora. BHMM1 and BHMM2 use hyperparameter inference; CRF/CE uses parameter selection based on an unlabeled development set. Standard deviations (σ) for the BHMM results fell below those shown for each corpus size.

5.2 Varying dictionary knowledge

In unsupervised learning, it is not always reasonable to assume that a large tag dictionary is available. To determine the effects of reduced or absent dictionary information, we ran a set of experiments inspired by those of Smith and Eisner (2005). First, we collapsed the set of 45 treebank tags onto a smaller set of 17 (the same set used by Smith and Eisner). We created a full tag dictionary for this set of tags from the entire treebank, and also created several reduced dictionaries. Each reduced dictionary contains the tag information only for words that appear at least d times in the training corpus (the 24k corpus, for these experiments). All other words are fully ambiguous between all 17 classes. We ran tests with $d = 1, 2, 3, 5, 10$, and ∞ (i.e., knowledge-free syntactic clustering).

With standard accuracy measures, it is difficult to

	Value of d					
Accuracy	1	2	3	5	10	∞
random	69.6	56.7	51.0	45.2	38.6	
MLHMM	83.2	70.6	65.5	59.0	50.9	
CRF/CE	90.4	77.0	71.7			
BHMM1	86.0	76.4	71.0	64.3	58.0	
BHMM2	87.3	79.6	65.0	59.2	49.7	
$\sigma <$	.2	.8	.6	.3	1.4	
VI						
random	2.65	3.96	4.38	4.75	5.13	7.29
MLHMM	1.13	2.51	3.00	3.41	3.89	6.50
BHMM1	1.09	2.44	2.82	3.19	3.47	4.30
BHMM2	**1.04**	**1.78**	**2.31**	**2.49**	**2.97**	**4.04**
$\sigma <$	.02	.03	.04	.03	.07	.17
Corpus stats						
% ambig.	49.0	61.3	66.3	70.9	75.8	100
tags/token	1.9	4.4	5.5	6.8	8.3	17

Table 3: Percentage of words tagged correctly and variation of information between clusterings induced by the assigned and gold standard tags as the amount of information in the dictionary is varied. Standard deviations (σ) for the BHMM results fell below those shown in each column. The percentage of ambiguous tokens and average number of tags per token for each value of d is also shown.

evaluate the quality of a syntactic clustering when no dictionary is used, since cluster names are interchangeable. We therefore introduce another evaluation measure for these experiments, a distance metric on clusterings known as *variation of information* (Meilă, 2002). The variation of information (VI) between two clusterings C (the gold standard) and C' (the found clustering) of a set of data points is a sum of the amount of information lost in moving from C to C', and the amount that must be gained. It is defined in terms of entropy H and mutual information I: $VI(C, C') = H(C) + H(C') - 2I(C, C')$. Even when accuracy can be measured, VI may be more informative: two different tag assignments may have the same accuracy but different VI with respect to the gold standard if the *errors* in one assignment are less consistent than those in the other.

Table 3 gives the results for this set of experiments. One or both versions of BHMM outperform MLHMM in terms of tag accuracy for all values of d, although the differences are not as great as in earlier experiments. The differences in VI are more striking, particularly as the amount of dictionary information is reduced. When ambiguity is greater, both versions of BHMM show less confusion with respect to the true tags than does MLHMM, and BHMM2 performs the best in all circumstances. The confusion matrices in Figure 3 provide a more intuitive picture of the very different sorts of clusterings produced by MLHMM and BHMM2 when no tag dictionary is available. Similar differences hold to a lesser degree when a partial dictionary is provided. With MLHMM, different tokens of the same word type are usually assigned to the same cluster, but types are assigned to clusters more or less at random, and all clusters have approximately the same number of types (542 on average, with a standard deviation of 174). The clusters found by BHMM2 tend to be more coherent and more variable in size: in the 5 runs of BHMM2, the average number of types per cluster ranged from 436 to 465 (i.e., tokens of the same word are spread over fewer clusters than in MLHMM), with a standard deviation between 460 and 674. Determiners, prepositions, the possessive marker, and various kinds of punctuation are mostly clustered coherently. Nouns are spread over a few clusters, partly due to a distinction found between common and proper nouns. Likewise, modal verbs and the copula are mostly separated from other verbs. Errors are often sensible: adjectives and nouns are frequently confused, as are verbs and adverbs.

The kinds of results produced by BHMM1 and BHMM2 are more similar to each other than to the results of MLHMM, but the differences are still informative. Recall that BHMM1 learns a single value for β that is used for all output distributions, while BHMM2 learns separate hyperparameters for each cluster. This leads to different treatments of difficult-to-classify low-frequency items. In BHMM1, these items tend to be spread evenly among all clusters, so that all clusters have similarly sparse output distributions. In BHMM2, the system creates one or two clusters consisting entirely of very infrequent items, where the priors on these clusters strongly prefer uniform outputs, and all other clusters prefer extremely sparse outputs (and are more coherent than in BHMM1). This explains the difference in VI between the two systems, as well as the higher accuracy of BHMM1 for $d \geq 3$: the single β discourages placing low-frequency items in their own cluster, so they are more likely to be clustered with items that have sim-

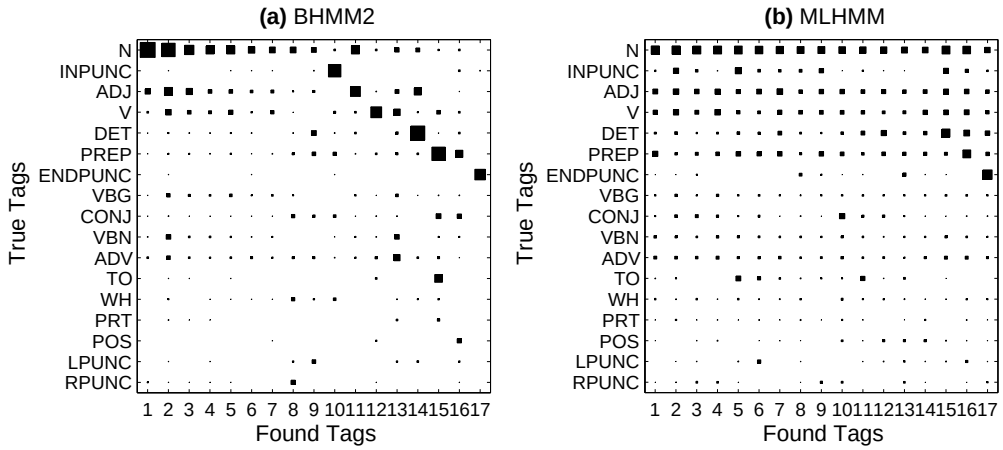

Figure 3: Confusion matrices for the dictionary-free clusterings found by (a) BHMM2 and (b) MLHMM.

ilar transition probabilities. The problem of junk clusters in BHMM2 might be alleviated by using a non-uniform prior over the hyperparameters to encourage some degree of sparsity in all clusters.

6 Conclusion

In this paper, we have demonstrated that, for a standard trigram HMM, taking a Bayesian approach to POS tagging dramatically improves performance over maximum-likelihood estimation. Integrating over possible parameter values leads to more robust solutions and allows the use of priors favoring sparse distributions. The Bayesian approach is particularly helpful when learning is less constrained, either because less data is available or because dictionary information is limited or absent. For knowledge-free clustering, our approach can also be extended through the use of infinite models so that the number of clusters need not be specified in advance. We hope that our success with POS tagging will inspire further research into Bayesian methods for other natural language learning tasks.

Abstract

We describe a new loss function, due to Jeon and Lin (2006), for estimating structured log-linear models on arbitrary features. The loss function can be seen as a (generative) alternative to maximum likelihood estimation with an interesting information-theoretic interpretation, and it is statistically consistent. It is substantially faster than maximum (conditional) likelihood estimation of conditional random fields (Lafferty et al., 2001; an order of magnitude or more). We compare its performance and training time to an HMM, a CRF, an MEMM, and pseudolikelihood on a shallow parsing task. These experiments help tease apart the contributions of rich features and discriminative training, which are shown to be more than additive.

1 Introduction

Log-linear models are a very popular tool in natural language processing, and are often lauded for permitting the use of "arbitrary" and "correlated" features of the data by a model. Users of log-linear models know, however, that this claim requires some qualification: any feature is permitted in principle, but training log-linear models (and decoding under them) is tractable only when the model's independence assumptions permit efficient inference procedures. For example, in the original conditional random fields (Lafferty et al., 2001), features were confined to locally-factored indicators on label bigrams and label unigrams (with any of the observation).

Even in cases where inference in log-linear models is tractable, it requires the computation of a partition function. More formally, a log-linear model for random variables X and Y over $\mathcal{X}, \mathcal{Y}$ defines:

$$p_{\mathbf{w}}(x, y) = \frac{e^{\mathbf{w}^\top \mathbf{f}(x,y)}}{\sum_{x',y' \in \mathcal{X} \times \mathcal{Y}} e^{\mathbf{w}^\top \mathbf{f}(x',y')}} = \frac{e^{\mathbf{w}^\top \mathbf{f}(x,y)}}{Z(\mathbf{w})} \quad (1)$$

where $\mathbf{f} : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^m$ is the feature vector-function and $\mathbf{w} \in \mathbb{R}^m$ is a weight vector that parameterizes the model. In NLP, we rarely train this model by maximizing *likelihood*, because the partition function $Z(\mathbf{w})$ is expensive to compute exactly. $Z(\mathbf{w})$ can be approximated (e.g., using Gibbs sampling; Rosenfeld, 1997).

In this paper, we propose the use of a new loss function that is computationally **efficient** and statistically **consistent** (§2). Notably, repeated inference is not required during estimation. This loss function can be seen as a case of M-estimation[1] that was originally developed by Jeon and Lin (2006) for nonparametric density estimation. This paper gives an information-theoretic motivation that helps elucidate the objective function (§3), shows how to apply the new estimator to structured models used in NLP (§4), and compares it to a state-of-the-art noun phrase chunker (§5). We discuss implications and future directions in §6.

2 Loss Function

As before, let X be a random variable over a high-dimensional space $\mathcal{X}$, and similarly Y over $\mathcal{Y}$. $\mathcal{X}$

[1] "M-estimation" is a generalization of MLE (van der Vaart, 1998); space does not permit a full discussion.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 752–759,
Prague, Czech Republic, June 2007.

might be the set of all sentences in a language, and $\mathcal{Y}$ the set of all POS tag sequences or the set of all parse trees. Let q_0 be a "base" distribution that is our first approximation to the true distribution over $\mathcal{X} \times \mathcal{Y}$. HMMs and PCFGs, while less accurate as predictors than the rich-featured log-linear models we desire, might be used to define q_0.

The model we estimate will have the form

$$p_{\mathbf{w}}(x, y) \propto q_0(x, y) e^{\mathbf{w}^\top \mathbf{f}(x,y)} \tag{2}$$

Notice that $p_{\mathbf{w}}(x, y) = 0$ whenever $q_0(x, y) = 0$. It is therefore important for q_0 to be smooth, since the support of $p_{\mathbf{w}}$ is a subset of the support of q_0. Notice that we have not written the partition function explicitly in Eq. 2; it will never need to be computed during estimation or inference. The unnormalized distribution will suffice for all computation.

Suppose we have observations $\langle x_1, x_2, ..., x_n \rangle$ with annotations $\langle y_1, ..., y_n \rangle$. The (unregularized) loss function, due to Jeon and Lin (2006), is[2]

$$\begin{aligned}
\ell(\mathbf{w}) &= \frac{1}{n} \sum_{i=1}^{n} e^{-\mathbf{w}^\top \mathbf{f}(x_i, y_i)} \\
&\quad + \sum_{x,y} q_0(x, y) \left(\mathbf{w}^\top \mathbf{f}(x, y) \right) \qquad (3) \\
&= \frac{1}{n} \sum_{i=1}^{n} e^{-\mathbf{w}^\top \mathbf{f}(x_i, y_i)} + \mathbf{w}^\top \sum_{x,y} q_0(x, y) \mathbf{f}(x, y) \\
&= \frac{1}{n} \sum_{i=1}^{n} e^{-\mathbf{w}^\top \mathbf{f}(x_i, y_i)} + \mathbf{w}^\top \underbrace{\mathbf{E}_{q_0(X,Y)}[\mathbf{f}(X, Y)]}_{\text{constant}(\mathbf{w})}
\end{aligned}$$

Before explaining this objective, we point out some attractive computational properties. Notice that $\mathbf{f}(x_i, y_i)$ (for all i) and the expectations of the feature vectors under q_0 are *constant* with respect to $\mathbf{w}$. Computing the function in Eq. 3, then, requires no inference and no dynamic programming, only $O(nm)$ floating-point operations.

3 An Interpretation

Here we give an account of the loss function as a way of "cleaning up" a mediocre model (q_0). We show that this estimate aims to *model* a presumed perturbation that created q_0, by minimizing the KL divergence between q_0 and a perturbed version of the sample distribution $\tilde{p}$.

Consider Eq. 2. Given a training dataset, maximizing *likelihood* under this model means assuming that there is some $\mathbf{w}^*$ for which the true distribution $p^*(x, y) = p_{\mathbf{w}^*}(x, y)$. Carrying out MLE, however, would require computing the partition function $\sum_{x',y'} q_0(x', y') e^{\mathbf{w}^\top \mathbf{f}(x',y')}$, which is in general intractable. Rearranging Eq. 2 slightly, we have

$$q_0(x, y) \propto p^*(x, y) e^{-\mathbf{w}^\top \mathbf{f}(x,y)} \tag{4}$$

If q_0 is close to the true model, $e^{-\mathbf{w}^\top \mathbf{f}(x,y)}$ should be close to 1 and $\mathbf{w}$ close to zero. In the sequence model setting, for example, if q_0 is an HMM that explains the data well, then the additional features are not necessary (equivalently, their weights should be 0). If q_0 is imperfect, we might wish to make it more powerful by adding features (e.g., $\mathbf{f}$), but q_0 nonetheless provides a reasonable "starting point" for defining our model.

So instead of maximizing likelihood, we will *minimize* the KL divergence between the two sides of Eq. 4.[3]

$$\begin{aligned}
&D_{\mathrm{KL}}(q_0(x, y) \| p^*(x, y) e^{-\mathbf{w}^\top \mathbf{f}(x,y)}) \qquad (5) \\
&= \sum_{x,y} q_0(x, y) \log \frac{q_0(x, y)}{p^*(x, y) e^{-\mathbf{w}^\top \mathbf{f}(x,y)}} \qquad (6) \\
&\quad + \sum_{x,y} p^*(x, y) e^{-\mathbf{w}^\top \mathbf{f}(x,y)} - \sum_{x,y} q_0(x, y) \\
&= -H(q_0) + \sum_{x,y} p^*(x, y) e^{-\mathbf{w}^\top \mathbf{f}(x,y)} - 1 \\
&\quad - \sum_{x,y} q_0(x, y) \log \left(p^*(x, y) e^{-\mathbf{w}^\top \mathbf{f}(x,y)} \right) \\
&= \text{constant}(\mathbf{w}) + \sum_{x,y} p^*(x, y) e^{-\mathbf{w}^\top \mathbf{f}(x,y)} \\
&\quad + \sum_{x,y} q_0(x, y) \left(\mathbf{w}^\top \mathbf{f}(x, y) \right)
\end{aligned}$$

[2] We give only the discrete version here, because it is most relevant for an ACL audience. Also, our linear function $\mathbf{w}^\top \mathbf{f}(x_i, y_i)$ is a simple case; another kernel (for example) could be used.

[3] The KL divergence here is generalized for unnormalized distributions, following O'Sullivan (1998):

$$D_{\mathrm{KL}}(\mathbf{u} \| \mathbf{v}) = \textstyle\sum_j \left(u_j \log \frac{u_j}{v_j} - u_j + v_j \right)$$

where $\mathbf{u}$ and $\mathbf{v}$ are nonnegative vectors defining unnormalized distributions over the same event space. Note that when $\sum_j u_j = \sum_j v_j = 1$, this formula takes on the more familiar form, as $-\sum_j u_j$ and $\sum_j v_j$ cancel.

If we replace p^* with the empirical (sampled) distribution $\tilde{p}$, minimizing the above KL divergence is equivalent to minimizing $\ell(\mathbf{w})$ (Eq. 3). It may be helpful to think of $-\mathbf{w}$ as the parameters of a process that "damage" the true model p^*, producing q_0, and the estimation of $\mathbf{w}$ as learning to undo that damage.

In the remainder of the paper, we use the general term "M-estimation" to refer to the minimization of $\ell(\mathbf{w})$ as a way of training a log-linear model.

4 Algorithms for Models of Sequences and Trees

We discuss here some implementation aspects of the application of M-estimation to NLP models.

4.1 Expectations under q_0

The base distribution q_0 enters into implementation in two places: $\mathbf{E}_{q_0(X,Y)}[\mathbf{f}(X,Y)]$ must be computed for training, and $q_0(x,y)$ is a factor in the model used in *decoding*.

If q_0 is a familiar stochastic grammar, such as an HMM or a PCFG, or any generative model from which sampling is straightforward, it is possible to estimate the feature expectations by sampling from the model directly; for sample $\langle(\tilde{x}_i, \tilde{y}_i)\rangle_{i=1}^{s}$ let:

$$\mathbf{E}_{q_0(X,Y)}[f_j(X,Y)] \leftarrow \frac{1}{s}\sum_{i=1}^{s} f_j(\tilde{x}_i, \tilde{y}_i) \quad (7)$$

If the feature space is sparse under q_0 (likely in most settings), then smoothing may be required.

If q_0 is an HMM or a PCFG, the expectation vector can be computed exactly by solving a system of equations. We will see that for the common cases where features are local substructures, inference is straightforward. We briefly describe how this can be done for a bigram HMM and a PCFG.

4.1.1 Expectations under an HMM

Let $\mathcal{S}$ be the state space of a first-order HMM. If $\mathbf{s} = \langle s_1, ..., s_k\rangle$ is a state sequence and $\mathbf{x} = \langle x_1, ..., x_k\rangle$ is an observed sequence of emissions, then:

$$q_0(\mathbf{s}, \mathbf{x}) = \left(\prod_{i=1}^{k} t_{s_{i-1}}(s_i) e_{s_i}(x_i)\right) t_{s_k}(\text{stop}) \quad (8)$$

(Assume $s_0 = \text{start}$ is the single, silent, initial state, and stop is the only stop state, also silent. We assume no other states are silent.)

The first step is to compute path-sums *into* and *out of* each state, under the HMM q_0. To do this, define i_s as the total weight of state-prefixes (beginning in start) ending in s and o_s as the total weight of state-suffixes beginning in s (and ending in stop):[4]

$$i_{\text{start}} = o_{\text{stop}} = 1 \quad (9)$$

$$\forall s \in \mathcal{S} \setminus \{\text{start}, \text{stop}\}:$$

$$\begin{aligned} i_s &= \sum_{n=1}^{\infty} \sum_{\langle s_1,...,s_n\rangle \in \mathcal{S}^n} \left(\prod_{i=1}^{n} t_{s_{i-1}}(s_i)\right) t_{s_n}(s) \\ &= \sum_{s' \in \mathcal{S}} i_{s'} t_{s'}(s) \quad (10) \\ o_s &= \sum_{n=1}^{\infty} \sum_{\langle s_1,...,s_n\rangle \in \mathcal{S}^n} t_s(s_1) \left(\prod_{i=2}^{n} t_{s_{i-1}}(s_i)\right) \\ &= \sum_{s' \in \mathcal{S}} t_s(s') o_{s'} \quad (11) \end{aligned}$$

This amounts to two linear systems given the transition probabilities t, where the variables are $i_\bullet$ and $o_\bullet$, respectively. In each system there are $|\mathcal{S}|$ variables and $|\mathcal{S}|$ equations. Once solved, expected counts of transition and emission features under q_0 are straightforward:

$$\begin{aligned} \mathbf{E}_{q_0}[s \overset{\text{transit}}{\rightarrow} s'] &= i_s t_s(s') o_{s'} \\ \mathbf{E}_{q_0}[s \overset{\text{emit}}{\rightarrow} x] &= i_s e_s(x) o_s \end{aligned}$$

Given i and o, $\mathbf{E}_{q_0}$ can be computed for other features in the model in a similar way, provided they correspond to contiguous substructures. For example, a feature f_{627} that counts occurrences of "$S_i = s$ and $X_{i+3} = x$" has expected value $\mathbf{E}_{q_0}[f_{627}] =$

$$\sum_{s',s'',s''' \in \mathcal{S}} i_s t_s(s') t_{s'}(s'') t_{s''}(s''') e_{s'''}(x) o_{s'''} \quad (12)$$

Non-contiguous substructure features with "gaps" require summing over paths between any pair of states. This is straightforward (we omit it for space), but of course using such features (while interesting) would complicate inference in decoding.

[4] It may be helpful to think of i as forward probabilities, but for the observation set $\mathcal{Y}^*$ rather than a *particular* observation $\mathbf{y}$. o are like backward probabilities. Note that, because some counted prefixes are prefixes of others, i can be > 1; similarly for o.

4.1.2 Expectations under a PCFG

In general, the expectations for a PCFG require solving a quadratic system of equations. The analogy this time is to inside and outside probabilities. Let the PCFG have nonterminal set $\mathcal{N}$, start symbol $S \in \mathcal{N}$, terminal alphabet Σ, and rules of the form $A \rightarrow B\ C$ and $A \rightarrow x$. (We assume Chomsky normal form for clarity; the generalization is straightforward.) Let $r_A(B\ C)$ and $r_A(x)$ denote the probabilities of nonterminal A rewriting to child sequence $B\ C$ or x, respectively. Then $\forall A \in \mathcal{N}$:

$$\begin{aligned} o_A &= \sum_{B \in \mathcal{N}} \sum_{C \in \mathcal{N}} o_B i_C [r_B(A\ C) + r_B(C\ A)] \\ &\quad + \begin{cases} 1 & \text{if } A = S \\ 0 & \text{otherwise} \end{cases} \\ i_A &= \sum_{B \in \mathcal{N}} \sum_{C \in \mathcal{N}} r_A(B\ C) i_B i_C\ + \sum_x r_A(x) i_x \\ o_x &= \sum_{A \in \mathcal{N}} o_A r_A(x), \forall x \in \Sigma \\ i_x &= 1, \forall x \in \Sigma \end{aligned}$$

In most practical applications, the PCFG will be "tight" (Booth and Thompson, 1973; Chi and Geman, 1998). Informally, this means that the probability of a derivation rooted in S failing to terminate is zero. If that is the case, then $i_A = 1$ for all $A \in \mathcal{N}$, and the system becomes linear (see also Corazza and Satta, 2006).[5] If tightness is not guaranteed, iterative propagation of weights, following Stolcke (1995), works well in our experience for solving the quadratic system, and converges quickly.

As in the HMM case, expected counts of arbitrary contiguous tree substructures can be computed as products of probabilities of rules appearing within the structure, factoring in the o value of the structure's root and the i values of the structure's leaves.

4.2 Optimization

To carry out M-estimation, we minimize the function $\ell(\mathbf{w})$ in Eq. 3. To apply gradient descent or a quasi-Newton numerical optimization method,[6] it suffices to specify the fixed quantities $\mathbf{f}(x_i, y_i)$ (for all $i \in \{1, 2, ..., n\}$) and the vector $\mathbf{E}_{q_0(X,Y)}[\mathbf{f}(X, Y)]$. The gradient is:[7]

$$\frac{\partial \ell}{\partial w_j} = -\sum_{i=1}^{n} e^{-\mathbf{w}^\top \mathbf{f}(x_i, y_i)} f_j(x_i, y_i) + \mathbf{E}_{q_0}[f_j] \tag{13}$$

The Hessian (matrix of second derivatives) can also be computed with relative ease, though the space requirement could become prohibitive. For problems where m is relatively small, this would allow the use of second-order optimization methods that are likely to converge in fewer iterations.

It is easy to see that Eq. 3 is convex in $\mathbf{w}$. Therefore, convergence to a global optimum is guaranteed and does not depend on the initializing value of $\mathbf{w}$.

4.3 Regularization

Regularization is a technique from pattern recognition that aims to keep parameters (like $\mathbf{w}$) from overfitting the training data. It is crucial to the performance of most statistical learning algorithms, and our experiments show it has a major effect on the success of the M-estimator. Here we use a quadratic regularizer, minimizing $\ell(\mathbf{w}) + (\mathbf{w}^\top \mathbf{w})/2c$. Note that this is also convex and differentiable if $c > 0$. The value of c can be chosen using a tuning dataset. This regularizer aims to keep each coordinate of $\mathbf{w}$ close to zero.

In the M-estimator, regularization is particularly important when the expectation of some feature f_j, $\mathbf{E}_{q_0(X,Y)}[f_j(X, Y)]$ is equal to zero. This can happen either due to sampling error (f_j simply failed to appear with a positive value in the finite sample) or because q_0 assigns zero probability mass to any $x \in \mathcal{X}, y \in \mathcal{Y}$ where $f_j(x, y) \neq 0$. Without regularization, the weight w_j will tend toward $\pm\infty$, but the quadratic penalty term will prevent that undesirable tendency. Just as the addition of a quadratic regularizer to likelihood can be interpreted as a zero-mean Gaussian prior on $\mathbf{w}$ (Chen and Rosenfeld, 2000), it can be so-interpreted here. The regularized objective is analogous to maximum *a posteriori* estimation.

5 Shallow Parsing

We compared M-estimation to a hidden Markov model and other training methods on English noun

[5] The same is true for HMMs: if the probability of nontermination is zero, then for all $s \in \mathcal{S}$, $o_s = 1$.

[6] We use L-BFGS (Liu and Nocedal, 1989) as implemented in the R language's `optim` function.

[7] Taking the limit as $n \rightarrow \infty$ and setting equal to zero, we have the basis for a proof that $\ell(\mathbf{w})$ is statistically consistent.

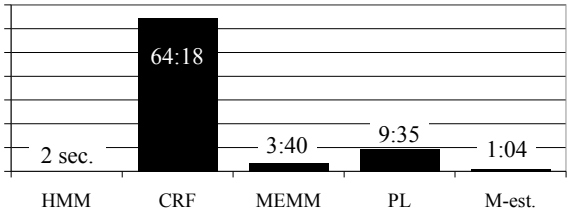

Figure 1: Wall time (hours:minutes) of training the HMM and 100 L-BFGS iterations for each of the extended-feature models on a 2.2 GHz Sun Opteron with 8GB RAM. See discussion in text for details.

phrase (NP) chunking. The dataset comes from the Conference on Natural Language Learning (CoNLL) 2000 shallow parsing shared task (Tjong Kim Sang and Buchholz, 2000); we apply the model to NP chunking only. About 900 sentences were reserved for tuning regularization parameters.

Baseline/q_0 In this experiment, the simple baseline is a second-order HMM. The states correspond to $\{\mathrm{B}, \mathrm{I}, \mathrm{O}\}$ labels, denoting the beginning, inside, and outside of noun phrases. Each state emits a tag and a word (independent of each other given the state). We replaced the first occurrence of every tag and of every word in the training data with an OOV symbol, giving a fixed tag vocabulary of 46 and a fixed word vocabulary of 9,014. Transition distributions were estimated using MLE, and tag- and word-emission distributions were estimated using add-1 smoothing. The HMM had 27,213 parameters. This HMM achieves 86.3% F_1-measure on the development dataset (slightly better than the lowest-scoring of the CoNLL-2000 systems). Heavier or weaker smoothing (an order of magnitude difference in add-λ) of the emission distributions had very little effect. Note that HMM training time is negligible (roughly 2 seconds); it requires counting events, smoothing the counts, and normalizing.

Extended Feature Set Sha and Pereira (2003) applied a conditional random field to the NP chunking task, achieving excellent results. To improve the performance of the HMM and test different estimation methods, we use Sha and Pereira's feature templates, which include subsequences of labels, tags, and words of different lengths and offsets. Here, we use only features observed to occur at least once in the training data, accounting (in addition to our OOV treatment) for the slight drop in performance compared to what Sha and Pereira report. There are 630,862 such features.

	prec.	recall	F_1
HMM features:			
HMM	85.60	88.68	87.11
CRF	90.40	89.56	89.98

MEMM	90.89	92.15	91.51
M-est.	88.88	90.42	89.64

Table 1: NP chunking accuracy on test data using different training methods. The effects of discriminative training (CRF) and extended feature sets (lower section) are more than additive.

Using the original HMM feature set and the extended feature set, we trained four models that can use arbitrary features: **conditional random fields** (a near-replication of Sha and Pereira, 2003), **maximum entropy Markov models** (MEMMs; McCallum et al., 2000), **pseudolikelihood** (Besag, 1975; see Toutanova et al., 2003, for a tagging application), and our M-estimator with the HMM as q_0. CRFs and MEMMs are discriminatively-trained to maximize conditional likelihood (the former is parameterized using a sequence-normalized log-linear model, the latter using a locally-normalized log-linear model). Pseudolikelihood is a consistent estimator for the *joint* likelihood, like our M-estimator; its objective function is a sum of log probabilities.

In each case, we trained seven models for each feature set with quadratic regularizers $c \in [10^{-1}, 10]$, spaced at equal intervals in the log-scale, plus an unregularized model ($c = \infty$). As discussed in §4.2, we trained using L-BFGS; training continued until relative improvement fell within machine precision or 100 iterations, whichever came first. After training, the value of c is chosen that maximizes F_1 accuracy on the tuning set.

Runtime Fig. 1 compares the wall time of carefully-timed training runs on a dedicated server. Note that Dyna, a high-level programming language, was used for dynamic programming (in the CRF)

and summations (MEMM and pseudolikelihood). The runtime overhead incurred by using Dyna is estimated as a slow-down factor of 3–5 against a hand-tuned implementation (Eisner et al., 2005), though the slow-down factor is almost certainly less for the MEMM and pseudolikelihood. All training (except the HMM, of course) was done using the R language implementation of L-BFGS. In our implementation, the M-estimator trained substantially faster than the other methods. Of the 64 minutes required to train the M-estimator, 6 minutes were spent precomputing $\mathbf{E}_{q_0(X,Y)}[\mathbf{f}(X,Y)]$ (this need not be repeated if the regularization settings are altered).

Accuracy Tab. 1 shows how NP chunking accuracy compares among the models. With HMM features, the M-estimator is about the same as the HMM and MEMM (better than PL and worse than the CRF). With extended features, the M-estimator lags behind the slower methods, but performs about the same as the HMM-featured CRF (2.5–3 points over the HMM). The full-featured CRF improves performance by another 4 points. Performance as a function of training set size is plotted in Fig. 2; the different methods behave relatively similarly as the training data are reduced. Fig. 3 plots accuracy (on tuning data) against training time, for a variety of training dataset sizes and regularizaton settings, under different training methods. This illustrates the training-time/accuracy tradeoff: the M-estimator, when well-regularized, is considerably faster than the other methods, at the expense of accuracy. This experiment gives some insight into the relative importance of extended **features** versus **estimation methods**. The M-estimated model is, like the maximum likelihood-estimated HMM, a generative model. Unlike the HMM, it uses a much larger set of features–the same features that the discriminative models use. Our result supports the claim that good features are necessary for state-of-the-art performance, but so is good training.

5.1 Effect of the Base Distribution

We now turn to the question of the base distribution q_0: how accurate does it need to be? Given that the M-estimator is consistent, it should be clear that, in the limit and assuming that our model family p is correct, q_0 should not matter (except in its support).

q_0	selection	prec.	recall	F_1
HMM	F_1, prec.	88.88	90.42	89.64
l.u.	F_1	72.91	57.56	64.33
	prec.	84.40	37.68	52.10
emp.	F_1	84.38	89.43	86.83

Table 2: NP chunking accuracy on test data using different base models for the M-estimator. The "selection" column shows which accuracy measure was optimized when selecting the hyperparameter c.

In NLP, we deal with finite datasets and imperfect models, so q_0 may have practical importance.

We next consider an alternative q_0 that is far less powerful; in fact, it is uninformative about the variable to be predicted. Let $\mathbf{x}$ be a sequence of words, $\mathbf{t}$ be a sequence of part-of-speech tags, and $\mathbf{y}$ be a sequence of $\{\mathrm{B}, \mathrm{I}, \mathrm{O}\}$-labels. The model is:

$$q_0^{\text{l.u.}}(\mathbf{x}, \mathbf{t}, \mathbf{y}) \stackrel{\text{def}}{=} \left(\prod_{i=1}^{|\mathbf{x}|} p_{\text{uni}}(x_i) p_{\text{uni}}(t_i) \frac{1}{N_{y_{i-1}}} \right) \frac{1}{N_{y_{|\mathbf{x}|}}} \tag{14}$$

where N_y is the number of labels (including stop) that can follow y (3 for O and $y_0 = \text{start}$, 4 for B and I). p_{uni} are the tag and word unigram distributions, estimated using MLE with add-1 smoothing. This model ignores temporal effects. On its own, this model achieves 0% precision and recall, because it labels every word O (the most likely label sequence is $\mathrm{O}^{|\mathbf{x}|}$). We call this model **l.u.** ("locally uniform").

Tab. 2 shows that, while an M-estimate that uses $q_0^{\text{l.u.}}$ is not nearly as accurate as the one based on an HMM, the M-estimator *did* manage to improve considerably over $q_0^{\text{l.u.}}$. So the M-estimator is far better than nothing, and in this case, tuning c to maximize precision (rather than F_1) led to an M-estimated model with precision competitive with the HMM. We point this out because, in applications involving very large corpora, a model with good precision may be useful even if its coverage is mediocre.

Another question about q_0 is whether it should take into account all possible values of the input variables (here, $\mathbf{x}$ and $\mathbf{t}$), or only those seen in training. Consider the following model:

$$q_0^{\text{emp}}(\mathbf{x}, \mathbf{t}, \mathbf{y}) \stackrel{\text{def}}{=} q_0(\mathbf{y} \mid \mathbf{x}, \mathbf{t}) \tilde{p}(\mathbf{x}, \mathbf{t}) \tag{15}$$

Here we use the empirical distribution over tag/word

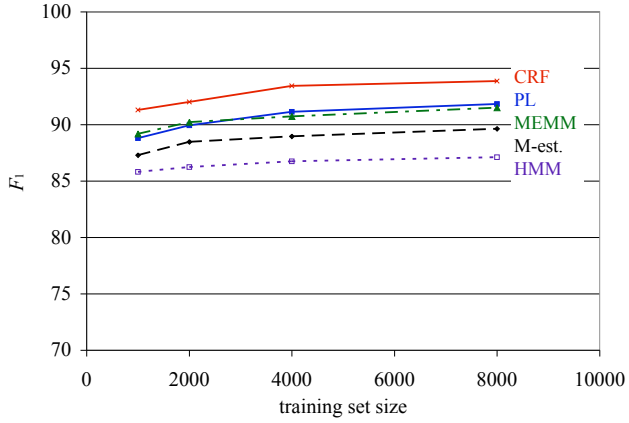

Figure 2: Learning curves for different estimators; all of these estimators except the HMM use the extended feature set.

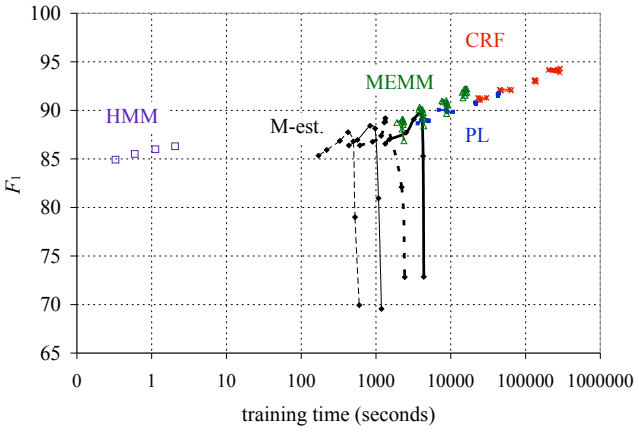

Figure 3: Accuracy (tuning data) vs. training time. The M-estimator trains notably faster. The points in a given curve correspond to different regularization strengths (c); M-estimation is more damaged by weak than strong regularization.

sequences, and the HMM to define the distribution over label sequences. The expectations $\mathbf{E}_{q_0^{\text{emp}}(X)}[\mathbf{f}(X)]$ can be computed using dynamic programming over the training data (recall that this only needs to be done once, cf. the CRF). Strictly speaking, q_0^{emp} assigns probability zero to any sequence not seen in training, but we can ignore the $\tilde{p}$ marginal at decoding time. As shown in Tab. 2, this model slightly improves recall over the HMM, but damages precision; the gains of M-estimation seen with the HMM as q_0, are not reproduced. From these experiments, we conclude that the M-estimator might perform considerably better, given a better q_0.

5.2 Input-Only Features

We present briefly one negative result. Noting that the M-estimator is a modeling technique that estimates a distribution over both input and output variables (i.e., a generative model), we wanted a way to make the objective more discriminative while still maintaining the computational property that inference (of any kind) not be required during the inner loop of iterative training.

The idea is to reduce the predictive burden on the feature weights for $\mathbf{f}$. When designing a CRF, features that do not depend on the output variable (here, $\mathbf{y}$) are unnecessary. They cannot distinguish between competing labelings for an input, and so their weights will be set to zero during conditional estimation. The feature vector function in Sha and Pereira's chunking model does not include such features. In M-estimation, however, adding such "input-only" features might permit better modeling of the data and, more importantly, use the original features primarily for the discriminative task of modeling $\mathbf{y}$ *given* the input.

Adding unigram, bigram, and trigram features to $\mathbf{f}$ for M-estimation resulted in a very small decrease in performance: selecting for F_1, this model achieves 89.33 F_1 on test data.

6 Discussion

M-estimation fills a gap in the plethora of training techniques that are available for NLP models today: it permits **arbitrary features** (like so-called conditional "maximum entropy" models such as CRFs) but estimates a **generative** model (permitting, among other things, classification on input variables and meaningful combination with other models). It is similar in spirit to **pseudolikelihood** (Besag, 1975), to which it compares favorably on training runtime and unfavorably on accuracy.

Further, since no inference is required during training, *any* features really are permitted, so long as their expected values can be estimated under the base model q_0. Indeed, M-estimation is considerably easier to implement than conditional estimation. Both require feature counts from the training data; M-estimation replaces repeated calculation and differentiation of normalizing constants with inference or sampling (once) under a base model. So

the M-estimator is much faster to train.

Generative and discriminative models have been compared and discussed a great deal (Ng and Jordan, 2002), including for NLP models (Johnson, 2001; Klein and Manning, 2002). Sutton and McCallum (2005) present approximate methods that keep a discriminative objective while avoiding full inference.

We see M-estimation as a particularly promising method in settings where performance depends on high-dimensional, highly-correlated feature spaces, where the desired features "large," making discriminative training too time-consuming—a compelling example is machine translation. Further, in some settings a locally-normalized conditional log-linear model (like an MEMM) may be difficult to design; our estimator avoids normalization altogether.[8] The M-estimator may also be useful as a tool in designing and selecting feature combinations, since more trials can be run in less time. After selecting a feature set under M-estimation, discriminative training can be applied on that set. The M-estimator might also serve as an *initializer* to discriminative models, perhaps reducing the number of times inference must be performed—this could be particularly useful in very-large data scenarios. In future work we hope to explore the use of the M-estimator within hidden variable learning, such as the Expectation-Maximization algorithm (Dempster et al., 1977).

7 Conclusions

We have presented a new loss function for generatively estimating the parameters of log-linear models. The M-estimator is fast to train, requiring no repeated, expensive calculation of normalization terms. It was shown to improve performance on a shallow parsing task over a baseline (generative) HMM, but it is not competitive with the state-of-the-art. Our sequence modeling experiments support the widely accepted claim that discriminative, rich-feature modeling works as well as it does *not just* because of rich features in the model, but also because of discriminative training. Our technique fills an important gap in the spectrum of learning methods for NLP models and shows promise for application when discriminative methods are too expensive.

[8] Note that MEMMs also require local partition functions—which may be expensive—to be computed at decoding time.

Abstract

In this paper, we propose guided learning, a new learning framework for bidirectional sequence classification. The tasks of learning the order of inference and training the local classifier are dynamically incorporated into a single Perceptron like learning algorithm. We apply this novel learning algorithm to POS tagging. It obtains an error rate of 2.67% on the standard PTB test set, which represents 3.3% relative error reduction over the previous best result on the same data set, while using fewer features.

1 Introduction

Many NLP tasks can be modeled as a sequence classification problem, such as POS tagging, chunking, and incremental parsing. A traditional method to solve this problem is to decompose the whole task into a set of individual tasks for each token in the input sequence, and solve these small tasks in a fixed order, usually from left to right. In this way, the output of the previous small tasks can be used as the input of the later tasks. HMM and MaxEnt Markov Model are examples of this method.

Lafferty et al. (2001) showed that this approach suffered from the so called *label bias problem* (Bottou, 1991). They proposed Conditional Random Fields (CRF) as a general solution for sequence classification. CRF models a sequence as an undirected graph, which means that all the individual tasks are solved simultaneously. Taskar et al. (2003) improved the CRF method by employing the large margin method to separate the gold standard sequence labeling from incorrect labellings. However, the complexity of quadratic programming for the large margin approach prevented it from being used in large scale NLP tasks.

Collins (2002) proposed a Perceptron like learning algorithm to solve sequence classification in the traditional left-to-right order. This solution does not suffer from the label bias problem. Compared to the undirected methods, the Perceptron like algorithm is faster in training. In this paper, we will improve upon Collins' algorithm by introducing a bidirectional searching strategy, so as to effectively utilize more context information at little extra cost.

When a bidirectional strategy is used, the main problem is how to select the order of inference. Tsuruoka and Tsujii (2005) proposed the *easiest-first* approach which greatly reduced the computation complexity of inference while maintaining the accuracy on labeling. However, the easiest-first approach only serves as a heuristic rule. The order of inference is not incorporated into the training of the MaxEnt classifier for individual labeling.

Here, we will propose a novel learning framework, namely *guided learning*, to integrate classification of individual tokens and inference order selection into a single learning task. We proposed a Perceptron like learning algorithm (Collins and Roark, 2004; Daumé III and Marcu, 2005) for guided learning. We apply this algorithm to POS tagging, a classic sequence learning problem. Our system reports an error rate of 2.67% on the standard PTB test set, a relative 3.3% error reduction of the previous best system (Toutanova et al., 2003) by using fewer features. By using deterministic search, it obtains an error rate of 2.73%, a 5.9% relative error reduction

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 760–767,
Prague, Czech Republic, June 2007.

over the previous best deterministic algorithm (Tsuruoka and Tsujii, 2005).

The new POS tagger is similar to (Toutanova et al., 2003; Tsuruoka and Tsujii, 2005) in the way that we employ context features. We use a bidirectional search strategy (Woods, 1976; Satta and Stock, 1994), and our algorithm is based on Perceptron learning (Collins, 2002). A unique contribution of our work is on the integration of individual classification and inference order selection, which are learned simultaneously.

2 Guided Learning for Bidirectional Labeling

We first present an example of POS tagging to show the idea of bidirectional labeling. Then we present the inference algorithm and the learning algorithm.

2.1 An Example of POS tagging

Suppose that we have an input sentence

```
Agatha found that book interesting
  w1    w2    w3   w4      w5
            (Step 0)
```

If we scan from left to right, we may find it difficult to resolve the ambiguity of the label for `that`, which could be either DT (determiner), or IN (preposition or subordinating conjunction) in the Penn Treebank. However, if we resolve the labels for `book` and `interesting`, it would be relatively easy to figure out the correct label for `that`.

Now, we show how bidirectional inference works on this sample. Suppose we use beam search with width of 2, and we use a window of (-2, 2) for context features.

For the first step, we enumerate hypotheses for each word. For example, `found` could have a label VBN or VBD. Suppose that at this point the most favorable action, out of the candidate hypotheses, is the assignment of NN to `book`, according to the context features defined on words. Then, we resolve the label for `book` first. We maintain the top two hypotheses as shown below. Here, the second most favorable label for `book` is VB.

```
                  NN
                  VB
Agatha found that book interesting
  w1    w2    w3   w4      w5
            (Step 1)
```

At the second step, assume the most favorable action is the assignment of label JJ to `interesting` in the context of NN for `book`. Then we maintain the top two hypotheses for span `book interesting` as shown below. The second most favorable label for `interesting` is still JJ, but in the context of VB for `book`.

```
                  NN------JJ
                  VB------JJ
Agatha found that book interesting
  w1    w2    w3   w4      w5
            (Step 2)
```

Then, suppose we are most confident for assigning labels VBD and VBN to `found`, in that order. We get two separated tagged spans as shown below.

```
        VBD         NN------JJ
        VBN         VB------JJ
Agatha found that book interesting
  w1    w2    w3   w4      w5
            (Step 3)
```

In the next step, suppose we are most confident for assigning label DT to `that` under the context of VBD on the left and NN-JJ on the right side, as shown below (second most favorable action, not discussed here, is also displayed). After tagging w_3, two separated spans merge into one, starting from `found` to `interesting`.

```
        VBD---DT---NN------JJ
        VBD---IN---NN------JJ
Agatha found that book interesting
  w1    w2    w3   w4      w5
            (Step 4)
```

For the last step, we assign label NNP to `Agatha`, which could be an out-of-vocabulary word, under the context of VBD-DT on the right.

```
  NNP---VBD---DT---NN------JJ
  NNP---VBD---IN---NN------JJ
Agatha found that book interesting
  w1    w2    w3   w4      w5
            (Step 5)
```

This simple example has shown the advantage of adopting a flexible search strategy. However, it is still unclear how we maintain the hypotheses, how we keep candidates and accepted labels and spans, and how we employ dynamic programming. We will answer these questions in the formal definition of the inference algorithm in the next section.

2.2 Inference Algorithm

Terminology: Let the input sequence be $w_1 w_2 \cdots w_n$. For each token w_i, we are expected to assign a label $t_i \in \mathbf{T}$, with $\mathbf{T}$ the label set.

A subsequence $w_i \cdots w_j$ is called a **span**, and is denoted $[i, j]$. Each span p considered by the algorithm is associated with one or more **hypotheses**, that is, sequences over $\mathbf{T}$ having the same length as p. Part of the label sequence of each hypothesis is used as a context for labeling tokens outside the span p. For example, if a tri-gram model is adopted, we use the two labels on the left boundary and the two labels on the right boundary of the hypothesis for labeling outside tokens. The left two labels are called the **left interface**, and the right two labels are called the **right interface**. Left and right interfaces have only one label in case of spans of length one.

A pair $s = (I_{left}, I_{right})$ with a left and a right interface is called a **state**. We partition the hypotheses associated with span p into sets compatible with the same state. In practice, for span p, we use a matrix M_p indexed by states, so that $M_p(s)$, $s = (I_{left}, I_{right})$, is the set of all hypotheses associated with p that are compatible with I_{left} and I_{right}.

For a span p and a state s, we denote the associated top hypothesis as

$$s.T = \operatorname*{argmax}_{h \in M_p(s)} V(h),$$

where V is the score of a hypothesis (defined in (1) below). Similarly, we denote the top state for p as

$$p.S = \operatorname*{argmax}_{s:\, M_p(s) \neq \emptyset} V(s.T).$$

Therefore, for each span p, we have a top hypothesis $p.S.T$, whose score is the highest among all the hypotheses for span p.

Hypotheses are started and grown by means of labeling actions. For each hypothesis h associated with a span p we maintain its most recent labeling action $h.A$, involving some token within p, as well as the states $h.S_L$ and $h.S_R$ that have been used as context by such an action, if any. Note that $h.S_L$ and $h.S_R$ refer to spans that are subsequences of p. We recursively compute the score of h as

$$V(h) = V(h.S_L.T) + V(h.S_R.T) + U(h.A), \quad (1)$$

Algorithm 1 Inference Algorithm

Require: token sequence $w_1 \cdots w_n$;
Require: beam width B;
Require: weight vector $\mathbf{w}$;
1: Initialize P, the set of accepted spans;
2: Initialize Q, the queue of candidate spans;
3: **repeat**
4: span $p' \leftarrow \operatorname{argmax}_{p \in Q} U(p.S.T.A)$;
5: Update P with p';
6: Update Q with p' and P;
7: **until** ($Q = \emptyset$)

where U is the score of an action. In other words, the score of an hypothesis is the sum of the score of the most recent action $h.A$ and the scores of the top hypotheses of the context states. The score of an action $h.A$ is computed through a linear function whose weight vector is $\mathbf{w}$, as

$$U(h.A) = \mathbf{w} \cdot \mathbf{f}(h.A), \quad (2)$$

where $\mathbf{f}(h.A)$ is the feature vector of action $h.A$, which depends on $h.S_L$ and $h.S_R$.

Algorithm: Algorithm 1 is the inference algorithm. We are given the input sequence and two parameters, beam width B to determine the number of states maintained for each span, and weight vector $\mathbf{w}$ used to compute the score of an action.

We first initialize the set P of accepted spans with the empty set. Then we initialize the queue Q of candidate spans with span $[i, i]$ for each token w_i, and for each $t \in \mathbf{T}$ assigned to w_i we set

$$M_{[i,i]}((t, t)) = \{i \rightarrow t\},$$

where $i \rightarrow t$ represents the hypothesis consisting of a single action which assigns label t to w_i. This provides the set of starting hypotheses.

As for the example `Agatha found that book interesting` in the previous subsection, we have

- $P = \emptyset$
- $Q = \{[1, 1], [2, 2], [3, 3], [4, 4], [5, 5]\}$

Suppose NN and VB are the two possible POS tags for w_4 `book`. We have

- $M_{[4,4]}(\text{NN, NN}) = \{h_{441} = 4 \rightarrow \text{NN}\}$
- $M_{[4,4]}(\text{VB, VB}) = \{h_{442} = 4 \rightarrow \text{VB}\}$

The most recent action of hypothesis h_{441} is to assign NN to w_4. According to Equation (2), the score

of this action $U(h_{441}.A)$ depends on the features defined on the local context of action. For example,

$$f_{1001}(h_{441}.A) = \begin{cases} 1 & \text{if } t = \text{NN} \wedge w^{-1} = \texttt{that} \\ 0 & \text{otherwise,} \end{cases}$$

where w^{-1} represents the left word. It should be noted that, for all the features depending on the neighboring tags, the value is always 0, since those tags are still unknown in the step of initialization. Since this operation does not depend on solved tags, we have $V(h_{441}) = U(h_{411}.A)$, according to Equation (1).

The core of the algorithm repeatedly selects a candidate span from Q, and uses it to update P and Q, until a span covering the whole sequence is added to P and Q becomes empty. This is explained in detail below.

At each step, we remove from Q the span p' such that the *action* (not hypothesis) score of its top hypothesis, $p'.S.T$, is the highest. This represents the labeling action for the next move that we are most confident about. Now we need to update P and Q with the selected span p'. We add p' to P, and remove from P the spans included in p', if any. Let $\mathcal{S}$ be the set of removed spans. We remove from Q each span which takes one of the spans in $\mathcal{S}$ as context, and replace it with a new candidate span taking p' (and another accepted span) as context. We always maintain B different states for each span.

Back to the previous example, after Step 3 is completed, w_2 `found`, w_4 `book` and w_5 `interesting` have been tagged and we have

- $P = \{[2, 2], [4, 5]\}$
- $Q = \{[1, 2], [2, 5]\}$

There are two candidate spans in Q, each with its associated hypotheses and most recent actions. More specifically, we can either solve w_1 based on the context hypotheses for $[2, 2]$, resulting in span $[1, 2]$, or else solve w_3 based on the context hypotheses in $[2, 2]$ and $[4, 5]$, resulting in span $[2, 5]$.

The top two states for span $[2, 2]$ are

- $M_{[2,2]}(\text{VBD, VBD}) = \{h_{221} = 2 \rightarrow \text{VBD}\}$
- $M_{[2,2]}(\text{VBN, VBN}) = \{h_{222} = 2 \rightarrow \text{VBN}\}$

and the top two states for span $[4, 5]$ are

- $M_{[4,5]}(\text{NN-JJ, NN-JJ})$ $= \{h_{451} = (\text{NN,NN})5 \rightarrow \text{JJ}\}$
- $M_{[4,5]}(\text{VB-JJ, VB-JJ})$ $= \{h_{452} = (\text{VB,VB})5 \rightarrow \text{JJ}\}$

Here $(\text{NN,NN})5 \rightarrow \text{JJ}$ represents the hypothesis coming from the action of assigning JJ to w_5 under the left context state of (NN,NN). $(\text{VB,VB})5 \rightarrow \text{JJ}$ has a similar meaning.[1]

We first compute the hypotheses resulting from all possible POS tag assignments to w_3, under all possible state combinations of the neighboring spans $[2, 2]$ and $[4, 5]$. Suppose the highest score action consists in the assignment of DT under the left context state (VBD, VBD) and the right context state (NN-JJ, NN-JJ). We obtain hypothesis $h_{251} = (\text{VBD,VBD})3 \rightarrow \text{DT}(\text{NN-JJ, NN-JJ})$ with

$$\begin{aligned} V(h_{251}) &= V((\text{VBD,VBD}).T) + \\ &\quad V((\text{NN-JJ,NN-JJ}).T) + U(h_{251}.A) \\ &= V(h_{221}) + V(h_{451}) + \mathbf{w} \cdot \mathbf{f}(h_{251}.A) \end{aligned}$$

Here, features for action $h_{251}.A$ may depend on the left tag VBD and right tags NN-JJ, which have been solved before. More details of the feature functions are given in Section 4.2. For example, we can have features like

$$f_{2002}(h_{251}.A) = \begin{cases} 1 & \text{if } t = \text{DT} \wedge t^{+2} = \text{JJ} \\ 0 & \text{otherwise,} \end{cases}$$

We maintain the top two states with the highest hypothesis scores, if the beam width is set to two. We have

- $M_{[2,5]}(\text{VBD-DT, NN-JJ}) = \{h_{251} = (\text{VBD,VBD})3 \rightarrow \text{DT}(\text{NN-JJ,NN-JJ})\}$
- $M_{[2,5]}(\text{VBD-IN, NN-JJ}) = \{h_{252} = (\text{VBD,VBD})3 \rightarrow \text{IN}(\text{NN-JJ,NN-JJ})\}$

Similarly, we compute the top hypotheses and states for span $[1, 2]$. Suppose now the hypothesis with the highest *action* score is h_{251}. Then we update P by adding $[2, 5]$ and removing $[2, 2]$ and $[4, 5]$, which are covered by $[2, 5]$. We also update Q by removing $[2, 5]$ and $[1, 2]$,[2] and add new candidate span $[1, 5]$ resulting in

- $P = \{[2, 5]\}$
- $Q = \{[1, 5]\}$

[1] It should be noted that, in these cases, each state contains only one hypothesis. However, if the span is longer than 4 words, there may exist multiple hypotheses for the same state. For example, hypotheses DT-NN-VBD-DT-JJ and DT-NN-VBN-DT-JJ have the same left interface DT-NN and right interface DT-JJ.

[2] Span $[1, 2]$ depends on $[2, 2]$ and $[2, 2]$ has been removed from P. So it is no longer a valid candidate given the accepted spans in P.

The algorithm is especially designed in such a way that, at each step, some new span is added to P or else some spans already present in P are extended by some token(s). Furthermore, no pair of overlapping spans is ever found in P, and the number of pairs of overlapping spans that may be found in Q is always bounded by a constant. This means that the algorithm performs at most n iterations, and its running time is therefore $\mathcal{O}(B^2 n)$, that is, linear in the length of the input sequence.

2.3 Learning Algorithm

In this section, we propose *guided learning*, a Perceptron like algorithm, to learn the weight vector $\mathbf{w}$, as shown in Algorithm 2. We use $p'.G$ to represent the gold standard hypothesis on span p'.

For each input sequence X_r and the gold standard sequence of labeling Y_r, we first initialize P and Q as in the inference algorithm. Then we select the span for the next move as in Algorithm 1. If $p'.S.T$, the top hypothesis of the selected span p', is compatible with the gold standard, we update P and Q as in Algorithm 1. Otherwise, we update the weight vector in the Perceptron style, by promoting the features of the gold standard action, and demoting the features of the action of the top hypothesis. Then we re-generate the queue Q with P and the updated weight vector $\mathbf{w}$. Specifically, we first remove all the elements in Q, and then generate hypotheses for all the possible spans based on the context spans in P. Hypothesis scores and action scores are calculated with the updated weight vector $\mathbf{w}$.

A special aspect of Algorithm 2 is that we maintain two scores: the score of the action represents the confidence for the next move, and the score of the hypothesis represents the overall quality of a partial result. The selection for the next action directly depends on the score of the action, but not on the score of the hypothesis. On the other hand, the score of the hypothesis is used to maintain top partial results for each span.

We briefly describe the soundness of the Guided Learning Algorithm in terms of two aspects. First, in Algorithm 2 weight update is activated whenever there exists an incorrect state s, the action score of whose top hypothesis $s.T$ is higher than that of any state in each span. We demote this action and promote the gold standard action on the same span.

Algorithm 2 Guided Learning Algorithm

Require: training sequence pairs $\{(X_r, Y_r)\}_{1 \le r \le R}$;
Require: beam width B and iterations I;
1: $\mathbf{w} \leftarrow \mathbf{0}$;
2: **for** ($i \leftarrow 1$; $i \le I$; i++) **do**
3: **for** ($r \leftarrow 1$; $r \le R$; r++) **do**
4: Load sequence X_r and gold labeling Y_r.
5: Initialize P, the set of accepted spans
6: Initialize Q, the queue of candidate spans;
7: **repeat**
8: $p' \leftarrow \text{argmax}_{p \in Q}\, U(p.S.T.A)$;
9: **if** ($p'.S.T = p'.G$) **then**
10: Update P with p';
11: Update Q with p' and P;
12: **else**
13: $promote(\mathbf{w}, \mathbf{f}(p'.G.A))$;
14: $demote(\mathbf{w}, \mathbf{f}(p'.S.T.A))$;
15: Re-generate Q with $\mathbf{w}$ and P;
16: **end if**
17: **until** ($Q = \emptyset$)
18: **end for**
19: **end for**

However, we do not automatically adopt the gold standard action on this span. Instead, in the next step, the top hypothesis of another span might be selected based on the score of action, which means that it becomes the most favorable action according to the updated weights.

As a second aspect, if the action score of a gold standard hypothesis is higher than that of any others, this hypothesis and the corresponding span are guaranteed to be selected at line 8 of Algorithm 2. The reason for this is that the scores of the context hypotheses of a gold standard hypothesis must be no less than those of other hypotheses of the same span. This could be shown recursively with respect to Equation 1, because the context hypotheses of a gold standard hypothesis are also compatible with the gold standard.

Furthermore, if we take

$$(\mathbf{x_i} = \mathbf{f}(p'.G.A) - \mathbf{f}(p'.S.T.A), y_i = +1)$$

as a positive sample, and

$$(\mathbf{x_j} = \mathbf{f}(p'.S.T.A) - \mathbf{f}(p'.G.A), y_j = -1)$$

as a negative sample, the weight updates at lines 13

and 14 are a stochastic approximation of gradient descent that minimizes the squared errors of the misclassified samples (Widrow and Hoff, 1960). What is special with our learning algorithm is the strategy used to select samples for training.

In general, this novel learning framework lies between supervised learning and reinforcement learning. Guided learning is more difficult than supervised learning, because we do not know the order of inference. The order is learned automatically, and partial output is in turn used to train the local classifier. Therefore, the order of inference and the local classification are dynamically incorporated in the learning phase.

Guided learning is not as hard as reinforcement learning. At each local step in learning, we always know the undesirable labeling actions according to the gold standard, although we do not know which is the most desirable. In this approach, we can easily collect the automatically generated negative samples, and use them in learning. These negative samples are exactly those we will face during inference with the current weight vector.

In our experiments, we have used Averaged Perceptron (Collins, 2002; Freund and Schapire, 1999) and Perceptron with margin (Krauth and Mézard, 1987) to improve performance.

3 Related Works

Tsuruoka and Tsujii (2005) proposed a bidirectional POS tagger, in which the order of inference is handled with the easiest-first heuristic. Giménez and Màrquez (2004) combined the results of a left-to-right scan and a right-to-left scan. In our model, the order of inference is dynamically incorporated into the training of the local classifier.

Toutanova et al. (2003) reported a POS tagger based on cyclic dependency network. In their work, the order of inference is fixed as from left to right. In this approach, large beam width is required to maintain the ambiguous hypotheses. In our approach, we can handle tokens that we are most confident about first, so that our system does not need a large beam. As shown in Section 4.2, even deterministic inference shows rather good results.

Our guided learning can be modeled as a search algorithm with Perceptron like learning (Daumé III and Marcu, 2005). However, as far as we know, the mechanism of bidirectional search with an online learning algorithm has not been investigated before. In (Daumé III and Marcu, 2005), as well as other similar works (Collins, 2002; Collins and Roark, 2004; Shen and Joshi, 2005), only left-to-right search was employed. Our guided learning algorithm provides more flexibility in search with an automatically learned order. In addition, our treatment of the score of action and the score of hypothesis is unique (see discussion in Section 2.3).

Data Set	Sections	Sentences	Tokens
Training	0-18	38,219	912,344
Develop	19-21	5,527	131,768
Test	22-24	5,462	129,654

Table 1: Data set splits

Furthermore, compared to the above works, our guided learning algorithm is more aggressive on learning. In (Collins and Roark, 2004; Shen and Joshi, 2005), a search stops if there is no hypothesis compatible with the gold standard in the queue of candidates. In (Daumé III and Marcu, 2005), the search is resumed after some gold standard compatible hypotheses are inserted into a queue for future expansion, and the weights are updated correspondingly. However, there is no guarantee that the updated weights assign a higher score to those inserted gold standard compatible hypotheses. In our algorithm, the gold standard compatible hypotheses are used for weight update only. As a result, after each sentence is processed, the weight vector can usually successfully predict the gold standard parse. Therefore our learning algorithm is *aggressive* on weight update.

As far as this aspect is concerned, our algorithm is similar to the MIRA algorithm in (Crammer and Singer, 2003). In MIRA, one always knows the correct hypothesis. In our case, we do not know the correct order of operations. So we use our form of weight update to implement aggressive learning.

4 Experiments on POS Tagging

4.1 Settings

We apply our guided learning algorithm to POS tagging. We carry out experiments on the standard data set of the Penn Treebank (PTB) (Marcus et al., 1994). Following (Ratnaparkhi, 1996; Collins, 2002; Toutanova et al., 2003; Tsuruoka and Tsujii, 2005),

Feature Sets	Templates	Error%
A	Ratnaparkhi's	3.05
B	A + $[t_0, t_1], [t_0, t_{-1}, t_1], [t_0, t_1, t_2]$	2.92
C	B + $[t_0, t_{-2}], [t_0, t_2], [t_0, t_{-2}, w_0], [t_0, t_{-1}, w_0], [t_0, t_1, w_0]$, $[t_0, t_2, w_0]$, $[t_0, t_{-2}, t_{-1}, w_0], [t_0, t_{-1}, t_1, w_0], [t_0, t_1, t_2, w_0]$	2.84
D	C + $[t_0, w_{-1}, w_0], [t_0, w_1, w_0]$	2.78
E	D + $[t_0, X =$ prefix or suffix of $w_0], 4 < \|X\| \leq 9$	2.72

Table 2: Experiments on the *development* data with beam width of 3

we cut the PTB into the training, development and test sets as shown in Table 1. We use tools provided by CoNLL-2005 [3] to extract POS tags from the *mrg* files of PTB. So the data set is the same as previous work. We use the development set to select features and estimate the number of iterations in training. In our experiments, we enumerate all the POS tags for each word instead of using a dictionary as in (Ratnaparkhi, 1996), since the size of the tag set is tractable and our learning algorithm is efficient enough.

4.2 Results

Effect of Features: We first run the experiments to evaluate the effect of features. We use templates to define features. For this set of experiments, we set the beam width $B = 3$ as a balance between speed and accuracy. The guided learning algorithm usually converges on the development data set in 4-8 iterations over the training data.

Table 2 shows the error rate on the development set with different features. We first use the same feature set used in (Ratnaparkhi, 1996), which includes a set of prefix, suffix and lexical features, as well as some bi-gram and tri-gram context features. Following (Collins, 2002), we do not distinguish rare words. On set A, Ratnaparkhi's feature set, our system reports an error rate of 3.05% on the development data set.

With set B, we include a few feature templates which are symmetric to those in Ratnaparkhi's set, but are only available with bidirectional search. With set C, we add more bi-gram and tri-gram features. With set D, we include bi-lexical features. With set E, we use prefixes and suffixes of length up to 9, as in (Toutanova et al., 2003; Tsuruoka and Tsujii, 2005). We obtain 2.72% of error rate. We will use this feature set on our final experiments on the test data.

Effect of Search and Learning Strategies: For the second set of experiments, we evaluate the effect of search methods, learning strategies, and beam width. We use feature set E for this set of experiments. Table 3 shows the error rates on the development data set with both left-to-right (L-to-R) and bidirectional (Bi-Dir) search methods. We also tested both aggressive learning and non-aggressive learning strategies with beam width of 1 and 3.

Search	Aggressive?	Beam=1	Beam=3
L-to-R	Yes	2.94	2.82
L-to-R	No	3.24	2.75
Bi-Dir	Yes	2.84	2.72
Bi-Dir	No	does not converge	

Table 3: Experiments on the *development* data

First, with non-aggressive learning on bidirectional search, the error rate does not converge to a comparable number. This is due to the fact that the search space is too large in bidirectional search, if we do not use aggressive learning to constrain the samples for learning.

With aggressive learning, the bidirectional approach always shows advantages over left-to-right search. However, the gap is not large. This is due to the fact that the accuracy of POS tagging is very high. As a result, we can always keep the gold-standard tags in the beam even with left-to-right search in training.

This can also explain why the performance of left-to-right search with non-aggressive learning is close to bidirectional search if the beam is large enough. However, with beam width = 1, non-aggressive learning over left-to-right search performs much worse, because in this case it is more likely that the gold-standard tag is not in the beam.

This set of experiments show that guided learning is more preferable for tasks with higher ambiguities. In our recent work (Shen and Joshi, 2007), we have applied a variant of this algorithm to dependency parsing, and showed significant improvement over left-to-right non-aggressive learning strategy.

Comparison: Table 4 shows the comparison with the previous works on the PTB test sections.

[3] http://www.lsi.upc.es/~srlconll/soft.html, package srlconll-1.1.tgz.

System	Beam	Error%
(Ratnaparkhi, 1996)	5	3.37
(Tsuruoka and Tsujii, 2005)	1	2.90
(Collins, 2002)	-	2.89
Guided Learning, feature B	3	2.85
(Tsuruoka and Tsujii, 2005)	all	2.85
(Giménez and Màrquez, 2004)	-	2.84
(Toutanova et al., 2003)	-	2.76
Guided Learning, feature E	1	2.73
Guided Learning, feature E	3	2.67

Table 4: Comparison with the previous works

According to the experiments shown above, we build our best system by using feature set E with beam width $B = 3$. The number of iterations on the training data is estimated with respect to the development data. We obtain an error rate of **2.67**% on the test data. With deterministic search, or beam with $B = 1$, we obtain an error rate of 2.73%.

Compared to previous best result on the same data set, 2.76% by (Toutanova et al., 2003), our best result shows a relative error reduction of 3.3%. This result is very promising, since we have not used any specially designed features in our experiments. It is reported in (Toutanova et al., 2003) that a crude company name detector was used to generate features, and it gave rise to significant improvement in performance. However, it is difficult for us to duplicate exactly the same feature for the purpose of comparison, although it is convenient to use features like that in our framework.

5 Conclusions

In this paper, we propose *guided learning*, a new learning framework for bidirectional sequence classification. The tasks of learning the order of inference and training the local classifier are dynamically incorporated into a single Perceptron like algorithm.

We apply this novel algorithm to POS tagging. It obtains an error rate of 2.67% on the standard PTB test set, which represents 3.3% relative error reduction over the previous best result (Toutanova et al., 2003) on the same data set, while using fewer features. By using deterministic search, it obtains an error rate of 2.73%, a 5.9% relative error reduction over the previous best deterministic algorithm (Tsuruoka and Tsujii, 2005). It should be noted that the error rate is close to the inter-annotator discrepancy on PTB, the standard test set for POS tagging, therefore it is very difficult to achieve improvement.

Abstract

The idea of "nugget pyramids" has recently been introduced as a refinement to the nugget-based methodology used to evaluate answers to complex questions in the TREC QA tracks. This paper examines data from the 2006 evaluation, the first large-scale deployment of the nugget pyramids scheme. We show that this method of combining judgments of nugget importance from multiple assessors increases the stability and discriminative power of the evaluation while introducing only a small additional burden in terms of manual assessment. We also consider an alternative method for combining assessor opinions, which yields a distinction similar to micro- and macro-averaging in the context of classification tasks. While the two approaches differ in terms of underlying assumptions, their results are nevertheless highly correlated.

1 Introduction

The emergence of question answering (QA) systems for addressing complex information needs has necessitated the development and refinement of new methodologies for evaluating and comparing systems. In the Text REtrieval Conference (TREC) QA tracks organized by the U.S. National Institute of Standards and Technology (NIST), improvements in evaluation processes have kept pace with the evolution of QA tasks. For the past several years, NIST has implemented an evaluation methodology based on the notion of "information nuggets" to assess answers to complex questions. As it has become the *de facto* standard for evaluating such systems, the research community stands to benefit from a better understanding of the characteristics of this evaluation methodology.

This paper explores recent refinements to the nugget-based evaluation methodology developed by NIST. In particular, we examine the recent so-called "pyramid extension" that incorporates relevance judgments from multiple assessors to improve evaluation stability (Lin and Demner-Fushman, 2006).

We organize our discussion as follows: The next section begins by providing a brief overview of nugget-based evaluations and the pyramid extension. Section 3 presents results from the first large-scale implementation of nugget pyramids for QA evaluation in TREC 2006. Analysis shows that this extension improves both stability and discriminative power. In Section 4, we discuss an alternative for combining multiple judgments that parallels the distinction between micro- and macro-averaging often seen in classification tasks. Experiments reveal that the methods yield almost exactly the same results, despite operating on different granularities (individual nuggets vs. individual users).

2 Evaluating Complex Questions

Complex questions are distinguished from factoid questions such as "Who shot Abraham Lincoln?" in that they cannot be answered by named entities (e.g., persons, organizations, dates, etc.). Typically, these information needs are embedded in the context of a scenario (i.e., user task) and often require systems to

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 768–775,
Prague, Czech Republic, June 2007.

synthesize information from multiple documents or to generate answers that cannot be easily extracted (e.g., by leveraging inference capabilities).

To date, NIST has already conducted several large-scale evaluations of complex questions: definition questions in TREC 2003, "Other" questions in TREC 2004–2006, "relationship" questions in TREC 2005, and the complex, interactive QA (ciQA) task in TREC 2006. Definition and Other questions are similar in that they both request novel facts about "targets", which can be persons, organizations, things, and events. Relationship questions evolved into the ciQA task and focus on information needs such as "What financial relationships exist between South American drug cartels and banks in Liechtenstein?" Such complex questions focus on ties (financial, military, familial, etc.) that connect two or more entities. All of these evaluations have employed the nugget-based methodology, which demonstrates its versatility and applicability to a wide range of information needs.

2.1 Basic Setup

In the TREC QA evaluations, an answer to a complex question consists of an unordered set of [document-id, answer string] pairs, where the strings are presumed to provide some relevant information that addresses the question. Although no explicit limit is placed on the length of the answer, the final metric penalizes verbosity (see below).

Evaluation of system output proceeds in two steps. First, answer strings from all submissions are gathered together and presented to a single assessor. The source of each answer string is blinded so that the assessor can not obviously tell which systems generated what output. Using these answers and searches performed during question development, the assessor creates a list of relevant nuggets. A nugget is a piece of information (i.e., "fact") that addresses one aspect of the user's question. Nuggets should be atomic, in the sense that an assessor should be able to make a binary decision as to whether the nugget appears in an answer string. Although a nugget represents a conceptual entity, the assessor provides a natural language description—primarily as a memory aid for the subsequent evaluation steps. These descriptions range from sentence-length document extracts to key phrases to telegraphic short-hand notes—their readability greatly varies from assessor to assessor.

r = # of *vital* nuggets returned
a = # of *okay* nuggets returned
R = # of *vital* nuggets in the answer key
l = # of non-whitespace characters in entire run

recall: $\mathcal{R} = r/R$

allowance: $\alpha = 100 \times (r + a)$

precision: $\mathcal{P} = \begin{cases} 1 & \text{if } l < \alpha \\ 1 - \frac{l-\alpha}{l} & \text{otherwise} \end{cases}$

$$F(\beta) = \frac{(\beta^2 + 1) \times \mathcal{P} \times \mathcal{R}}{\beta^2 \times \mathcal{P} + \mathcal{R}}$$

Figure 1: Official definition of F-score for nugget evaluation in TREC.

The assessor also manually classifies each nugget as either *vital* or *okay* (non-vital). Vital nuggets represent concepts that must be present in a "good" answer. Okay nuggets may contain interesting information, but are not essential.

In the second step, the same assessor who created the nuggets reads each system's output in turn and marks the appearance of the nuggets. An answer string contains a nugget if there is a *conceptual* match; that is, the match is independent of the particular wording used in the system's output. A nugget match is marked at most once per run—i.e., a system is not rewarded for retrieving a nugget multiple times. If the system's output contains more than one match for a nugget, the best match is selected and the rest are left unmarked. A single [document-id, answer string] pair in a system response can match 0, 1, or multiple nuggets.

The final F-score for an answer is calculated in the manner described in Figure 1, and the final score of a run is the average across the F-scores of all questions. The metric is a weighted harmonic mean between nugget precision and nugget recall, where recall is heavily favored (controlled by the β parameter, usually set to three). Nugget recall is calculated solely on vital nuggets, while nugget precision is approximated by a length allowance based on the number of both vital and okay nuggets returned. In an

earlier pilot study, researchers discovered that it was not possible for assessors to consistently enumerate the total set of nuggets contained in an answer, which corresponds to the denominator in a precision calculation (Voorhees, 2003). Thus, a penalty for verbosity serves as a surrogate for precision.

2.2 The Pyramid Extension

The vital/okay distinction has been identified as a weakness in the TREC nugget-based evaluation methodology (Hildebrandt et al., 2004; Lin and Demner-Fushman, 2005; Lin and Demner-Fushman, 2006). There do not appear to be any reliable indicators for predicting nugget importance, which makes it challenging to develop algorithms sensitive to this consideration. Since only vital nuggets affect nugget recall, it is difficult for systems to achieve non-zero scores on topics with few vital nuggets in the answer key. Thus, scores are easily affected by assessor errors and other random variations in evaluation conditions.

One direct consequence is that in previous TREC evaluations, the median score for many questions turned out to be zero. A binary distinction on nugget importance is insufficient to discriminate between the quality of runs that return no vital nuggets but different numbers of okay nuggets. Also, a score distribution heavily skewed towards zero makes meta-analyses of evaluation stability difficult to perform (Voorhees, 2005).

The pyramid extension (Lin and Demner-Fushman, 2006) was proposed to address the issues mentioned above. The idea was relatively simple: by soliciting vital/okay judgments from multiple assessors (after the list of nuggets has been produced by a primary assessor), it is possible to define nugget importance with greater granularity. Each nugget is assigned a weight between zero and one that is proportional to the number of assessors who judged it to be vital. Nugget recall from Figure 1 can be redefined to incorporate these weights:

$$\mathcal{R} = \frac{\sum_{m \in A} w_m}{\sum_{n \in V} w_n}$$

Where A is the set of reference nuggets that are matched in a system's output and V is the set of all reference nuggets; w_m and w_n are the weights of nuggets m and n, respectively.[1] The calculation of nugget precision remains the same.

3 Nugget Pyramids in TREC 2006

Lin and Demner-Fushman (2006) present experimental evidence in support of nugget pyramids by applying the proposal to results from previous TREC QA evaluations. Their simulation studies appear to support the assertion that pyramids address many of the issues raised in Section 2.2. Based on the results, NIST proceeded with a trial deployment of nugget pyramids in the TREC 2006 QA track. Although scores based on the binary vital/okay distinction were retained as the "official" metric, pyramid scores were simultaneously computed. This provided an opportunity to compare the two methodologies on a large scale.

3.1 The Data

The basic unit of evaluation for the main QA task at TREC 2006 was the "question series". Each series focused on a "target", which could be a person, organization, thing, or event. Individual questions in a series inquired about different facets of the target, and were explicitly classified as factoid, list, or Other. One complete series is shown in Figure 2. The Other questions can be best paraphrased as "Tell me interesting things about *X* that I haven't already explicitly asked about." It was the system's task to retrieve interesting nuggets about the target (in the opinion of the assessor), but credit was not given for retrieving facts already explicitly asked for in the factoid and list questions. The Other questions were evaluated using the nugget-based methodology, and are the subject of this analysis.

The QA test set in TREC 2006 contained 75 series. Of the 75 targets, 19 were persons, 19 were organizations, 19 were events, and 18 were things. The series contained a total of 75 Other questions (one per target). Each series contained 6–9 questions (counting the Other question), with most series containing 8 questions. The task employed the AQUAINT collection of newswire text (LDC catalog number LDC2002T31), consisting of English data drawn from three sources: the New York Times,

[1] Note that this new scoring model captures the existing binary vital/okay distinction in a straightforward way: vital nuggets get a score of one, and okay nuggets zero.

147	Britain's Prince Edward marries		
	147.1	FACTOID	When did Prince Edward engage to marry?

they were married in St. Georges Chapel, Windsor	1	1	1	0	1	0	1	1	0

Figure 3: Multiple assessors' judgments of nugget importance for Series 147 (vital=1, okay=0). Assessor 2 was the same as the primary assessor (assessor 0), but judgments were elicited at different times.

the Associated Press, and the Xinhua News Service. There are approximately one million articles in the collection, totaling roughly three gigabytes. In total, 59 runs from 27 participants were submitted to NIST. For more details, see (Dang et al., 2006).

For the Other questions, nine sets of judgments were elicited from eight judges (the primary assessor who originally created the nuggets later annotated the nuggets once again). Each assessor was asked to assign the vital/okay label in a rapid fashion, without giving each decision much thought. Figure 3 gives an example of the multiple judgments for nuggets in Series 147. There is variation in notions of importance not only between different assessors, but also for a single assessor over time.

3.2 Results

After the human annotation process, nugget pyramids were built in the manner described by Lin and Demner-Fushman (2006). Two scores were computed for each run submitted to the TREC 2006 main QA task: one based on the vital/okay judgments of the primary assessor (which we call the binary F-score) and one based on the nugget pyramids (the pyramid F-score). The characteristics of the pyramid method can be inferred by comparing these two sets of scores.

Figure 4 plots the average binary and average pyramid F-scores for each run (which represents average performance across all series). Even though the nugget pyramid does not represent any single real user (a point we return to later), pyramid F-scores do correlate highly with the binary F-scores. The Pearson's correlation is 0.987, with a 95% confidence interval of [0.980, 1.00].

While the average F-score for a run is stable given a sufficient number of questions, the F-score for a single Other question exhibits greater variability across assessors. This is shown in Figure 5, which plots binary and pyramid F-scores for individual questions from all runs. In this case, the Pearson correlation is 0.870, with a 95% confidence interval of [0.863, 1.00].

For 16.4% of all Other questions, the nugget pyramid assigned a non-zero F-score where the original binary F-score was zero. This can be seen in the band of points on the left edge of the plot in Figure 5. This highlights the strength of nugget

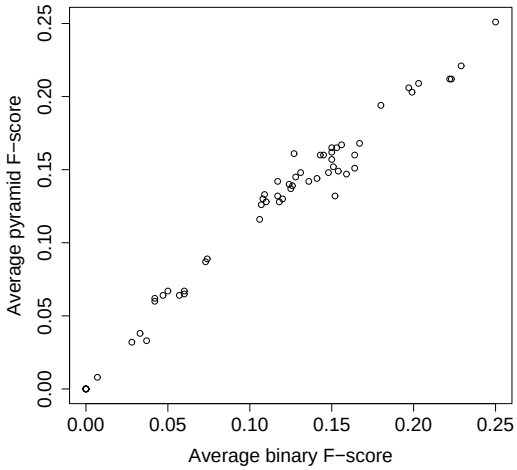

Figure 4: Scatter plot comparing the binary and pyramid F-scores for each run.

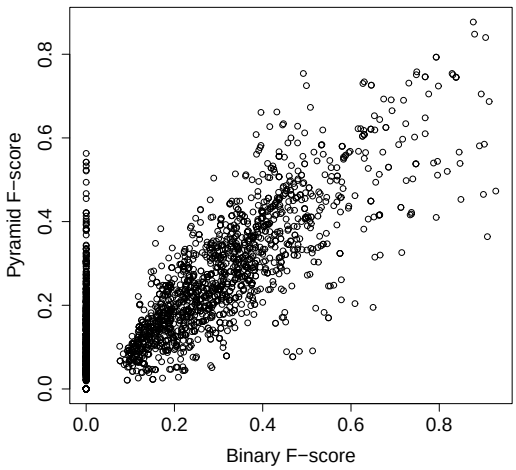

Figure 5: Scatter plot comparing the binary and pyramid F-scores for each Other question.

pyramids—their ability to smooth out assessor differences and more finely discriminate among system outputs. This is a key capability that is useful for system developers, particularly since algorithmic improvements are often incremental and small.

Because it is more stable than the single-assessor method of evaluation, the pyramid method also appears to have greater discriminative power. We fit a two-way analysis of variance model with the series and run as factors, and the binary F-score as the dependent variable. We found significant differences between series and between runs (p essentially equal to 0 for both factors). To determine which runs were significantly different from each other, we performed a multiple comparison using Tukey's honestly significant difference criterion and controlling for the experiment-wise Type I error so that the probability of declaring a difference between two runs to be significant, when it is actually not, is at most 5%. With 59 runs, there are $C_2^{59} = 1711$ different pairs that can be compared. The single-assessor method was able to declare one run to be significantly better than the other in 557 of these pairs. Using the pyramid F-scores, it was possible to find significant differences in performance between runs in 617 pairs.

3.3 Discussion

Any evaluation represents a compromise between effort (which correlates with cost) and insightfulness of results. The level of detail and meaningfulness of evaluations are constantly in tension with the availability of resources. Modifications to existing processes usually come at a cost that needs to be weighed against potential gains. Based on these considerations, the balance sheet for nugget pyramids shows a favorable orientation. In the TREC 2006 QA evaluation, soliciting vital/okay judgments from multiple assessors was not very time-consuming (a couple of hours per assessor). Analysis confirms that pyramid scores confer many benefits at an acceptable cost, thus arguing for its adoption in future evaluations.

Cost considerations precluded exploring other refinements to the nugget-based evaluation methodology. One possible alternative would involve asking multiple assessors to create different sets of nuggets from scratch. Not only would this be time-consuming, one would then need to deal with the additional complexities of aligning each assessor's nuggets list. This includes resolving issues such as nugget granularity, overlap in information content, implicature and other relations between nuggets, etc.

4 Exploration of Alternative Structures

Despite the demonstrated effectiveness of nugget pyramids, there are a few potential drawbacks that are worth discussing. One downside is that the nugget pyramid does not represent a single assessor. The nugget weights reflect the aggregation of opinions across a sample population, but there is no guar-

antee that the method for computing those weights actually captures any aspect of real user behavior. It can be argued that the binary F-score is more realistic since it reflects the opinion of a real user (the primary assessor), whereas the pyramid F-score tries to model the opinion of a mythical average user.

Although this point may seem somewhat counterintuitive, it represents a well-established tradition in the information retrieval literature (Voorhees, 2002). In document retrieval, for example, relevance judgments are provided by a single assessor—even though it is well known that there are large individual differences in notions of relevance. IR researchers believe that human idiosyncrasies are an inescapable fact present in any system designed for human users, and hence any attempt to remove those elements in the evaluation setup is actually undesirable. It is the responsibility of researchers to develop systems that are robust and flexible. This premise, however, does not mean that IR evaluation results are unstable or unreliable. Analyses have shown that despite large variations in human opinions, system rankings are remarkably stable (Voorhees, 2000; Sormunen, 2002)—that is, one can usually be confident about system comparisons.

The philosophy in IR sharply contrasts with work in NLP annotation tasks such as parsing, word sense disambiguation, and semantic role labeling—where researchers strive for high levels of interannotator agreement, often through elaborate guidelines. The difference in philosophies arises because unlike these NLP annotation tasks, where the products are used primarily by other NLP system components, IR (and likewise QA) is an end-user task. These systems are intended for real world use. Since people differ, systems must be able to accommodate these differences. Hence, there is a strong preference in QA for evaluations that maintain a model of the individual user.

4.1 Micro- vs. Macro-Averaging

The current nugget pyramid method leverages multiple judgments to define a weight for each individual nugget, and then incorporates this weight into the F-score computation. As an alternative, we propose another method for combining the opinions of multiple assessors: evaluate system responses individually against N sets of binary judgments, and then compute the mean across those scores. We define the macro-averaged binary F-score over a set $A = \{a_1, ..., a_N\}$ of N assessors as:

$$\mathcal{F} = \frac{\sum_{a \in A} F_a}{N}$$

Where F_a is the binary F-score according to the vital/okay judgments of assessor a. The differences between the pyramid F-score and the macro-averaged binary F-score correspond to the distinction between micro- and macro-averaging discussed in the context of text classification (Lewis, 1991). In those applications, both measures are meaningful depending on focus: individual instances or entire classes. In tasks where it is important to correctly classify individual instances, micro-averaging is more appropriate. In tasks where it is important to correctly identify a class, macro-averaging better quantifies performance. In classification tasks, imbalance in the prevalence of each class can lead to large differences in macro- and micro-averaged scores. Analogizing to our work, the original formulation of nugget pyramids corresponds to micro-averaging (since we focus on individual nuggets), while the alternative corresponds to macro-averaging (since we focus on the assessor).

We additionally note that the two methods encode different assumptions. Macro-averaging assumes that there is nothing intrinsically interesting about a nugget—it is simply a matter of a particular user with particular needs finding a particular nugget to be of interest. Micro-averaging, on the other hand, assumes that some nuggets are inherently interesting, independent of the particular interests of users.[2]

Each approach has characteristics that make it desirable. From the perspective of evaluators, the macro-averaged binary F-score is preferable because it models real users; each set of binary judgments represents the information need of a real user, each binary F-score represents how well an answer will satisfy a real user, and the macro-averaged binary F-score represents how well an answer will satisfy, on average, a sample population of real users. From the perspective of QA system developers, the micro-averaged nugget pyramid F-score is preferable because it allows finer discrimination in in-

[2] We are grateful to an anonymous reviewer for this insight.

dividual nugget performance, which enables better techniques for system training and optimization.

The macro-averaged binary F-score has the same desirable properties as the micro-averaged pyramid F-score in that fewer responses will have zero F-scores as compared to the single-assessor binary F-score. We demonstrate this as follows. Let X be a response that receives a non-zero pyramid F-score. Let $A = \{a_1, a_2, a_3, ..., a_N\}$ be the set of N assessors. Then it can be proven that X also receives a non-zero macro-averaged binary F-score:

1. There exists some nugget v with weight greater than 0, such that an answer string r in X matches v. *(def. of pyramid recall)*
2. There exists some assessor $a_p \in A$ who marked v as vital. *(def. of pyramid nugget weight)*
3. To show that X will also receive a non-zero macro-averaged binary score, it is sufficient to show that there is some assessor $a_m \in A$ such that X receives a non-zero F-score when evaluated using just the vital/okay judgments of a_m. *(def. of macro-averaged binary F-score)*
4. But, such an assessor does exist, namely assessor a_p: Consider the binary F-score assigned to X according to just assessor a_p. The recall of X is greater than zero, since X contains the response r that matches the nugget v that was marked as vital by a_p *(from (2), (1), and the def. of recall)*. The precision must also be greater than zero *(def. of precision)*. Therefore, the macro-averaged binary F-score of X is non-zero. *(def. of F-score)*

4.2 Analysis from TREC 2006

While the macro-averaged method is guaranteed to produce no more zero-valued scores than the micro-averaged pyramid method, it is not guaranteed that the scores will be the same for any given response. What are the empirical characteristics of each approach? To explore this question, we once again examined data from TREC 2006.

Figure 6 shows a scatter plot of the pyramid F-score and macro-averaged binary F-score for every Other questions in all runs from the TREC 2006 QA track main task. Despite focusing on different aspects of the evaluation setup, these measures

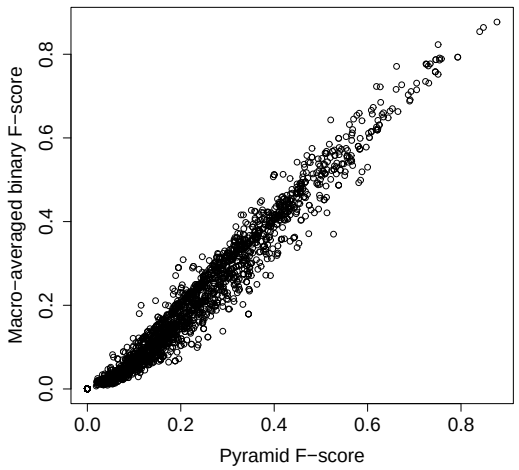

Figure 6: Scatter plot comparing the pyramid and macro-averaged binary F-scores for all questions.

	binary	micro	macro
binary	1.000/1.000	0.870/0.987	0.861/0.988
micro	-	1.000/1.000	0.985/0.996
macro	-	-	1.000/1.000

Table 1: Pearson's correlation of F-scores, by question and by run.

are highly correlated, even at the level of individual questions. Table 1 provides a summary of the correlations between the original binary F-score, the (micro-averaged) pyramid F-score, and the macro-averaged binary F-score. Pearson's r is given for F-scores at the individual question level (first number) and at the run level (second number). The correlation between all three variants are about equal at the level of system runs. At the level of individual questions, the micro- and macro-averaged F-scores (using multiple judgments) are still highly correlated with each other, but each is less correlated with the single-assessor binary F-score.

4.3 Discussion

The differences between macro- and micro-averaging methods invoke a more general discussion on notions of nugget importance. There are actually two different issues we are attempting to address with our different approaches: the first is a more granular scale of nugget importance, the second is variations across a population of users. In

the micro-averaged pyramid F-scores, we achieve the first by leveraging the second, i.e., binary judgments from a large population are combined to yield weights for individual nuggets. In the macro-averaged binary F-score, we focus solely on population effects without addressing granularity of nugget importance.

Exploring this thread of argument, we can formulate additional approaches for tackling these issues. We could, for example, solicit more granular individual judgments on each nugget from each assessor, perhaps on a Likert scale or as a continuous quantity ranging from zero to one. This would yield two more methods for computing F-scores, both a macro-averaged and a micro-averaged variant. The macro-averaged variant would be especially attractive because it reflects real users and yet individual F-scores remain discriminative. Despite its possible advantages, this extension is rejected based on resource considerations; making snap binary judgments on individual nuggets is much quicker than a multi-scaled value assignment—at least at present, the additional costs are not sufficient to offset the potential gains.

5 Conclusion

The important role that large-scale evaluations play in guiding research in human language technologies means that the community must "get it right." This would ordinarily call for a more conservative approach to avoid changes that might have unintended consequences. However, evaluation methodologies must evolve to reflect the shifting interests of the research community to remain relevant. Thus, organizers of evaluations must walk a fine line between progress and chaos. Nevertheless, the introduction of nugget pyramids in the TREC QA evaluation provides a case study showing how this fine balance can indeed be achieved. The addition of multiple judgments of nugget importance yields an evaluation that is both more stable and more discriminative than the original single-assessor evaluation, while requiring only a small additional cost in terms of human labor.

We have explored two different methods for combining judgments from multiple assessors to address shortcomings in the original nugget-based evaluation setup. Although they make different assumptions about the evaluation, results from both approaches are highly correlated. Thus, we can continue employing the pyramid-based method, which is well-suited for developing systems, and still be assured that the results remain consistent with an evaluation method that maintains a model of real individual users.

Abstract

We study the impact of syntactic and shallow semantic information in automatic classification of questions and answers and answer re-ranking. We define (a) new tree structures based on shallow semantics encoded in Predicate Argument Structures (PASs) and (b) new kernel functions to exploit the representational power of such structures with Support Vector Machines. Our experiments suggest that syntactic information helps tasks such as question/answer classification and that shallow semantics gives remarkable contribution when a reliable set of PASs can be extracted, e.g. from answers.

1 Introduction

Question answering (QA) is as a form of information retrieval where one or more answers are returned to a question in natural language in the form of sentences or phrases. The typical QA system architecture consists of three phases: question processing, document retrieval and answer extraction (Kwok et al., 2001).

Question processing is often centered on question classification, which selects one of k expected answer classes. Most accurate models apply supervised machine learning techniques, e.g. SNoW (Li and Roth, 2005), where questions are encoded using various lexical, syntactic and semantic features. The retrieval and answer extraction phases consist in retrieving relevant documents (Collins-Thompson et al., 2004) and selecting candidate answer passages from them. A further answer re-ranking phase is optionally applied. Here, too, the syntactic structure of a sentence appears to provide more useful information than a bag of words (Chen et al., 2006), although the correct way to exploit it is still an open problem.

An effective way to integrate syntactic structures in machine learning algorithms is the use of tree kernel (TK) functions (Collins and Duffy, 2002), which have been successfully applied to question classification (Zhang and Lee, 2003; Moschitti, 2006) and other tasks, e.g. relation extraction (Zelenko et al., 2003; Moschitti, 2006). In more complex tasks such as computing the relatedness between questions and answers in answer re-ranking, to our knowledge no study uses kernel functions to encode syntactic information. Moreover, the study of shallow semantic information such as predicate argument structures annotated in the PropBank (PB) project (Kingsbury and Palmer, 2002) (www.cis.upenn.edu/~ace) is a promising research direction. We argue that semantic structures can be used to characterize the relation between a question and a candidate answer.

In this paper, we extensively study new structural representations, encoding parse trees, bag-of-words, POS tags and predicate argument structures (PASs) for question classification and answer re-ranking. We define new tree representations for both simple and nested PASs, i.e. PASs whose arguments are other predicates (Section 2). Moreover, we define new kernel functions to exploit PASs, which we automatically derive with our SRL system (Moschitti et al., 2005) (Section 3).

Our experiments using SVMs and the above ker-

Prague, Czech Republic, June 2007.

nels and data (Section 4) shows the following: (a) our approach reaches state-of-the-art accuracy on question classification. (b) PB predicative structures are not effective for question classification but show promising results for answer classification on a corpus of answers to TREC-QA 2001 description questions. We created such dataset by using YourQA (Quarteroni and Manandhar, 2006), our basic Web-based QA system[1]. (c) The answer classifier increases the ranking accuracy of our QA system by about 25%.

Our results show that PAS and syntactic parsing are promising methods to address tasks affected by data sparseness like question/answer categorization.

2 Encoding Shallow Semantic Structures

Traditionally, information retrieval techniques are based on the *bag-of-words* (BOW) approach augmented by language modeling (Allan et al., 2002). When the task requires the use of more complex semantics, the above approaches are often inadequate to perform fine-level textual analysis.

An improvement on BOW is given by the use of syntactic parse trees, e.g. for question classification (Zhang and Lee, 2003), but these, too are inadequate when dealing with definitional answers expressed by long and articulated sentences or even paragraphs. On the contrary, shallow semantic representations, bearing a more "compact" information, could prevent the sparseness of deep structural approaches and the weakness of BOW models.

Initiatives such as PropBank (PB) (Kingsbury and Palmer, 2002) have made possible the design of accurate automatic Semantic Role Labeling (SRL) systems (Carreras and Màrquez, 2005). Attempting an application of SRL to QA hence seems natural, as pinpointing the answer to a question relies on a deep understanding of the semantics of both.
Let us consider the PB annotation: [$_{ARG1}$ Antigens] were [$_{AM-TMP}$ originally] [$_{rel}$ defined] [$_{ARG2}$ as non-self molecules].
Such annotation can be used to design a shallow semantic representation that can be matched against other semantically similar sentences, e.g. [$_{ARG0}$ Researchers] [$_{rel}$ describe] [$_{ARG1}$ antigens] [$_{ARG2}$ as foreign molecules] [$_{ARGM-LOC}$ in the body].
For this purpose, we can represent the above annotated sentences using the tree structures described in Figure 1. In this compact representation, hereafter Predicate-Argument Structures (PAS), arguments are replaced with their most important word – often referred to as the semantic head. This reduces data sparseness with respect to a typical BOW representation.

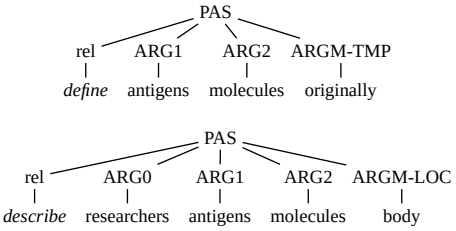

Figure 1: Compact predicate argument structures of two different sentences.

However, sentences rarely contain a single predicate; it happens more generally that propositions contain one or more subordinate clauses. For instance let us consider a slight modification of the first sentence: "Antigens were originally defined as non-self molecules *which bound specifically to antibodies*[2]." Here, the main predicate is "defined", followed by a subordinate predicate "bound". Our SRL system outputs the following *two* annotations:
(1) [$_{ARG1}$ Antigens] were [$_{ARGM-TMP}$ originally] [$_{rel}$ defined] [$_{ARG2}$ as non-self molecules which bound specifically to antibodies].
(2) Antigens were originally defined as [$_{ARG1}$ non-self molecules] [$_{R-A1}$ which] [$_{rel}$ bound] [$_{ARGM-MNR}$ specifically] [$_{ARG2}$ to antibodies].
giving the PASs in Figure 2.(a) resp. 2.(b).

As visible in Figure 2.(a), when an argument node corresponds to an entire subordinate clause, we label its leaf with PAS, e.g. the leaf of ARG2. Such PAS node is actually the root of the subordinate clause in Figure 2.(b). Taken as standalone, such PASs do not express the whole meaning of the sentence; it is more accurate to define a single structure encoding the dependency between the two predicates as in

[1]Demo at: http://cs.york.ac.uk/aig/aqua.

[2]This is an actual answer to "What are antibodies?" from our question answering system, YourQA.

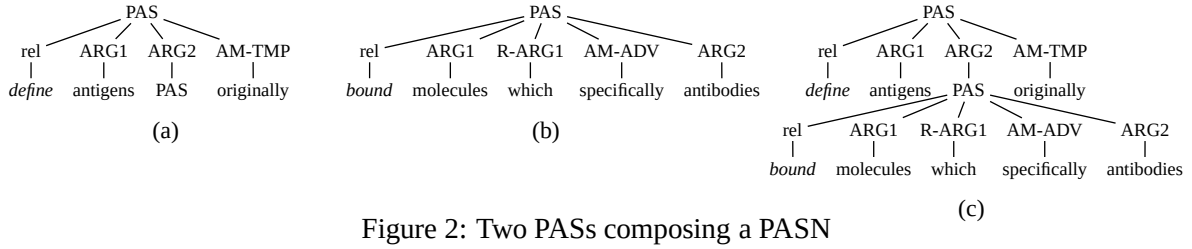

Figure 2: Two PASs composing a PASN

Figure 2.(c). We refer to nested PASs as PASNs.

It is worth to note that semantically equivalent sentences syntactically expressed in different ways share the same PB arguments and the same PASs, whereas semantically different sentences result in different PASs. For example, the sentence: "Antigens were originally defined as *antibodies* which bound specifically to *non-self molecules*", uses the same words as (2) but has different meaning. Its PB annotation:

(3) `Antigens were originally defined as [`$_{ARG1}$ `antibodies] [`$_{R-A1}$ `which] [`$_{rel}$ `bound] [`$_{ARGM-MNR}$ `specifically] [`$_{ARG2}$ `to non-self molecules]`,

clearly differs from (2), as ARG2 is now *non-self molecules*; consequently, the PASs are also different.

Once we have assumed that parse trees and PASs can improve on the simple BOW representation, we face the problem of representing tree structures in learning machines. Section 3 introduces a viable approach based on tree kernels.

3 Syntactic and Semantic Kernels for Text

As mentioned above, encoding syntactic/semantic information represented by means of tree structures in the learning algorithm is problematic. A first solution is to use all its possible substructures as features. Given the combinatorial explosion of considering subparts, the resulting feature space is usually very large. A tree kernel (TK) function which computes the number of common subtrees between two syntactic parse trees has been given in (Collins and Duffy, 2002). Unfortunately, such subtrees are subject to the constraint that their nodes are taken with all or none of the children they have in the original tree. This makes the TK function not well suited for the PAS trees defined above. For instance, although the two PASs of Figure 1 share most of the subtrees rooted in the PAS node, Collins and Duffy's kernel would compute no match.

In the next section we describe a new kernel derived from the above tree kernel, able to evaluate the meaningful substructures for PAS trees. Moreover, as a single PAS may not be sufficient for text representation, we propose a new kernel that combines the contributions of different PASs.

3.1 Tree kernels

Given two trees T_1 and T_2, let $\{f_1, f_2, ..\} = \mathcal{F}$ be the set of substructures (fragments) and $I_i(n)$ be equal to 1 if f_i is rooted at node n, 0 otherwise. Collins and Duffy's kernel is defined as

$$TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2), \quad (1)$$

where N_{T_1} and N_{T_2} are the sets of nodes in T_1 and T_2, respectively and $\Delta(n_1, n_2) = \sum_{i=1}^{|\mathcal{F}|} I_i(n_1) I_i(n_2)$. The latter is equal to the number of common fragments rooted in nodes n_1 and n_2. Δ can be computed as follows:

(1) if the productions (i.e. the nodes with their direct children) at n_1 and n_2 are different then $\Delta(n_1, n_2) = 0$;

(2) if the productions at n_1 and n_2 are the same, and n_1 and n_2 only have leaf children (i.e. they are pre-terminal symbols) then $\Delta(n_1, n_2) = 1$;

(3) if the productions at n_1 and n_2 are the same, and n_1 and n_2 are not pre-terminals then $\Delta(n_1, n_2) = \prod_{j=1}^{nc(n_1)} (1 + \Delta(c_{n_1}^j, c_{n_2}^j))$, where $nc(n_1)$ is the number of children of n_1 and c_n^j is the j-th child of n.

Such tree kernel can be normalized and a λ factor can be added to reduce the weight of large structures (refer to (Collins and Duffy, 2002) for a complete description). The critical aspect of steps (1), (2) and (3) is that the productions of two evaluated nodes have to be identical to allow the match of further descendants. This means that common substructures cannot be composed by a node with only some of its

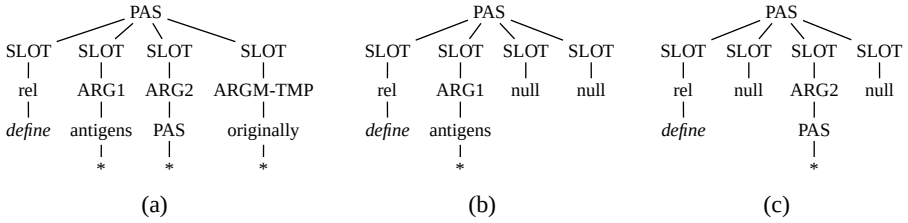

Figure 3: A PAS with some of its fragments.

children as an effective PAS representation would require. We solve this problem by designing the Shallow Semantic Tree Kernel (SSTK) which allows to match portions of a PAS.

3.2 The Shallow Semantic Tree Kernel (SSTK)

The SSTK is based on two ideas: first, we change the PAS, as shown in Figure 3.(a) by adding *SLOT* nodes. These accommodate argument labels in a specific order, i.e. we provide a fixed number of slots, possibly filled with *null* arguments, that encode all possible predicate arguments. For simplicity, the figure shows a structure of just 4 arguments, but more can be added to accommodate the maximum number of arguments a predicate can have. Leaf nodes are filled with the wildcard character * but they may alternatively accommodate additional information.

The slot nodes are used in such a way that the adopted TK function can generate fragments containing one or more children like for example those shown in frames (b) and (c) of Figure 3. As previously pointed out, if the arguments were directly attached to the root node, the kernel function would only generate the structure with all children (or the structure with no children, i.e. empty).

Second, as the original tree kernel would generate many matches with slots filled with the null label, we have set a new step 0:

(0) if n_1 (or n_2) is a pre-terminal node and its child label is *null*, $\Delta(n_1, n_2) = 0$;

and subtract one unit to $\Delta(n_1, n_2)$, in step 3:

(3) $\Delta(n_1, n_2) = \prod_{j=1}^{nc(n_1)}(1 + \Delta(c_{n_1}^j, c_{n_2}^j)) - 1$,

The above changes generate a new Δ which, when substituted (in place of the original Δ) in Eq. 1, gives the new Shallow Semantic Tree Kernel. To show that SSTK is effective in counting the number of relations shared by two PASs, we propose the following:

Proposition 1 *The new Δ function applied to the modified PAS counts the number of all possible k-ary relations derivable from a set of k arguments, i.e. $\sum_{i=1}^{k}\binom{k}{i}$ relations of arity from 1 to k (the predicate being considered as a special argument).*

Proof We observe that a kernel applied to a tree and itself computes all its substructures, thus if we evaluate SSTK between a PAS and itself we must obtain the number of generated k-ary relations. We prove by induction the above claim.

For the base case ($k = 0$): we use a PAS with no arguments, i.e. all its slots are filled with null labels. Let r be the PAS root; since r is not a pre-terminal, step 3 is selected and Δ is recursively applied to all r's children, i.e. the slot nodes. For the latter, step 0 assigns $\Delta(c_r^j, c_r^j) = 0$. As a result, $\Delta(r, r) = \prod_{j=1}^{nc(r)}(1 + 0) - 1 = 0$ and the base case holds.

For the general case, r is the root of a PAS with $k+1$ arguments. $\Delta(r, r) = \prod_{j=1}^{nc(r)}(1 + \Delta(c_r^j, c_r^j)) - 1$ $=\prod_{j=1}^{k}(1+\Delta(c_r^j, c_r^j))\times(1+\Delta(c_r^{k+1}, c_r^{k+1}))-1$. For k arguments, we assume by induction that $\prod_{j=1}^{k}(1+\Delta(c_r^j, c_r^j)) - 1 = \sum_{i=1}^{k}\binom{k}{i}$, i.e. the number of k-ary relations. Moreover, $(1 + \Delta(c_r^{k+1}, c_r^{k+1})) = 2$, thus $\Delta(r, r) = \sum_{i=1}^{k}\binom{k}{i} \times 2 = 2^k \times 2 = 2^{k+1} = \sum_{i=1}^{k+1}\binom{k+1}{i}$, i.e. all the relations until arity $k + 1$ □

TK functions can be applied to sentence parse trees, therefore their usefulness for text processing applications, e.g. question classification, is evident. On the contrary, the SSTK applied to one PAS extracted from a text fragment may not be meaningful since its representation needs to take into account all the PASs that it contains. We address such problem

by defining a kernel on *multiple* PASs.

Let P_t and $P_{t'}$ be the sets of PASs extracted from the text fragment t and t'. We define:

$$K_{\texttt{all}}(P_t, P_{t'}) = \sum_{p \in P_t} \sum_{p' \in P_{t'}} SSTK(p, p'), \quad (2)$$

While during the experiments (Sect. 4) the $K_{\texttt{all}}$ kernel is used to handle predicate argument structures, TK (Eq. 1) is used to process parse trees and the linear kernel to handle POS and BOW features.

4 Experiments

The purpose of our experiments is to study the impact of the new representations introduced earlier for QA tasks. In particular, we focus on question classification and answer re-ranking for Web-based QA systems.

In the question classification task, we extend previous studies, e.g. (Zhang and Lee, 2003; Moschitti, 2006), by testing a set of previously designed kernels and their combination with our new Shallow Semantic Tree Kernel. In the answer re-ranking task, we approach the problem of detecting description answers, among the most complex in the literature (Cui et al., 2005; Kazawa et al., 2001).

The representations that we adopt are: bag-of-words (BOW), bag-of-POS tags (POS), parse tree (PT), predicate argument structure (PAS) and nested PAS (PASN). BOW and POS are processed by means of a linear kernel, PT is processed with TK, PAS and PASN are processed by SSTK. We implemented the proposed kernels in the SVM-light-TK software available at `ai-nlp.info.uniroma2.it/moschitti/` which encodes tree kernel functions in SVM-light (Joachims, 1999).

4.1 Question classification

As a first experiment, we focus on question classification, for which benchmarks and baseline results are available (Zhang and Lee, 2003; Li and Roth, 2005). We design a question multi-classifier by combining n binary SVMs[3] according to the ONE-vs-ALL scheme, where the final output class is the one associated with the most probable prediction. The PASs were automatically derived by our SRL system which achieves a 76% F1-measure (Moschitti et al., 2005).

As benchmark data, we use the question training and test set available at: `l2r.cs.uiuc.edu/~cogcomp/Data/QA/QC/`, where the test set are the 500 TREC 2001 test questions (Voorhees, 2001). We refer to this split as UIUC. The performance of the multi-classifier and the individual binary classifiers is measured with accuracy resp. F1-measure. To collect statistically significant information, we run 10-fold cross validation on the 6,000 questions.

Features	Accuracy (UIUC)	Accuracy (c.v.)
PT	90.4	84.8±1.2
BOW	90.6	84.7±1.2
PAS	34.2	43.0±1.9
POS	26.4	32.4±2.1
PT+BOW	**91.8**	**86.1±1.1**
PT+BOW+POS	91.8	84.7±1.5
PAS+BOW	90.0	82.1±1.3
PAS+BOW+POS	88.8	81.0±1.5

Table 1: Accuracy of the question classifier with different feature combinations

Question classification results Table 1 shows the accuracy of different question representations on the UIUC split (Column 1) and the average accuracy ± the corresponding confidence limit (at 90% significance) on the cross validation splits (Column 2).(i) The TK on PT and the linear kernel on BOW produce a very high result, i.e. about 90.5%. This is higher than the best outcome derived in (Zhang and Lee, 2003), i.e. 90%, obtained with a kernel combining BOW and PT on the same data. Combined with PT, BOW reaches 91.8%, very close to the 92.5% accuracy reached in (Li and Roth, 2005) using complex semantic information from external resources.
(ii) The PAS feature provides no improvement. This is mainly because at least half of the training and test questions only contain the predicate "to be", for which a PAS cannot be derived by a PB-based shallow semantic parser.
(iii) The 10-fold cross-validation experiments confirm the trends observed in the UIUC split. The best model (according to statistical significance) is PT+BOW, achieving an 86.1% average accuracy[4].

[3] We adopted the default regularization parameter (i.e., the average of $1/||\vec{x}||$) and tried a few cost-factor values to adjust the rate between Precision and Recall on the development set.

[4] This value is lower than the UIUC split one as the UIUC test set is not consistent with the training set (it contains the

4.2 Answer classification

Question classification does not allow to fully exploit the PAS potential since questions tend to be short and with few verbal predicates (i.e. the only ones that our SRL system can extract). A different scenario is answer classification, i.e. deciding if a passage/sentence correctly answers a question. Here, the semantics to be generated by the classifier are not constrained to a small taxonomy and answer length may make the PT-based representation too sparse.

We learn answer classification with a binary SVM which determines if an answer is correct for the target question: here, the classification instances are ⟨question, answer⟩ pairs. Each pair component can be encoded with PT, BOW, PAS and PASN representations (processed by previous kernels).

As test data, we collected the 138 TREC 2001 test questions labeled as "description" and for each, we obtained a list of answer paragraphs extracted from Web documents using YourQA. Each paragraph sentence was manually evaluated based on whether it contained an answer to the corresponding question. Moreover, to simplify the classification problem, we isolated for each paragraph the sentence which obtained the maximal judgment (in case more than one sentence in the paragraph had the same judgment, we chose the first one). We collected a corpus containing 1309 sentences, 416 of which – labeled "+1" – answered the question either concisely or with noise; the rest – labeled "-1"– were either irrelevant to the question or contained hints relating to the question but could not be judged as valid answers[5].

Answer classification results To test the impact of our models on answer classification, we ran 5-fold cross-validation, with the constraint that two pairs $\langle q, a_1 \rangle$ and $\langle q, a_2 \rangle$ associated with the same question q could not be split between training and testing. Hence, each reported value is the average over 5 different outcomes. The standard deviations ranged

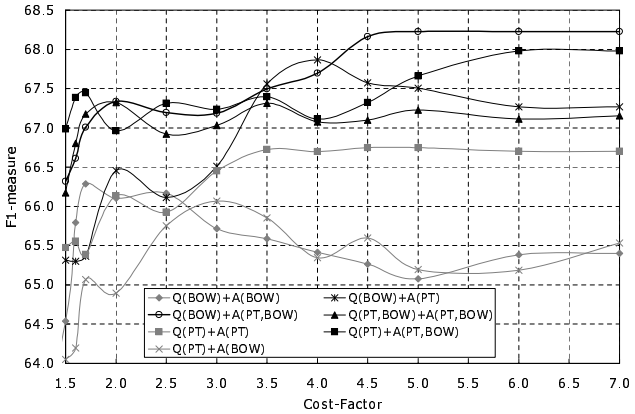

Figure 4: Impact of the BOW and PT features on answer classification

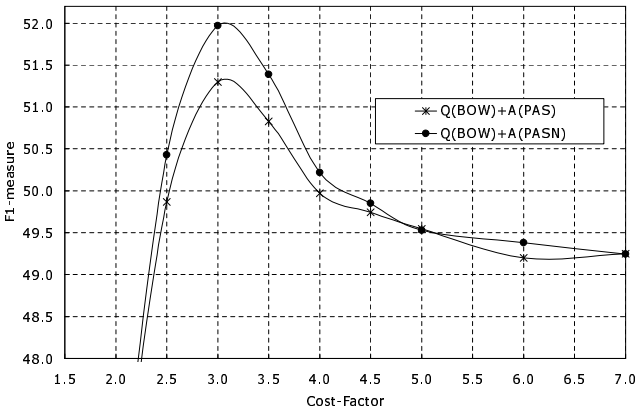

Figure 6: Comparison between PAS and PASN when used as standalone features for the answer on answer classification

TREC 2001 questions) and includes a larger percentage of easily classified question types, e.g. the numeric (22.6%) and description classes (27.6%) whose percentage in training is 16.4% resp. 16.2%.

[5]For instance, given the question "What are invertebrates?", the sentence "At least 99% of all animal species are invertebrates, comprising . . . " was labeled "-1" , while "Invertebrates are animals without backbones." was labeled "+1".

approximately between 2.5 and 5. The experiments were organized as follows:

First, we examined the contributions of BOW and PT representations as they proved very important for question classification. Figure 4 reports the plot of the F1-measure of answer classifiers trained with all combinations of the above models according to different values of the cost-factor parameter, adjusting the rate between Precision and Recall. We see here that the most accurate classifiers are the ones using both the answer's BOW and PT feature and either the question's PT or BOW feature (i.e. Q(BOW) + A(PT,BOW) resp. Q(PT) + A(PT,BOW) combinations). When PT is used for the answer the simple BOW model is outperformed by 2 to 3 points. Hence, we infer that both the answer's PT and BOW features are very useful in the classification task. However, PT does not seem to provide additional information to BOW when used for question representation. This can be explained by considering that answer classification (restricted to description questions) does not require question type classification since its main purpose is to detect question/answer relations. In this scenario, the question's syntactic structure does not seem to provide much more information than BOW.

Secondly, we evaluated the impact of the newly defined PAS and PASN features combined with the best performing previous model, i.e. Q(BOW) + A(PT,BOW). Figure 5 illustrates the F1-measure plots again according to the cost-factor parameter. We observe here that model Q(BOW) + A(PT,BOW,PAS) greatly outperforms model Q(BOW) + A(PT,BOW), proving that the PAS feature is very useful for answer classification, i.e. the improvement is about 2 to 3 points while the difference with the BOW model, i.e. Q(BOW) + A(BOW), exceeds 3 points. The Q(BOW) + A(PT,BOW,PASN) model is not more effective than Q(BOW) + A(PT,BOW,PAS). This suggests either that PAS is more effective than PASN or that when the PT information is added, the PASN contribution fades out.

To further investigate the previous issue, we finally compared the contribution of the PAS and PASN when combined with the question's BOW feature alone, i.e. no PT is used. The results, reported in Figure 6, show that this time PASN performs better than PAS. This suggests that the dependencies between the nested PASs are in some way captured by the PT information. Indeed, it should be noted that we join predicates only in case one is subordinate to the other, thus considering only a restricted set of all possible predicate dependencies. However, the improvement over PAS confirms that PASN is the right direction to encode shallow semantics from different sentence predicates.

Baseline	P	R	F1-measure
Gg@5	39.22±3.59	33.15±4.22	35.92±3.95
QA@5	39.72±3.44	34.22±3.63	36.76±3.56
Gg@all	31.58±0.58	100	48.02±0.67
QA@all	31.58±0.58	100	48.02±0.67
	Gg	QA	Re-ranker
MRR	48.97±3.77	56.21±3.18	81.12±2.12

Table 2: Baseline classifiers accuracy and MRR of YourQA (QA), Google (Gg) and the best re-ranker

4.3 Answer re-ranking

The output of the answer classifier can be used to re-rank the list of candidate answers of a QA system. Starting from the top answer, each instance can be classified based on its correctness with respect to the question. If it is classified as correct its rank is unchanged; otherwise it is pushed down, until a lower ranked incorrect answer is found.

We used the answer classifier with the highest F1-measure on the development set according to different cost-factor values[6]. We applied such model to the Google ranks and to the ranks of our Web-based QA system, i.e. YourQA. The latter uses Web documents corresponding to the top 20 Google results for the question. Then, each sentence in each document is compared to the question via a blend of similarity metrics used in the answer extraction phase to select the most relevant sentence. A passage of up to 750 bytes is then created around the sentence and returned as an answer.

Table 2 illustrates the results of the answer classifiers derived by exploiting Google (Gg) and YourQA (QA) ranks: the top N ranked results are considered as correct definitions and the remaining ones as in-

[6]However, by observing the curves in Fig. 5, the selected parameters appear as pessimistic estimates for the best model improvement: the one for BOW is the absolute maximum, but an average one is selected for the best model.

correct for different values of N. We show N = 5 and the maximum N (all), i.e. all the available answers. Each measure is the average of the Precision, Recall and F1-measure from cross validation. The F1-measure of Google and YourQA are greatly outperformed by our answer classifier.

The last row of Table 2 reports the MRR[7] achieved by Google, YourQA (QA) and YourQA after re-ranking (Re-ranker). We note that Google is outperformed by YourQA since its ranks are based on whole documents, not on single passages. Thus Google may rank a document containing several sparsely distributed question words higher than documents with several words concentrated in one passage, which are more interesting. When the answer classifier is applied to improve the YourQA ranking, the MRR reaches 81.1%, rising by about 25%.

Finally, it is worth to note that the answer classifier based on Q(BOW)+A(BOW,PT,PAS) model (parameterized as described) gave a 4% higher MRR than the one based on the simple BOW features. As an example, for question "What is foreclosure?", the sentence "Foreclosure means that the lender takes possession of your home and sells it in order to get its money back." was correctly classified by the best model, while BOW failed.

5 Conclusion

In this paper, we have introduced new structures to represent textual information in three question answering tasks: question classification, answer classification and answer re-ranking. We have defined tree structures (PAS and PASN) to represent predicate-argument relations, which we automatically extract using our SRL system. We have also introduced two functions, $SSTK$ and $K_{\texttt{all}}$, to exploit their representative power.

Our experiments with SVMs and the above models suggest that syntactic information helps tasks such as question classification whereas semantic information contained in PAS and PASN gives promising results in answer classification.

In the future, we aim to study ways to capture relations between predicates so that more general semantics can be encoded by PASN. Forms of generalization for predicates and arguments within PASNs like LSA clusters, WordNet synsets and FrameNet (roles and frames) information also appear as a promising research area.

[7]The Mean Reciprocal Rank is defined as: $MRR = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{rank_i}$, where n is the number of questions and $rank_i$ is the rank of the first correct answer to question i.

Abstract

This paper presents a language-independent probabilistic answer ranking framework for question answering. The framework estimates the probability of an individual answer candidate given the degree of answer relevance and the amount of supporting evidence provided in the set of answer candidates for the question. Our approach was evaluated by comparing the candidate answer sets generated by Chinese and Japanese answer extractors with the re-ranked answer sets produced by the answer ranking framework. Empirical results from testing on NTCIR factoid questions show a 40% performance improvement in Chinese answer selection and a 45% improvement in Japanese answer selection.

1 Introduction

Question answering (QA) systems aim at finding precise answers to natural language questions from large document collections. Typical QA systems (Prager et al., 2000; Clarke et al., 2001; Harabagiu et al., 2000) adopt a pipeline architecture that incorporates four major steps: (1) question analysis, (2) document retrieval, (3) answer extraction and (4) answer selection. Question analysis is a process which analyzes a question and produces a list of keywords. Document retrieval is a step that searches for relevant documents or passages. Answer extraction extracts a list of answer candidates from the retrieved documents. Answer selection is a process which pinpoints correct answer(s) from the extracted candidate answers.

Since the first three steps in the QA pipeline may produce erroneous outputs, the final answer selection step often entails identifying correct answer(s) amongst many incorrect ones. For example, given the question *"Which Chinese city has the largest number of foreign financial companies?"*, the answer extraction component produces a ranked list of five answer candidates: Beijing (AP880603-0268)[1], Hong Kong (WSJ920110-0013), Shanghai (FBIS3-58), Taiwan (FT942-2016) and Shanghai (FBIS3-45320). Due to imprecision in answer extraction, an incorrect answer ("Beijing") can be ranked in the first position, and the correct answer ("Shanghai") was extracted from two different documents and ranked in the third and the fifth positions. In order to rank "Shanghai" in the top position, we have to address two interesting challenges:

- *Answer Similarity*. How do we exploit similarity among answer candidates? For example, when the candidates list contains redundant answers (e.g., "Shanghai" as above) or several answers which represent a single instance (e.g. "U.S.A." and "the United States"), how much should we boost the rank of the redundant answers?

- *Answer Relevance*. How do we identify relevant answer(s) amongst irrelevant ones? This task may involve searching for evidence of a relationship between the answer

[1] Answer candidates are shown with the identifier of the TREC document where they were found.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 784–791,
Prague, Czech Republic, June 2007.

and the answer type or a question keyword. For example, we might wish to query a knowledge base to determine if "Shanghai" is a city (`IS-A(Shanghai, city)`), or to determine if Shanghai is in China (`IS-IN(Shanghai, China)`).

The first challenge is to exploit redundancy in the set of answer candidates. As answer candidates are extracted from different documents, they may contain identical, similar or complementary text snippets. For example, "U.S." can appear as "United States" or "USA" in different documents. It is important to detect redundant information and boost answer confidence, especially for list questions that require a set of unique answers. One approach is to perform answer clustering (Nyberg et al., 2002; Jijkoun et al., 2006). However, the use of clustering raises additional questions: how to calculate the score of the clustered answers, and how to select the cluster label.

To address the second question, several answer selection approaches have used external knowledge resources such as WordNet, CYC and gazetteers for answer validation or answer reranking. Answer candidates are either removed or discounted if they are not of the expected answer type (Xu et al., 2002; Moldovan et al., 2003; Chu-Carroll et al., 2003; Echihabi et al., 2004). The Web also has been used for answer reranking by exploiting search engine results produced by queries containing the answer candidate and question keywords (Magnini et al., 2002). This approach has been used in various languages for answer validation. Wikipedia's structured information was used for Spanish answer type checking (Buscaldi and Rosso, 2006).

Although many QA systems have incorporated individual features and/or resources for answer selection in a single language, there has been little research on a generalized probabilistic framework that supports answer ranking in multiple languages using any answer relevance and answer similarity features that are appropriate for the language in question.

In this paper, we describe a probabilistic answer ranking framework for multiple languages. The framework uses logistic regression to estimate the probability that an answer candidate is correct given multiple answer relevance features and answer similarity features. An existing framework which was originally developed for English (Ko et al., 2007) was extended for Chinese and Japanese answer ranking by incorporating language-specific features. Empirical results on NTCIR Chinese and Japanese factoid questions show that the framework significantly improved answer selection performance; Chinese performance improved by 40% over the baseline, and Japanese performance improved by 45% over the baseline.

The remainder of this paper is organized as follows: Section 2 contains an overview of the answer ranking task. Section 3 summarizes the answer ranking framework. In Section 4, we explain how we extended the framework by incorporating language-specific features. Section 5 describes the experimental methodology and results. Finally, Section 6 concludes with suggestions for future research.

2 Answer Ranking Task

The relevance of an answer to a question can be estimated by the probability P($correct(A_i)$ $|A_i, Q$), where Q is a question and A_i is an answer candidate. To exploit answer similarity, we estimate the probability $P(correct(A_i)\ |A_i, A_j)$, where A_j is similar to A_i. Since both probabilities influence overall answer ranking performance, it is important to combine them in a unified framework and estimate the probability of an answer candidate as: $P(correct(A_i)|Q, A_1, ..., A_n)$.

The estimated probability is used to rank answer candidates and select final answers from the list. For factoid questions, the top answer is selected as a final answer to the question. In addition, we can use the estimated probability to classify incorrect answers: if the probability of an answer candidate is lower than 0.5, it is considered to be a wrong answer and is filtered out of the answer list. This is useful in deciding whether or not a valid answer to a question exists in a given corpus (Voorhees, 2002). The estimated probability can also be used in conjunction with a cutoff threshold when selecting multiple answers to list questions.

3 Answer Ranking Framework

This section summarizes our answer ranking framework, originally developed for English answers (Ko

$$
\begin{aligned}
&P(correct(A_i)|Q, A_1, ..., A_n) \\
&\quad \approx P(correct(A_i)|rel_1(A_i), ..., rel_{K1}(A_i), sim_1(A_i), ..., sim_{K2}(A_i)) \\
&\quad = \frac{exp(\alpha_0 + \sum_{k=1}^{K1} \beta_k rel_k(A_i) + \sum_{k=1}^{K2} \lambda_k sim_k(A_i))}{1 + exp(\alpha_0 + \sum_{k=1}^{K1} \beta_k rel_k(A_i) + \sum_{k=1}^{K2} \lambda_k sim_k(A_i))} \\
&\quad where, sim_k(A_i) = \sum_{j=1(j \neq i)}^{N} sim'_k(A_i, A_j).
\end{aligned}
$$

Figure 1: Estimating correctness of an answer candidate given a question and a set of answer candidates

et al., 2007). The model uses logistic regression to estimate the probability of an answer candidate (Figure 1). Each $\text{rel}_k(\text{A}_i)$ is a feature function used to produce an answer relevance score for an answer candidate A_i. Each $\text{sim}'_k(A_i, A_j)$ is a similarity function used to calculate an answer similarity between A_i and A_j. K1 and K2 are the number of answer relevance and answer similarity features, respectively. N is the number of answer candidates.

To incorporate multiple similarity features, each $\text{sim}_k(A_i)$ is obtained from an individual similarity metric, $\text{sim}'_k(A_i, A_j)$. For example, if Levenshtein distance is used as one similarity metric, $\text{sim}_k(A_i)$ is calculated by summing N-1 Levenshtein distances between one answer candidate and all other candidates.

The parameters α, β, λ were estimated from training data by maximizing the log likelihood. We used the Quasi-Newton algorithm (Minka, 2003) for parameter estimation.

Multiple features were used to generate answer relevance scores and answer similarity scores; these are discussed below.

3.1 Answer Relevance Features

Answer relevance features can be classified into knowledge-based features or data-driven features.

1) Knowledge-based features

Gazetteers: Gazetteers provide geographic information, which allows us to identify strings as instances of countries, their cities, continents, capitals, etc. For answer ranking, three gazetteer resources were used: the Tipster Gazetteer, the CIA World Factbook and information about the US states provided by 50states.com. These resources were used to assign an answer relevance score between -1 and 1 to each candidate. For example, given the question "Which city in China has the largest number of foreign financial companies?", the candidate "Shanghai" receives a score of 0.5 because it is a city in the gazetteers. But "Taiwan" receives a score of -1.0 because it is not a city in the gazetteers. A score of 0 means the gazetteers did not contribute to the answer selection process for that candidate.

Ontology: Ontologies such as WordNet contain information about relationships between words and general meaning types (synsets, semantic categories, etc.). WordNet was used to identify answer relevance in a manner analogous to the use of gazetteers. For example, given the question "Who wrote the book 'Song of Solomon'?", the candidate "Mark Twain" receives a score of 0.5 because its hypernyms include "writer".

2) Data-driven features

Wikipedia: Wikipedia was used to generate an answer relevance score. If there is a Wikipedia document whose title matches an answer candidate, the document is analyzed to obtain the term frequency (tf) and the inverse term frequency (idf) of the candidate, from which a tf.idf score is calculated. When there is no matched document, each question keyword is also processed as a back-off strategy, and the answer relevance score is calculated by summing the tf.idf scores obtained from individual keywords.

Google: Following Magnini et al. (2002), a query consisting of an answer candidate and question key-

words was sent to the Google search engine. Then the top 10 text snippets returned by Google were analyzed to generate an answer relevance score by computing the minimum number of words between a keyword and the answer candidate.

3.2 Answer Similarity Features

Answer similarity is calculated using multiple string distance metrics and a list of synonyms.

String Distance Metrics: String distance metrics such as Levenshtein, Jaro-Winkler, and Cosine similarity were used to calculate the similarity between two English answer candidates.

Synonyms: Synonyms can be used as another metric to calculate answer similarity. If one answer is synonym of another answer, the score is 1. Otherwise the score is 0. To get a list of synonyms, three knowledge bases were used: WordNet, Wikipedia and the CIA World Factbook. In addition, manually generated rules were used to obtain synonyms for different types of answer candidates. For example, "April 12 1914" and "12th Apr. 1914" are converted into "1914-04-12" and treated as synonyms.

4 Extensions for Multiple Languages

We extended the framework for Chinese and Japanese QA. This section details how we incorporated language-specific resources into the framework. As logistic regression is based on a probabilistic framework, the model does not need to be changed to support other languages. We only retrained the model for individual languages. To support Chinese and Japanese QA, we incorporated new features for individual languages.

4.1 Answer Relevance Features

We replaced the English gazetteers and WordNet with language-specific resources for Japanese and Chinese. As Wikipedia and the Web support multiple languages, the same algorithm was used in searching language-specific corpora for the two languages.

1) Knowledge-based features

The knowledge-based features involve searching for facts in a knowledge base such as gazetteers and WordNet. We utilized comparable resources for Chinese and Japanese. Using language-specific resources, the same algorithms were applied to generate an answer relevance score between -1 and 1.

Language	#Articles	
	Nov. 2005	Aug. 2006
English	1,811,554	3,583,699
Japanese	201,703	446,122
Chinese	69,936	197,447

Table 1: Articles in Wikipedia for different languages

Gazetteers: There are few available gazetteers for Chinese and Japanese. Therefore, we extracted location data from language-specific resources. For Japanese, we extracted Japanese location information from Yahoo[2], which contains many location names in Japan and the relationships among them. For Chinese, we extracted location names from the Web. In addition, we translated country names provided by the CIA World Factbook and the Tipster gazetteers into Chinese and Japanese names. As there is more than one translation, top 3 translations were used.

Ontology: For Chinese, we used HowNet (Dong, 2000) which is a Chinese version of WordNet. It contains 65,000 Chinese concepts and 75,000 corresponding English equivalents. For Japanese, we used semantic classes provided by Gengo GoiTaikei[3]. Gengo GoiTaikei is a Japanese lexicon containing 300,000 Japanese words with their associated 3,000 semantic classes. The semantic information provided by HowNet and Gengo GoiTaikei was used to assign an answer relevance score between -1 and 1.

2) Data-driven features

Wikipedia: As Wikipedia supports more than 200 language editions, the approach used in English can be used for different languages without any modification. Table 1 shows the number of text articles in three different languages. Wikipedia's current coverage in Japanese and Chinese does not match its coverage in English, but coverage in these languages continues to improve.

To supplement the small corpus of Chinese documents available, we used Baidu

[2]http://map.yahoo.co.jp/

[3]http://www.kecl.ntt.co.jp/mtg/resources/GoiTaikei

(http://baike.baidu.com), which is similar to Wikipedia but contains more articles written in Chinese. We first search for Chinese Wikipedia. When there is no matching document in Wikipedia, each answer candidate is sent to Baidu and the retrieved document is analyzed in the same way to analyze Wikipedia documents.

The idf score was calculated using word statistics from Japanese Yomiuri newspaper corpus and the NTCIR Chinese corpus.

Google: The same algorithm was applied to analyze Japanese and Chinese snippets returned from Google. But we restricted the language to Chinese or Japanese so that Google returned only Chinese or Japanese documents. To calculate the distance between an answer candidate and question keywords, segmentation was done with linguistic tools. For Japanese, Chasen[4] was used. For Chinese segmentation, a maximum-entropy based parser was used (Wang et al., 2006).

3) Manual Filtering

Other than the features mentioned above, we manually created many rules for numeric and temporal questions to filter out invalid answers. For example, when the question is looking for a year as an answer, an answer candidate which contains only the month receives a score of -1. Otherwise, the score is 0.

4.2 Answer Similarity Features

The same features used for English were applied to calculate the similarity of Chinese/Japanese answer candidates. To identify synonyms, Wikipedia were used for both Chinese and Japanese. EIJIRO dictionary was used to obtain Japanese synonyms. EIJIRO is a English-Japanese dictionary containing 1,576,138 words and provides synonyms for Japanese words.

As there are several different ways to represent temporal and numeric expressions (Nyberg et al., 2002; Greenwood, 2006), language-specific conversion rules were applied to convert them into a canonical format; for example, a rule to convert Japanese Kanji characters to Arabic numbers is shown in Figure 2.

５割	50 %

Figure 2: Example of normalized answer strings

5 Experiments

This section describes the experiments to evaluate the extended answer ranking framework for Chinese and Japanese QA.

5.1 Experimental Setup

We used Chinese and Japanese questions provided by the NTCIR (NII Test Collection for IR Systems), which focuses on evaluating cross-lingual and monolingual QA tasks for Chinese, Japanese and English. For Chinese, a total of 550 factoid questions from the NTCIR5-6 QA evaluations served as the dataset. Among them, 200 questions were used to train the Chinese answer extractor and 350 questions were used to evaluate our answer ranking framework. For Japanese, 700 questions from the NTCIR5-6 QA evaluations served as the dataset. Among them, 300 questions were used to train the Japanese answer extractor and 400 questions were used to evaluate our framework.

Both the Chinese and Japanese answer extractors use maximum-entropy to extract answer candidates based on multiple features such as named entity, dependency structures and some language-dependent features.

Performance of the answer ranking framework was measured by average answer accuracy: the number of correct top answers divided by the number of questions where at least one correct answer exists in the candidate list provided by an extractor. Mean Reciprocal Rank (MRR5) was also used to calculate the average reciprocal rank of the first correct answer in the top 5 answers.

The baseline for average answer accuracy was calculated using the answer candidate likelihood scores provided by each individual extractor; the

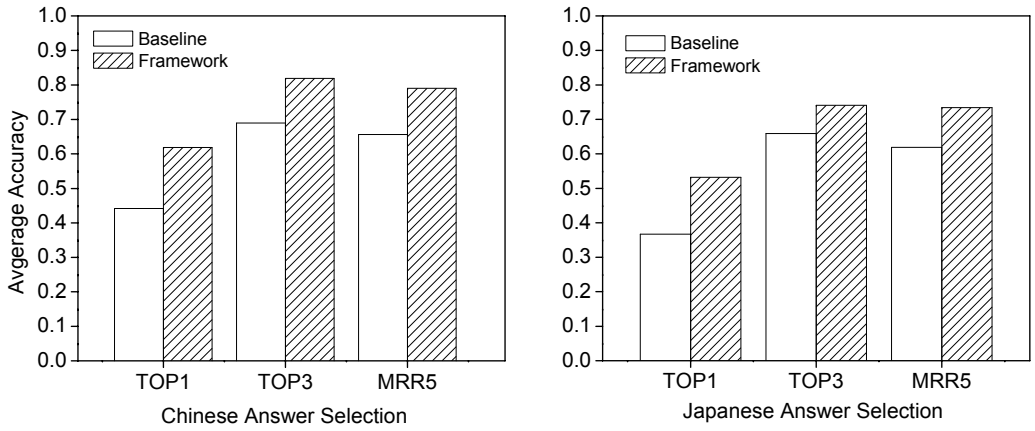

Figure 3: Performance of the answer ranking framework for Chinese and Japanese answer selection (TOP1: average accuracy of top answer, TOP3: average accuracy of top 3 answers, MRR5: average of mean reciprocal rank of top 5 answers)

answer with the best extractor score was chosen, and no validation or similarity processing was performed.

3-fold cross-validation was performed, and we used a version of Wikipedia downloaded in Aug 2006.

5.2 Results and Analysis

We first analyzed the average accuracy of top 1, top3 and top 5 answers. Figure 3 compares the average accuracy using the baseline and the answer selection framework. As can be seen, the answer ranking framework significantly improved performance on both Chinese and Japanese answer selection. As for the average top answer accuracy, there were 40% improvement over the baseline (Chinese) and 45% improvement over the baseline (Japanese).

We also analyzed the degree to which the average accuracy was affected by answer similarity and relevance features. Table 2 compares the average top answer accuracy using the baseline, the answer relevance features, the answer similarity features and all feature combinations. Both the similarity and the relevance features significantly improved answer selection performance compared to the baseline, and combining both sets of features together produced the best performance.

We further analyzed the utility of individual relevance features (Figure 4). For both languages, filtering was useful in ruling out wrong answers. The impact of the ontology was more positive for Japanese; we assume that this is because the Chinese ontology (HowNet) contains much less information overall than the Japanese ontology (Gengo GoiTaikei). The comparative impact of Wikipedia was similar. For Chinese, there were many fewer Wikipedia documents available. Even though we used Baidu as a supplemental resource for Chinese, this did not improve answer selection performance. On the other hand, the use of Wikipedia was very helpful for Japanese, improving performance by 26% over the baseline. This shows that the quality of answer relevance estimation is significantly affected by resource coverage.

	Baseline	Rel	Sim	All
Chinese	0.442	0.482	0.597	0.619
Japanese	0.367	0.463	0.502	0.532

Table 2: Average top answer accuracy of individual features (Rel: merging relevance features, Sim: merging similarity features, ALL: merging all features).

When comparing the data-driven features with the knowledge-based features, the data-driven features (such as Wikipedia and Google) tended to increase performance more than the knowledge-based features (such as gazetteers and WordNet).

Table 3 shows the effect of individual similarity features on Chinese and Japanese answer selec-

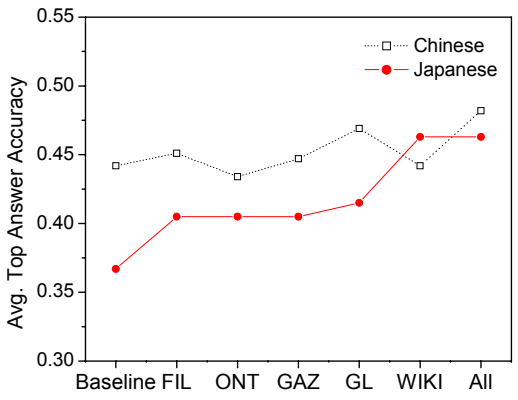

Figure 4: Average top answer accuracy of individual answer relevance features.(FIL: filtering, ONT, ontology, GAZ: gazetteers, GL: Google, WIKI: Wikipedia, ALL: combination of all relevance features)

Jaro-Winkler	0.544	0.518	0.410	0.415
Levenshtein	0.558	0.544	0.434	0.449
Synonyms	0.527	0.527	0.493	0.493
All	0.588	0.580	**0.502**	0.488

Table 3: Average accuracy using individual similarity features under different thresholds: 0.3 and 0.5 ("All": combination of all similarity metrics)

tion. As some string similarity features (e.g., Levenshtein distance) produce a number between 0 and 1 (where 1 means two strings are identical and 0 means they are different), similarity scores less than a threshold can be ignored. We used two thresholds: 0.3 and 0.5. In our experiments, using 0.3 as a threshold produced better results in Chinese. In Japanese, 0,5 was a better threshold for individual features. Among three different string similarity features (Levenshtein, Jaro-Winkler and Cosine similarity), cosine similarity tended to perform better than the others.

When comparing synonym features with string similarity features, synonyms performed better than string similarity in Japanese, but not in Chinese. We had many more synonyms available for Japanese and they helped the system to better exploit answer redundancy.

	Data-driven features	All features
Chinese	0.606	0.619
Japanese	0.517	0.532

Table 4: Average top answer accuracy when using data-driven features v.s. when using all features.

We also analyzed answer selection performance when combining all four similarity features ("All" in Table 3). Combining all similarity features improved the performance in Japanese, but hurt the performance in Chinese, because adding a small set of synonyms to the string metrics worsened the performance of logistic regression.

5.3 Utility of data-driven features

In our experiments we used data-driven features as well as knowledge-based features. As knowledge-based features need manual effort to access language-specific resources for individual languages, we conducted an additional experiment only with data-driven features in order to see how much performance gain is available without the manual work. As Google, Wikipedia and string similarity metrics can be used without any additional manual effort when extended to other languages, we used these three features and compared the performance.

Table 4 shows the performance when using data-driven features v.s. all features. It can be seen that data-driven features alone achieved significant improvement over the baseline. This indicates that the framework can easily be extended to any language where appropriate data resources are available, even if knowledge-based features and resources for the language are still under development.

6 Conclusion

In this paper, we presented a generalized answer selection framework which was applied to Chinese and Japanese question answering. An empirical evaluation using NTCIR test questions showed that the framework significantly improves baseline answer selection performance. For Chinese, the performance improved by 40% over the baseline. For Japanese, the performance improved by 45% over

the baseline. This shows that our probabilistic framework can be easily extended for multiple languages by reusing data-driven features (with new corpora) and adding language-specific resources (ontologies, gazetteers) for knowledge-based features.

In our previous work, we evaluated the performance of the framework for English QA using questions from past TREC evaluations (Ko et al., 2007). The experimental results showed that the combination of all answer ranking features improved performance by an average of 102% over the baseline. The relevance features improved performance by an average of 99% over the baseline, and the similarity features improved performance by an average of 46% over the baseline. Our hypothesis is that answer relevance features had a greater impact for English QA because the quality and coverage of the data resources available for English answer validation is much higher than the quality and coverage of existing resources for Japanese and Chinese. In future work, we will continue to evaluate the robustness of the framework. It is also clear from our comparison with English QA that more work can and should be done in acquiring data resources for answer validation in Chinese and Japanese.

Abstract

This paper describes a method for automatically learning effective dialogue strategies, generated from a library of dialogue content, using reinforcement learning from user feedback. This library includes greetings, social dialogue, chit-chat, jokes and relationship building, as well as the more usual clarification and verification components of dialogue. We tested the method through a motivational dialogue system that encourages take-up of exercise and show that it can be used to construct good dialogue strategies with little effort.

1 Introduction

Interactions between humans and machines have become quite common in our daily life. Many services that used to be performed by humans have been automated by natural language dialogue systems, including information seeking functions, as in timetable or banking applications, but also more complex areas such as tutoring, health coaching and sales where communication is much richer, embedding the provision and gathering of information in e.g. social dialogue. In the latter category of dialogue systems, a high level of naturalness of interaction and the occurrence of longer periods of satisfactory engagement with the system are a prerequisite for task completion and user satisfaction.

Typically, such systems are based on a dialogue strategy that is manually designed by an expert based on knowledge of the system and the domain, and on continuous experimentation with test users. In this process, the expert has to make many design choices which influence task completion and user satisfaction in a manner which is hard to assess, because the effectiveness of a strategy depends on many different factors, such as classification/ASR performance, the dialogue domain and task, and, perhaps most importantly, personality characteristics and knowledge of the user.

We believe that the key to maximum dialogue effectiveness is to listen to the user. This paper describes the development of an adaptive dialogue system that uses the feedback of users to automatically improve its strategy. The system starts with a library of generic and task-/domain-specific dialogue components, including social dialogue, chit-chat, entertaining parts, profiling questions, and informative and diagnostic parts. Given this variety of possible dialogue actions, the system can follow many different strategies within the dialogue state space. We conducted training sessions in which users interacted with a version of the system which randomly generates a possible dialogue strategy for each interaction (restricted by global dialogue constraints). After each interaction, the users were asked to reward different aspects of the conversation. We applied reinforcement learning to use this feedback to compute the optimal dialogue policy.

The following section provides a brief overview of previous research related to this area and how our work differs from these studies. We then proceed with a concise description of the dialogue system used for our experiments in section 3. Section 4 is about the training process and the reward model. Section 5 goes into detail about dialogue policy op-

timization with reinforcement learning. In section 6 we discuss our experimental results.

2 Related Work

Previous work has examined learning of effective dialogue strategies for information seeking spoken dialogue systems, and in particular the use of reinforcement learning methods to learn policies for action selection in dialogue management (see e.g. Levin et al., 2000; Walker, 2000; Scheffler and Young, 2002; Peek and Chickering, 2005; Frampton and Lemon, 2006), for selecting initiative and confirmation strategies (Singh et al., 2002); for detecting speech recognition problem (Litman and Pan, 2002); changing the dialogue according to the expertise of the user (Maloor and Chai, 2000); adapting responses according to previous interactions with the users (Rudary et al., 2004); optimizing mixed initiative in collaborative dialogue (English and Heeman, 2005), and optimizing confirmations (Cuayáhuitl et al., 2006). Other researchers have focussed their attention on the learning aspect of the task, examining, for example hybrid reinforcement/supervised learning (Henderson et al., 2005).

Previous work on learning dialogue management strategies has however generally been limited to well defined areas of the dialogue, in particular dealing with speech recognition and clarification problems, with small state spaces and a limited set of actions to choose from (Henderson et al., 2005). In a number of contexts, however, dialogues need to have a far greater degree of complexity not just in the number of states and possible actions but also in the variety of dialogue acts: for example in motivational dialogue systems where the task is not limited to information gathering, slot-filling or querying of a database, and where dialogues must contain more social and relational elements to be successful (for the usefulness of social dialogue see e.g. Bickmore, 2003; Liu and Picard, 2005). Only little effort has been directed to the question what dialogue components should make up the dialogue, involving decisions like how much and what type of social interaction should be used, different ways of forming a relationship with the user such as using chit-chat (for example asking about a user's hobbies or asking for the user's name), using humour, as well as the more conventional tasks of clarifying user input, establishing common ground and ensuring system replies are appropriate. Our work has focused on these aspects of dialogue strategy construction, in order to create good dialogue strategies incorporating appropriate levels of social interaction, humour, chit-chat, as well as successful information gathering and provision.

3 A Motivational Dialogue System

The domain of our system is physical exercise. The system is set up as an exercise advisor that asks the user what is preventing him/her from exercising more. After the user has worded his/her exercise 'barrier', the system will give motivational advice for how to overcome this barrier. As an illustration, Table 1 shows an example dialogue, generated by our system. Our dialogue system is *text*-based, so it does not involve speech recognition. This section describes the system's three main modules: the dialogue state/action manager, the utterance classifier and the dialogue component library.

Speaker	Utterance
system	*Good evening!*
system	*What's your name?*
user	**my name is Brenda**
system	*So Brenda, how are you today?*
user	**fine thank you**
system	*Tell me what is preventing you from exercising more.*
user	**I don't have anyone to exercise with...**
system	*So your barrier is Loneliness (e.g. You don't like exercising on your own).*
user	**sort of, yeah**
system	*A solution for this barrier is: Try going on your own and see whether it's really that different to going with a friend. Try talking to other people who are exercising, you're likely to find they welcome a little conversation!*
system	*Did you find this solution useful?*
user	**I guess...**
system	*Ok. Try to work on this to overcome your barrier.*
system	*Bye!*

Table 1: Example dialogue.

3.1 Dialogue state/action management

The dialogue state is unique at every stage of the conversation and is represented as a vector of feature-values. We use only a limited set of features because, as also noted in (Singh et al., 2002; Levin et al., 2000), it is important to keep the state space as small as possible (but with enough distinc-

tive power to support learning) so we can construct a non-sparse Markov decision process (see section 5) based on our limited training dialogues. The state features are listed in Table 2.

Feature	Values	Description
curnode	$c \in N$	the current dialogue node
actiontype	$utt, trans$	action type
trigger	$t \in T$	utterance classifier category
confidence	$1, 0$	category confidence
problem	$1, 0$	communication problem earlier

Table 2: Dialogue state features.

In each dialogue state, the dialogue manager will look up the next action that should be taken. In our system, an action is either a *system utterance* or a *transition* in the dialogue structure. In the initial system, the dialogue structure was manually constructed. In many states, the next action requires a choice to be made. Dialogue states in which the system can choose among several possible actions are called *choice-states*. For example, in our system, immediately after greeting the user, the dialogue structure allows for different directions: the system can first ask some personal questions, or it can immediately discuss the main topic without any digressions. Utterance actions may also require a choice (e.g. *directive* versus *open* formulation of a question). In training mode, the system will make random choices in the choice-states. This approach will generate many different dialogue strategies, i.e. *paths* through the dialogue structure.

User replies are sent to an utterance classifier. The category assigned by this classifier is returned to the dialogue manager and triggers a transition to the next node in the dialogue structure. The system also accommodates a simple rule-based extraction module, which can be used to extract information from user utterances (e.g. the user's name, which is templated in subsequent system prompts in order to personalize the dialogue).

3.2 Utterance classification

The (memory-based) classifier uses a rich set of features for accurate classification, including words, phrases, regular expressions, domain-specific word-relations (using a taxonomy-plugin) and syntactically motivated expressions. For utterance parsing we used a memory-based shallow parser, called MBSP (Daelemans et al., 1999). This parser provides part of speech labels, chunk brackets, subject-verb-object relations, and has been enriched with detection of negation scope and clause boundaries.

The feature-matching mechanism in our classification system can match terms or phrases at specified positions in the token stream of the utterance, also in combination with syntactic and semantic class labels. This allows us to define features that are particularly useful for resolving confusing linguistic phenomena like ambiguity and negation. A base feature set was generated automatically, but quite a lot of features were manually tuned or added to cope with certain common dialogue situations. The overall classification accuracy, measured on the dialogues that were produced during the training phase, is 93.6%. Average precision/recall is 98.6/97.3% for the non-barrier categories (*confirmation*, *negation*, *unwillingness*, etc.), and 99.1/83.4% for the barrier categories (*injury*, *lack of motivation*, etc.).

3.3 Dialogue Component Library

The dialogue component library contains generic as well as task-/domain-specific dialogue content, combining different aspects of dialogue (task/topic structure, communication goals, etc.). Table 3 lists all components in the library that was used for training our dialogue system. A dialogue component is basically a coherent set of dialogue node representations with a certain dialogue function. The library is set up in a flexible, generic way: new components can easily be plugged in to test their usefulness in different dialogue contexts or for new domains.

4 Training the Dialogue System

4.1 Random strategy generation

In its training mode, the dialogue system uses random exploration: it generates different dialogue strategies by choosing randomly among the *allowed actions* in the choice-states. Note that dialogue generation is constrained to contain certain fixed actions that are essential for task completion (e.g. asking the exercise barrier, giving a solution, closing the session). This excludes a vast number of useless strategies from exploration by the system. Still, given all action choices and possible user reactions, the total number of unique dialogues that can be generated by

Component	Description	p_a	p_e
StartSession	Dialogue openings, including various greetings	•	•
PersonalQuestionnaire	Personal questions, e.g. name; age; hobbies; interests, *how are you today?*	•	
ElizaChitChat	Eliza-like chit-chat, e.g. *please go on...*		
ExerciseChitChat	Chit-chat about exercise, e.g. *have you been doing any exercise this week?*	○	
Barrier	Prompts concerning the barrier, e.g. ask the barrier; barrier verification; ask a rephrase	•	•
Solution	Prompts concerning the solution, e.g. give the solution; verify usefulness	•	•
GiveBenefits	Talk about the benefits of exercising		
AskCommitment	Ask user to commit his implementation of the given solution	•	
Encourage	Encourage the user to work on the given solution	•	•
GiveJoke	The humor component: ask if the user wants to hear a joke; tell random jokes	○	•
VerifyCloseSession	Verification for closing the session (*are you sure you want to close this session?*)	○	○
CloseSession	Dialogue endings, including various farewells	•	•

Table 3: Components in the dialogue component library. The last two columns show which of the components was used in the learned policy (p_a) and the expert policy (p_e), discussed in section 6. • means the component is always used, ○ means it is sometimes used, depending on the dialogue state.

the system is approximately 345000 (many of which are unlikely to ever occur). During training, the system generated 490 different strategies. There are 71 choice-states that can actually occur in a dialogue. In our training dialogues, the opening state was obviously visited most frequently (572 times), almost 60% of all states was visited at least 50 times, and only 16 states were visited less than 10 times.

4.2 The reward model

When the dialogue has reached its final state, a survey is presented to the user for dialogue evaluation. The survey consists of five statements that can each be rated on a five-point scale (indicating the user's level of agreement). The responses are mapped to rewards of -2 to 2. The statements we used are partly based on the user survey that was used in (Singh et al., 2002). We considered these statements to reflect the most important aspects of conversation that are relevant for learning a good dialogue policy. The five statements we used are listed below.

M1 *Overall, this conversation went well*

M2 *The system understood what I said*

M3 *I knew what I could say at each point in the dialogue*

M4 *I found this conversation engaging*

M5 *The system provided useful advice*

4.3 Training set-up

Eight subjects carried out a total of 572 conversations with the system. Because of the variety of possible exercise barriers known by the system (52 in total) and the fact that some of these barriers are more complex or harder to detect than others, the system's classification accuracy depends largely on the user's barrier. To prevent classification accuracy distorting the user evaluations, we asked the subjects to act as if they had one of five predefined exercise barriers (e.g. *Imagine that you don't feel comfortable exercising in public. See what the advisor recommends for this barrier to your exercise*).

5 Dialogue Policy Optimization with Reinforcement Learning

Reinforcement learning refers to a class of machine learning algorithms in which an agent explores an environment and takes actions based on its current state. In certain states, the environment provides a reward. Reinforcement learning algorithms attempt to find the optimal policy, i.e. the policy that maximizes cumulative reward for the agent over the course of the problem. In our case, a policy can be seen as a mapping from the dialogue states to the possible actions in those states. The environment is typically formulated as a Markov decision process (MDP).

The idea of using reinforcement learning to automate the design of strategies for dialogue systems was first proposed by Levin et al. (2000) and has subsequently been applied in a.o. (Walker, 2000; Singh et al., 2002; Frampton and Lemon, 2006; Williams et al., 2005).

5.1 Markov decision processes

We follow past lines of research (such as Levin et al., 2000; Singh et al., 2002) by representing a dialogue as a trajectory in the state space, determined

by the user responses and system actions: $s_1 \xrightarrow{a_1,r_1} s_2 \xrightarrow{a_2,r_2} \ldots s_n \xrightarrow{a_n,r_n} s_{n+1}$, in which $s_i \xrightarrow{a_i,r_i} s_{i+1}$ means that the system performed action a_i in state s_i, received[1] reward r_i and changed to state s_{i+1}. In our system, a state is a dialogue context vector of feature values. This feature vector contains the available information about the dialogue so far that is relevant for deciding what action to take next in the current dialogue state. We want the system to learn the optimal decisions, i.e. to choose the actions that maximize the expected reward.

5.2 Q-value iteration

The field of reinforcement learning includes many algorithms for finding the optimal policy in an MDP (see Sutton and Barto, 1998). We applied the algorithm of (Singh et al., 2002), as their experimental set-up is similar to ours, constisting of: generation of (limited) exploratory dialogue data, using a training system; creating an MDP from these data and the rewards assigned by the training users; off-line policy learning based on this MDP.

The Q-function for a certain action taken in a certain state describes the total reward expected between taking that action and the end of the dialogue. For each state-action pair (s, a), we calculated this expected cumulative reward $Q(s, a)$ of taking action a from state s, with the following equation (Sutton and Barto, 1998; Singh et al., 2002):

$$Q(s,a) = R(s,a) + \gamma \sum_{s'} P(s'|s,a) \max_{a'} Q(s',a') \quad (1)$$

where: $P(s'|s,a)$ is the probability of a transition from state s to state s' by taking action a, and $R(s,a)$ is the expected reward obtained when taking action a in state s. γ is a weight ($0 \leq \gamma \leq 1$), that discounts rewards obtained later in time when it is set to a value < 1. In our system, γ was set to 1. Equation 1 is recursive: the Q-value of a certain state is computed in terms of the Q-values of its successor states. The Q-values can be estimated to within a desired threshold using Q-value iteration (Sutton and Barto, 1998). Once the value iteration process is completed, by selecting the action with the maximum Q-value (the maximum expected future reward) at each choice-state, we can obtain the optimal dialogue policy π.

[1]In our experiments, we did not make use of immediate rewarding (e.g. at every turn) during the conversation. Rewards were given after the final state of the dialogue had been reached.

6 Results and Discussion

6.1 Reward analysis

Figure 1 shows a graph of the distribution of the five different evaluation measures in the training data (see section 4.2 for the statement wordings). M1 is probably the most important measure of success. The distribution of this reward is quite symmetrical, with a slightly higher peak in the positive area. The distribution of M2 shows that M1 and M2 are related. From the distribution of M4 we can conclude that the majority of dialogues during the training phase was not very engaging. Users obviously had a good feeling about what they could say at each point in the dialogue (M3), which implies good quality of the system prompts. The judgement about the usefulness of the provided advice is pretty average, tending a bit more to negative than to positive. We do think that this measure might be distorted by the fact that we asked the subjects to *imagine* that they have the given exercise barriers. Furthermore, they were sometimes confronted with advice that had already been presented to them in earlier conversations.

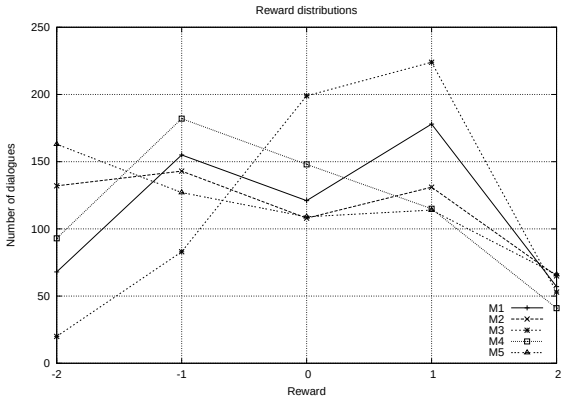

Figure 1: Reward distributions in the training data.

In our analysis of the users' rewarding behavior, we found several significant correlations. We found that longer dialogues (> 3 user turns) are appreciated more than short ones (< 4 user turns), which seems rather logical, as dialogues in which the user

barely gets to say anything are neither natural nor engaging.

We also looked at the relationship between user input verification and the given rewards. Our intuition is that the choice of barrier verification is one of the most important choices the system can make in the dialogue. We found that it is much better to first verify the detected barrier than to immediately give advice. The percentage of appropriate advice provided in dialogues with barrier verification is significantly higher than in dialogues without verification.

In several states of the dialogue, we let the system choose from different wordings of the system prompt. One of these choices is whether to use an open question to ask what the user's barrier is (*How can I help you?*), or a directive question (*Tell me what is preventing you from exercising more.*). The motivation behind the open question is that the user gets the initiative and is basically free to talk about anything he/she likes. Naturally, the advantage of directive questions is that the chance of making classification errors is much lower than with open questions because the user will be better able to assess what kind of answer the system expects. Dialogues in which the key-question (asking the user's barrier) was directive, were rewarded more positively than dialogues with the open question.

6.2 Learned dialogue policies

We learned a different policy for each evaluation measure separately (by only using the rewards given for that particular measure), and a policy based on a combination (sum) of the rewards for all evaluation measures. We found that the learned policy based on the combination of all measures, and the policy based on measure M1 alone (*Overall, this conversation went well*) were nearly identical. Table 4 compares the most important decisions of the different policies. For convenience of comparison, we only listed the main, structural choices. Table 3 shows which of the dialogue components in the library were used in the learned and the expert policy.

Note that, for the sake of clarity, the state descriptions in Table 4 are basically summaries of a set of more specific states since a state is a specific representation of the dialogue context at a particular moment (composed of the values of the features listed in Table 2). For instance, in the p_a policy, the decision in the last row of the table (give a joke or not), depends on whether or not there has been a classification failure (i.e. a communication problem earlier in the dialogue). If there has been a classification failure, the policy prescribes the decision *not* to give a joke, as it was not appreciated by the training users in that context. Otherwise, if there were no communication problems during the conversation, the users *did* appreciate a joke.

6.3 Evaluation

We compared the learned dialogue policy with a policy which was independently hand-designed by experts[2] for this system. The decisions made in the learned strategy were very similar to the ones made by the experts, with only a few differences, indicating that the automated method would indeed perform as well as an expert. The main differences were the inclusion of a personal questionnaire for relation building at the beginning of the dialogue and a commitment question at the end of the dialogue. Another difference was the more restricted use of the humour element, described in section 6.2 which turns out to be intuitively better than the expert's decision to simply always include a joke. Of course, we can only draw conclusions with regard to the effectiveness of these two policies if we empirically compare them with real test users. Such evaluations are planned as part of our future research.

As some additional evidence against the possibility that the learned policy was generated by chance, we performed a simple experiment in which we took several random samples of 300 training dialogues from the complete training set. For each sample, we learned the optimal policy. We mutually compared these policies and found that they were very similar: only in 15-20% of the states, the policies disagreed on which action to take next. On closer inspection we found that this disagreement mainly concerned states that were poorly visited (1-10 times) in these samples. These results suggest that the learned policy is unreliable at infrequently visited states. Note however, that all main decisions listed in Table 4 are

[2]The experts were a team made up of psychologists with experience in the psychology of health behaviour change and a scientist with experience in the design of automated dialogue systems.

State description	Action choices	p_1	p_2	p_3	p_4	p_5	p_a	p_e
After greeting the user	- ask the exercise barrier - ask personal information - chit-chat about exercise	•	•	•	•	•	•	•
When asking the barrier	- use a directive question - use an open question	•	•	•	•	•	•	•
User gives exercise barrier	- verify detected barrier - give solution	•	•	•	•	•	•	•
User rephrased barrier	- verify detected barrier - give solution	•	•	•	•	•	•	•
Before presenting solution	- ask if the user wants to see a solution for the barrier - give a solution	•	•	•	•	•	•	•
After presenting solution	- verify solution usefulness - encourage the user to work on the given solution - ask user to commit solution implementation	•	•	•	•	•	•	•

User found solution not useful	- give another solution - ask the user wants to propose his own solution	•	•	•	•	•	•	•
After giving second solution	- verify solution usefulness - encourage the user to work on the given solution - ask user to commit solution implementation	•	•	•	•	•	•	•
End of dialogue	- close the session - ask if the user wants to hear a joke	•	•	•	•	•	•	•

Table 4: Comparison of the most important decisions made by the learned policies. p_n is the policy based on evaluation measure n; p_a is the policy based on all measures; p_e contains the decisions made by experts in the manually designed policy.

made at frequently visited states. The only disagreement in frequently visited states concerned system-prompt choices. We might conclude that these particular (often very subtle) system-prompt choices (e.g. careful versus direct formulation of the exercise barrier) are harder to learn than the more noticable dialogue structure-related choices.

7 Conclusions and Future Work

We have explored reinforcement learning for automatic dialogue policy optimization in a question-based motivational dialogue system. Our system can automatically compose a dialogue strategy from a library of dialogue components, that is very similar to a manually designed expert strategy, by learning from user feedback.

Thus, in order to build a new dialogue system, dialogue system engineers will have to set up a rough dialogue template containing several 'multiple choice'-action nodes. At these nodes, various dialogue components or prompt wordings (e.g. entertaining parts, clarification questions, social dialogue, personal questions) from an existing or self-made library can be plugged in without knowing beforehand which of them would be most effective.

The automatically generated dialogue policy is very similar (see Table 4) –but arguably improved in many details– to the hand-designed policy for this system. Automatically learning dialogue policies also allows us to test a number of interesting issues in parallel, for example, we have learned that users appreciated dialogues that were longer, starting with some personal questions (e.g *What is your name?*, *What are your hobbies?*). We think that altogether, this relation building component gave the dialogue a more natural and engaging character, although it was left out in the expert strategy.

We think that the methodology described in this paper may be able to yield more effective dialogue policies than experts. Especially in complicated dialogue systems with large state spaces. In our system, state representations are composed of multiple context feature values (e.g. communication problem earlier in the dialogue, the confidence of the utterance classifier). Our experiments showed that sometimes different decisions were learned in dialogue contexts where only one of these features was different (for example use humour only if the system has been successful in recognising a user's exercise barrier): all context features are implicitly used to learn the optimal decisions and when hand-designing a di-

alogue policy, experts can impossibly take into account all possible different dialogue contexts.

With respect to future work, we plan to examine the impact of different state representations. We did not yet empirically compare the effects of each feature on policy learning or experiment with other features than the ones listed in Table 2. As Tetreault and Litman (2006) show, incorporating more or different information into the state representation might however result in different policies.

Furthermore, we will evaluate the actual genericity of our approach by applying it to different domains. As part of that, we will look at automatically mining libraries of dialogue components from existing dialogue transcript data (e.g. available scripts or transcripts of films, tv series and interviews containing real-life examples of different types of dialogue). These components can then be plugged into our current adaptive system in order to discover what works best in dialogue for new domains. We should note here that extending the system's dialogue component library will automatically increase the state space and thus policy generation and optimization will become more difficult and require more training data. It will therefore be very important to carefully control the size of the state space and the global structure of the dialogue.

Acknowledgements

The authors would like to thank Piroska Lendvai Rudenko, Walter Daelemans, and Bob Hurling for their contributions and helpful comments. We also thank the anonymous reviewers for their useful comments on the initial version of this paper.

On the role of context and prosody in the interpretation of 'okay'

Abstract

We examine the effect of contextual and acoustic cues in the disambiguation of three discourse-pragmatic functions of the word *okay*. Results of a perception study show that contextual cues are stronger predictors of discourse function than acoustic cues. However, acoustic features capturing the pitch excursion at the right edge of *okay* feature prominently in disambiguation, whether other contextual cues are present or not.

1 Introduction

CUE PHRASES (also known as DISCOURSE MARKERS) are linguistic expressions that can be used to convey explicit information about the structure of a discourse **or** to convey a semantic contribution (Grosz and Sidner, 1986; Reichman, 1985; Cohen, 1984). For example, the word *okay* can be used to convey a 'satisfactory' evaluation of some entity in the discourse (*the movie was okay*); as a backchannel in a dialogue to indicate that one interlocutor is still attending to another; to convey acknowledgment or agreement; or, in its 'cue' use, to start or finish a discourse segment (Jefferson, 1972; Schegloff and Sacks, 1973; Kowtko, 1997; Ward and Tsukahara, 2000). A major question is how speakers indicate and listeners interpret such variation in meaning. From a practical perspective, understanding how speakers and listeners disambiguate cue phrases is important to spoken dialogue systems, so that systems can convey potentially ambiguous terms with their intended meaning and can interpret user input correctly.

There is considerable evidence that the different uses of individual cue phrases can be distinguished by variation in the prosody with which they are realized. For example, (Hirschberg and Litman, 1993) found that cue phrases in general could be disambiguated between their 'semantic' and their 'discourse marker' uses in terms of the type of pitch accent borne by the cue phrase, the position of the phrase in the intonational phrase, and the amount of additional information in the phrase. Despite the frequence of the word *okay* in natural dialogues, relatively little attention has been paid to the relationship between its use and its prosodic realization. (Hockey, 1993) did find that *okay* differs in terms of the pitch contour speakers use in uttering it, suggesting that a final rising pitch contour "categorically marks a turn change," while a downstepped falling pitch contour usually indicates a discourse segment boundary. However, it is not clear which, if any, of the prosodic differences identified in this study are actually used by listeners in interpreting these potentially ambiguous items.

In this study, we address the question of how hearers disambiguate the interpretation of *okay*. Our goal is to identify the acoustic, prosodic and phonetic features of *okay* tokens for which listeners assign different meanings. Additionally, we want to determine the role that discourse context plays in this classification: i.e., can subjects classify *okay* tokens reliably from the word alone or do they require additional context?

Below we describe a perception study in which listeners were presented with a number of spoken productions of *okay*, taken from a corpus of dialogues between subjects playing a computer game. The tokens were presented both in isolation and in context. Users were asked to select the meaning

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 800–807,
Prague, Czech Republic, June 2007.

of each token from three of the meanings that *okay* can take on: ACKNOWLEDGEMENT/AGREEMENT, BACKCHANNEL, and CUE OF AN INITIAL DISCOURSE SEGMENT. Subsequently, we examined the acoustic, prosodic and phonetic correlates of these classifications to try to infer what cues listeners used to interpret the tokens, and how these varied by context condition. Section 2 describes our corpus. Section 3 describes the perception experiment. In Section 4 we analyze inter-subject agreement, introduce a novel representation of subject judgments, and examine the acoustic, prosodic, phonetic and contextual correlates of subject classification of *okay*s. In Section 5 we discuss our results and future work.

2 Corpus

The materials for our perception study were selected from a portion of the Columbia Games Corpus, a collection of 12 spontaneous task-oriented dyadic conversations elicited from speakers of Standard American English. The corpus was collected and annotated jointly by the Spoken Language Group at Columbia University and the Department of Linguistics at Northwestern University.

Subjects were paid to play two series of computer games (the CARDS GAMES and the OBJECTS GAMES), requiring collaboration between partners to achieve a common goal. Participants sat in front of laptops in a soundproof booth with a curtain between them, so that all communication would be verbal. Each player played with two different partners in two different sessions. On average, each session took 45m 39s, totalling 9h 8m of dialogue for the whole corpus. All interactions were recorded, digitized, and downsampled to 16K.

The recordings were orthographically transcribed and words were aligned by hand by trained annotators in a ToBI (Beckman and Hirschberg, 1994) orthographic tier using Praat (Boersma and Weenink, 2001) to manipulate waveforms. The corpus contains 2239 unique words, with 73,831 words in total. Nearly all of the Objects Games part of the corpus has been intonationally transcribed, using the ToBI conventions. Pitch, energy and duration information has been extracted for the entire corpus automatically, using Praat.

In the Objects Games portion of the corpus each player's laptop displayed a gameboard containing 5–7 objects (Figure 1). In each segment of the game, both players saw the same set of objects at the same position on each screen, except for one object (the TARGET). For one player (the DESCRIBER), this target appeared in a random location among other objects on the screen. For the other player (the FOLLOWER), the target object appeared at the bottom of the screen. The describer was instructed to describe the position of the target object on their screen so that the follower could move their representation of the target to the same location on their own screen. After the players had negotiated what they determined to be the best location, they were awarded up to 100 points based on the actual match of the target location on the two screens. The game proceeded in this way through 14 tasks, with describer and follower alternating roles. On average, the Objects Games portion of each session took 21m 36s, resulting in 4h 19m of dialogue for the twelve sessions in the corpus. There are 1484 unique words in this portion of the corpus, and 36,503 words in total.

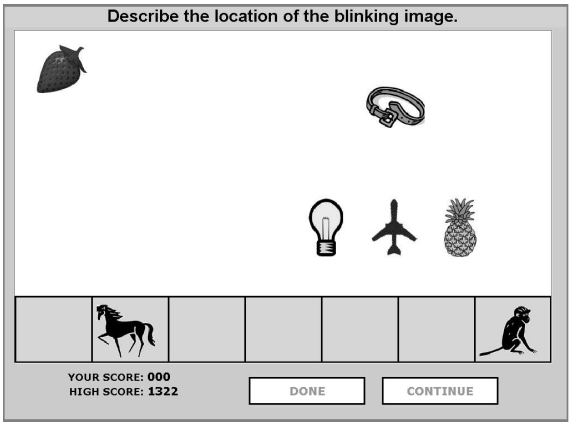

Figure 1: Sample screen of the Objects Games.

Throughout the Objects Games, we noted that subjects made frequent use of affirmative cue words, such as *okay*, *yeah*, *alright*, which appeared to vary in meaning. To investigate the discourse functions of such words, we first asked three labelers to independently classify all occurrences of *alright, gotcha, huh, mmhm, okay, right, uhhuh, yeah, yep, yes, yup* in the entire Games Corpus into one of ten categories, including acknowledgment/agreement, cue beginning or ending discourse segment, backchannel, and literal modifier. Labelers were asked to

choose the most appropriate category for each token, or indicate with '?' if they could not make a decision. They were allowed to read the transcripts and listen to the speech as they labeled.

For our perception experiment we chose materials from the tokens of the most frequent of our labeled affirmative words, *okay*, from the Objects Games, which contained most of these tokens. Altogether, there are 1151 instances of *okay* in this part of the corpus; it is the third most frequent word, following *the*, with 4565 instances, and *of*, with 1534. At least two labelers agreed on the functional category of 902 (78%) *okay* tokens. Of those tokens, 286 (32%) were classified as BACKCHANNEL, 255 (28%) as ACKNOWLEDGEMENT/AGREEMENT, 141 (16%) as CUE BEGINNING, 116 (13%) as PIVOT BEGINNING (a function that combines Acknowledgement/agreement and Cue beginning), and 104 (11%) as one of the other functions. We sampled from tokens the annotators had labeled as Cue beginning discourse segment, Backchannel, and Acknowledgement/agreement, the most frequent categories in the corpus; we will refer to these below simply as 'C', 'B', and 'A' classes, respectively.

3 Experiment

We next designed a perception experiment to examine naive subjects' perception of these tokens of *okay*. To obtain good coverage both of the (labeled) A, B, and C classes, as well as the degrees of potential ambiguity among these classes, we identified 9 categories of *okay* tokens to include in the experiment: 3 classes (A, B, C) $\times$ 3 levels of labeler agreement (UNANIMOUS, MAJORITY, NO-AGREEMENT). 'Unanimous' refers to tokens assigned to a particular class label by all 3 labelers, 'majority' to tokens assigned to this class by 2 of the 3 labelers, and 'no-agreement' to tokens assigned to this class by only 1 labeler. To decrease variability in the stimuli, we selected tokens only from speakers who produced at least one token for each of the 9 conditions. There were 6 such speakers (3 female, 3 male), which gave us a total of 54 tokens.

To see whether subjects' classifications of *okay* were dependent upon contextual information or not, we prepared two versions of each token. The isolated versions consisted of only the word *okay* extracted from the waveform. For the contextualized versions, we extracted two full speaker turns for each *okay* including the full turn[1] containing the target *okay* plus the full turn of the previous speaker. In the following three sample contexts, pauses are indicated with '#', and the target *okay*s are underlined:

Speaker A: yeah # um there's like there's some space there's
Speaker B: okay # I think I got it

Speaker A: but it's gonna be below the onion
Speaker B: okay

Speaker A: okay # alright # I'll try it # okay
Speaker B: okay the owl is blinking

The isolated *okay* tokens were single channel audio files; the contextualized *okay* tokens were formatted so that each speaker was presented to subjects on a different channel, with the speaker uttering the target *okay* consistently on the same channel.

The perception study was divided into two parts. In the first part, each subject was presented with the 54 isolated *okay* tokens, in a different random ordering for each subject. They were given a forced choice task to classify them as A, B, or C, with the corresponding labels (Acknowledgement/agreement, Backchannel, and Cue beginning) also presented in a random order for each token. In the second part, the same subject was given 54 contextualized tokens, presented in a different random order, and asked to make the same choice.

We recruited 20 (paid) subjects for the study, 10 female, and 10 male, all between the ages of 20 and 60. All subjects were native speakers of Standard American English, except for one subject who was born in Jamaica but a native speaker of English. All subjects reported no hearing problems. Subjects performed the study in a quiet lab using headphones to listen to the tokens and indicating their classification decisions in a GUI interface on a lab workstation. They were given instructions on how to use the interface before each of the two sections of the study.

For the study itself, for each token in the **isolated** condition, subjects were shown a screen with the three randomly ordered classes and a link to the token's sound file. They could listen to the sound files as many times as they wished but were instructed not to be concerned with answering the questions

[1] We define a TURN as a maximal sequence of words spoken by the same speaker during which the speaker holds the floor.

"correctly", but to answer with their immediate response if possible. However, they were allowed to change their selection as many times as they liked before moving to the next screen. In the **contextualized** condition, they were also shown an orthographic transcription of part of the contextualized token, to help them identify the target *okay*. The mean duration of the first part of the study was 25 minutes, and of the second part, 27 minutes.

4 Results

4.1 Subject ratings

The distribution of class labels in each experimental condition is shown in Table 1. While this distribution roughly mirrors our selection of equal numbers of tokens from each previously-labeled class, in both parts of the study more tokens were labeled as A (*acknowledgment/agreement*) than as B (*backchannel*) or C (*cue to topic beginning*). This supports the hypothesis that *acknowledgment/agreement* may function as the default interpretation of *okay*.

	Isolated	**Contextualized**
A	426 (39%)	452 (42%)
B	324 (30%)	306 (28%)
C	330 (31%)	322 (30%)
Total	1080 (100%)	1080 (100%)

Table 1: Distribution of label classes in each study condition.

We examined inter-subject agreement using Fleiss' κ measure of inter-rater agreement for multiple raters (Fleiss, 1971).[2] Table 2 shows Fleiss' κ calculated for each individual label vs. the other two labels and for all three labels, in both study conditions. From this table we see that, while there is very little overall agreement among subjects about how to classify tokens in the **isolated** condition, agreement is higher in the **contextualized** condition, with a moderate agreement for class C (κ score of .497). This suggests that context helps distinguish the *cue beginning discourse segment* function more than the other two functions of *okay*.

[2] This measure of agreement above chance is interpreted as follows: 0 = None, 0 - 0.2 = Small, 0.2 - 0.4 = Fair, 0.4 - 0.6 = Moderate, 0.6 - 0.8 = Substantial, 0.8 - 1 = Almost perfect.

	Isolated	**Contextualized**
A vs. rest	.089	.227
B vs. rest	.118	.164
C vs. rest	.157	.497
all	.120	.293

Table 2: Fleiss' κ for each label class in each study condition.

Recall from Section 3 that the *okay* tokens were chosen in equal numbers from three classes according to the level of agreement of our three original labelers (unanimous, majority, and no-agreement), who had the full dialogue context to use in making their decisions. Table 3 shows Fleiss' κ measure now grouped by amount of agreement of the original labelers, again presented for each context condition. We see here that the inter-subject agreement

	Isolated	**Context.**	**OL**
no-agreement	.085	.104	-
majority	.092	.299	-
unanimous	.158	.452	-
all	.120	.293	.312

Table 3: Fleiss' κ in each study condition, grouped by agreement of the three original labelers ('OL').

also mirrors the agreement of the three original labelers. In both study conditions, tokens which the original labelers agreed on also had the highest κ scores, followed by tokens in the majority and no-agreement classes, in that order. In all cases, tokens which subjects heard in context showed more agreement than those they heard in isolation.

The overall κ is small at .120 for the **isolated** condition, and fair at .293 for the **contextualized** condition. The three original labelers also achieved fair agreement at .312.[3] The similarity between the latter two κ scores suggests that the full context available to the original labelers and the limited context presented to the experiment subjets offer comparable amounts of information to disambiguate between the three functions, although lack of any context clearly affected subjects' decisions. We conclude

[3] For the calculation of this κ, we considered four label classes: A, B, C, and a fourth class 'other' that comprises the remaining 7 word functions mentioned in Section 2. In consequence, these κ scores should be compared with caution.

from these results that context is of considerable importance in the interpretation of the word *okay*, although even a very limited context appears to suffice.

4.2 Representing subject judgments

In this section, we present a graphical representation of subject decisions, useful for interpreting, visualizing, and comparing the way our subjects interpreted the different tokens of *okay*. For each individual *okay* in the study, we define an associated three-dimensional VOTE VECTOR, whose components are the proportions of subjects that classified the token as A, B or C. For example, if a particular *okay* was labeled as A by 5 subjects, as B by 3, and as C by 12, then its associated vote vector is $\left(\frac{5}{20}, \frac{3}{20}, \frac{12}{20}\right) = (0.25, 0.15, 0.6)$. Following this definition, the vectors $\mathcal{A} = (1, 0, 0)$, $\mathcal{B} = (0, 1, 0)$ and $\mathcal{C} = (0, 0, 1)$ correspond to the ideal situations in which all 20 subjects agreed on the label. We call these vectors the UNANIMOUS-VOTE VECTORS.

Figure 2.i shows a two-dimensional representation that illustrates these definitions. The black dot

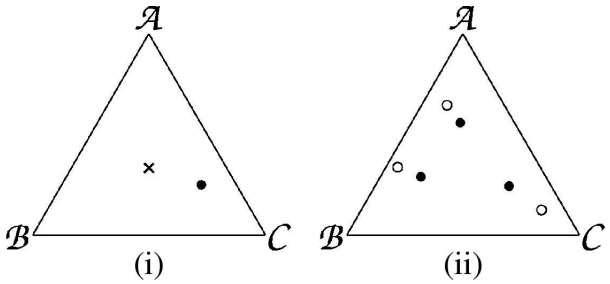

Figure 2: 2D representation of a vote vector (i) and of the cluster centroids (ii).

represents the vote vector for our example *okay*, the vertices of the triangle correspond to the three unanimous-vote vectors ($\mathcal{A}$, $\mathcal{B}$ and $\mathcal{C}$), and the cross in the center of the triangle represents the vote vector of a three-way tie between the labelers $\left(\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right)$.

We are thus able to calculate the Euclidean distance of a vote vector to each of the unanimous-vote vectors. The shortest of these distances corresponds to the label assigned by the plurality[4] of subjects. Also, the smaller that distance, the higher the inter-subject agreement for that particular token. For our example *okay*, the distances to $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{C}$ are 0.972, 1.070 and 0.495, respectively; its plurality label is C.

In our experiment, each *okay* has two associated vote vectors, one for each context condition. To illustrate the relationship between decisions in the **isolated** and the **contextualized** conditions, we first grouped each condition's 54 vote vectors into three clusters, according to their plurality label. Figure 2.ii shows the cluster centroids in a two-dimensional representation of vote vectors. The filled dots correspond to the cluster centroids of the **isolated** condition, and the empty dots, to the centroids of the **contextualized** condition. Table 4 shows the distances in each condition from the cluster centroids (denoted A_c, B_c, C_c) to the respective unanimous-vote vectors ($\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$), and also the distance between each pair of cluster centroids.

	Isolated	**Contextualized**
$d(A_c, \mathcal{A})$	.54	.44 (–18%)
$d(B_c, \mathcal{B})$	.57	.52 (–10%)
$d(C_c, \mathcal{C})$	.52	.28 (–47%)
$d(A_c, B_c)$	.41	.48 (+17%)
$d(A_c, C_c)$	.49	.86 (+75%)
$d(B_c, C_c)$	.54	.91 (+69%)

Table 4: Distances from the cluster centroids (A_c, B_c, C_c) to the unanimous-vote vectors ($\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$) and between cluster centroids, in each condition.

In the **isolated** condition, the three cluster centroids are approximately equidistant from each other —that is, the three word functions appear to be equally confusable. In the **contextualized** condition, while C_c is further apart from the other two centroids, the distance between A_c and B_c remains practically the same. This suggests that, with some context available, A and B tokens are still fairly confusable, while both are more easily distinguished from C tokens. We posit two possible explanations for this: First, C is the only function for which the speaker uttering the *okay* necessarily continues speaking; thus the role of context in disambiguating seems quite clear. Second, both A and B have a common element of 'acknowledgement' that might affect inter-subject agreement.

[4] *Plurality* is also known as *simple majority*: the candidate who gets more votes than any other candidate is the winner.

4.3 Features of the *okay* tokens

In this section, we describe a set of acoustic, prosodic, phonetic and contextual features which may help to explain why subjects interpret *okay* differently. Acoustic features were extracted automatically using Praat. Phonetic and prosodic features were hand-labeled by expert annotators. Contextual features were considered only in the analysis of the **contextualized** condition, since they were not available to subjects in the **isolated** condition.

We examined a number of phonetic features to determine whether these correlated with subject classifications. We first looked at the production of the three phonemes in the target *okay* (/oʊ/, /k/, /eɪ/), noting the following possible variations:

- /oʊ/: [], [ɑ], [ɐ], [ɔ], [ɔʊ], [m], [ŋ], [ə], [əʊ].
- /k/: [ɣ], [k], [kx], [q], [x].
- /eɪ/: [e], [eɪ], [ɛ], [eə].

We also calculated the duration of each phone and of the velar closure. Whether the target *okay* was at least partially whispered or not, and whether there was glottalization in the target *okay* were also noted.

For each target *okay*, we also examined its duration and its maximum, mean and minimum pitch and intensity, as well as the speaker-normalized versions of these values.[5] We considered its pitch slope, intensity slope, and stylized pitch slope, calculated over the whole target *okay*, its last 50, 80 and 100 milliseconds, its second half, its second syllable, and the second half of its second syllable, as well.

We used the ToBI labeling scheme (Pitrelli et al., 1994) to label the prosody of the target *okay*s and their surrounding context.

- Pitch accent, if any, of the target *okay* (e.g., H*, H+!H*, L*).
- Break index after the target *okay* (0-4).
- Phrase accent and boundary tone, if any, following the target *okay* (e.g., L-L%, !H-H%).

For contextualized tokens, we included several features related to the exchange between the speaker uttering the target *okay* (*Speaker B*) and the other speaker (*Speaker A*).

- Number of words uttered by *Speaker A* in the context, before and after the target *okay*. Same for *Speaker B*.
- Latency of *Speaker A* before *Speaker B*'s turn.
- Duration of silence of *Speaker B* before and after the target *okay*.
- Duration of speech by *Speaker B* immediately before and after the target *okay* and up to a silence.

4.4 Cues to interpretation

We conducted a series of Pearson's tests to look for correlations between the proportion of subjects that chose each label and the numeric features described in Section 4.3, together with two-sided t-tests to find whether such correlations differed significantly from zero. Tables 5 and 6 show the significant results (two-sided t-tests, $p < 0.05$) for the **isolated** and **contextualized** conditions, respectively.

Acknowledgement/agreement	r
duration of realization of /k/	–0.299
Backchannel	r
stylized pitch slope over 2nd half 2nd syl.	0.752
pitch slope over 2nd half of 2nd syllable	0.409
speaker-normalized maximum intensity	–0.372
pitch slope over last 80 ms	0.349
speaker-normalized mean intensity	–0.327
duration of realization of /eɪ/	0.278
word duration	0.277
Cue to discourse segment beginning	r
stylized pitch slope over the whole word	–0.380
pitch slope over the whole word	–0.342
pitch slope over 2nd half of 2nd syllable	–0.319

Table 5: Features correlated to the proportion of votes for each label. **Isolated** condition.

Table 5 shows that in the **isolated** condition, subjects tended to classify tokens of *okay* as Acknowledgment/agreement (A) which had a longer realization of the /k/ phoneme. They tended to classify tokens as Backchannels (B) which had a lower intensity, a longer duration, a longer realization of the /eɪ/ phoneme, and a final rising pitch. They tended to classify tokens as C (cue to topic beginning) that ended with falling pitch.

[5] Speaker-normalized features were normalized by computing z-scores ($z = (X - mean)/st.dev$) for the feature, where $mean$ and $st.dev$ were calculated from all *okay*s uttered by the speaker in the session.

Acknowledgement/agreement	r
latency of *Spkr A* before *Spkr B*'s turn	–0.528
duration of silence by *Spkr B* before *okay*	–0.404
number of words by *Spkr B* after *okay*	–0.277
Backchannel	r
pitch slope over 2nd half of 2nd syllable	0.520
pitch slope over last 80 ms	0.455
number of words by *Spkr A* before *okay*	0.451
number of words by *Spkr B* after *okay*	–0.433
duration of speech by *Spkr B* after *okay*	–0.413
latency of *Spkr A* before *Spkr B*'s turn	–0.385
duration of silence by *Spkr B* before *okay*	0.295
intensity slope over 2nd syllable	–0.279
Cue to discourse segment beginning	r
latency of *Spkr A* before *Spkr B*'s turn	0.645
number of words by *Spkr B* after *okay*	0.481
number of words by *Spkr A* before *okay*	–0.426
pitch slope over 2nd half of 2nd syllable	–0.385
pitch slope over last 80 ms	–0.377
duration of speech by *Spkr B* after *okay*	0.338

Table 6: Features correlated to the proportion of votes for each label. **Contextualized** condition.

In the **contextualized** condition, we find very different correlations. Table 6 shows that nearly all of the strong correlations in this condition involve contextual features, such as the latency before *Speaker B*'s turn, or the number of words by each speaker before and after the target *okay*. Notably, only one of the features that show strong correlations in the **isolated** condition shows the same strong correlation in the **contextualized** condition: the pitch slope at the end of the word. In both conditions subjects tended to label tokens with a final rising pitch contour as B, and tokens with a final falling pitch contour as C. This supports (Hockey, 1993)'s findings on the role of pitch contour in disambiguating *okay*.

We next conducted a series of two-sided Fisher's exact tests to find correlations between subjects' labelings of *okay* and the nominal features described in Section 4.3. We found significant associations between the realization of the /oʊ/ phoneme and the *okay* function in the **isolated** condition ($p < 0.005$). Table 7 shows that, in particular, [m] seems to be the preferred realization for B *okay*s, while [ə] seems to be the preferred one for A *okay*s, and [ɔʊ] and [ɔ] for A and C *okay*s.

	?	[ɑ]	[ɐ]	[ɔʊ]	[ɔ]	[ŋ]	[əʊ]	[ə]	[]	[m]
A	0	0	5	6	4	0	0	8	0	0
B	2	0	4	1	0	1	0	1	1	5
C	1	1	2	3	4	0	1	3	0	0

Table 7: Realization of the /oʊ/ phoneme, grouped by subject plurality label. **Isolated** condition only.

Notably, we did not find such significant associations in the **contextualized** condition. We did find significant correlations in both conditions, however, between *okay* classifications and the type of phrase accent and boundary tone following the target (Fisher's Exact Test, $p < 0.05$ for the **isolated** condition, $p < 0.005$ for the **contextualized** condition). Table 8 shows that L-L% tends to be associated with A and C classes, H-H% with B classes, and L-H% with A and B classes. In this case, such correlations are present in the **isolated** condition, and sustained or enhanced in the **contextualized** condition.

		H-H%	H-L%	L-H%	L-L%	other
Isolated	A	0	2	4	8	9
	B	3	3	1	5	3
	C	1	1	0	8	5
Context.	A	0	2	3	10	10
	B	4	3	2	1	2
	C	0	1	0	10	5

Table 8: Phrase accent and boundary tone, grouped by subject plurality label.

Summing up, when subjects listened to the *okay* tokens in isolation, with only their acoustic, prosodic and phonetic properties available, a few features seem to strongly correlate with the perception of word function; for example, maximum intensity, word duration, and realizing the /oʊ/ phoneme as [m] tend to be associated with *backchannel*, while the duration of the realization of the /k/ phoneme, and realizing the /oʊ/ phoneme as [ə] tend to be associated with *acknowledgment/agreement*.

In the second part of the study, when subjects listened to contextualized versions of the same tokens of *okay*, most of the strong correlations of word function with acoustic, prosodic and phonetic features were replaced by correlations with contextual features, like latency and turn duration. In other words, these results suggest that contextual features

might override the effect of most acoustic, prosodic and phonetic features of *okay*. There is nonetheless one notable exception: word final intonation — captured by the pitch slope and the ToBI labels for phrase accent and boundary tone — seems to play a central role in the interpretation of both isolated and contextualized *okay*s.

5 Conclusion and future work

In this study, we have presented evidence of differences in the interpretation of the function of isolated and contextualized *okay*s. We have shown that word final intonation strongly correlates with the subjects' classification of *okay*s in both conditions. Additionally, the higher degree of inter-subject agreement in the contextualized condition, along with the strong correlations found for contextualized features, suggests that context, when available, plays a central role in the disambiguation of *okay*. (Note, however, that further research is needed in order to assess whether these features are indeed, in fact, perceptually important, both individually and combined.)

We have also presented results suggesting that *acknowledgment/agreement* acts as a default function for both isolated an contextualized *okay*s. Furthermore, while that function remains confusable with *backchannel* in both conditions, the availability of some context helps in distinguishing those two functions from *cue to topic beginning*.

These results are relevant to spoken dialogue systems in suggesting how systems can convey the cue word *okay* with the intended meaning and can interpret users' productions of *okay* correctly. How these results extend to other cue words and to other word functions remains an open question.

As future work, we will extend this study to include the over 5800 occurrences of *alright, gotcha, huh, mmhm, okay, right, uhhuh, yeah, yep, yes, yup* in the entire Games Corpus, and all 10 discourse functions mentioned in Section 2, as annotated by our three original labelers. Since we have observed considerable differences in conversation style in the two parts of the corpus (the Objects Games elicited more 'dynamic' conversations, with more overlaps and interruptions than the Cards Games), we will compare cue phrase usage in these two settings. Finally, we are also interested in examining speaker entrainment in cue phrase usage, or how subjects adapt their choice and production of cue phrases to their conversation partner's.

Acknowledgments

This work was funded in part by NSF IIS-0307905. We thank Gregory Ward, Elisa Sneed, and Michael Mulley for their valuable help in collecting and labeling the data, and the anonymous reviewers for helpful comments and suggestions.

Predicting Success in Dialogue

Abstract

Task-solving in dialogue depends on the linguistic alignment of the interlocutors, which Pickering & Garrod (2004) have suggested to be based on mechanistic repetition effects. In this paper, we seek confirmation of this hypothesis by looking at repetition in corpora, and whether repetition is correlated with task success. We show that the relevant repetition tendency is based on slow adaptation rather than short-term priming and demonstrate that lexical and syntactic repetition is a reliable predictor of task success given the first five minutes of a task-oriented dialogue.

1 Introduction

While humans are remarkably efficient, flexible and reliable communicators, we are far from perfect. Our dialogues differ in how successfully information is conveyed. In task-oriented dialogue, where the interlocutors are communicating to solve a problem, task success is a crucial indicator of the success of the communication.

An automatic measure of task success would be useful for evaluating conversations among humans, e.g., for evaluating agents in a call center. In human-computer dialogues, predicting the task success after just a first few turns of the conversation could avoid disappointment: if the conversation isn't going well, a caller may be passed on to a human operator, or the system may switch dialogue strategies. As a first step, we focus on human-human dialogue, since current spoken dialogue systems do not yet yield long, syntactically complex conversations.

In this paper, we use syntactic and lexical features to predict task success in an environment where we assume no speaker model, no semantic information and no information typical for a human-computer dialogue system, e.g., ASR confidence. The features we use are based on a psychological theory, linking alignment between dialogue participants to low-level syntactic priming. An examination of this priming reveals differences between short-term and long-term effects.

1.1 Repetition supports dialogue

In their *Interactive Alignment Model* (IAM), Pickering and Garrod (2004) suggest that dialogue between humans is greatly aided by *aligning* representations on several linguistic and conceptual levels. This effect is assumed to be driven by a cascade of linguistic priming effects, where interlocutors tend to re-use lexical, syntactic and other linguistic structures after their introduction. Such reuse leads speakers to agree on a common situation model. Several studies have shown that speakers copy their interlocutor's syntax (Branigan et al., 1999). This effect is usually referred to as *structural* (or: *syntactic*) *priming*. These persistence effects are inter-related, as lexical repetition implies preferences for syntactic choices, and syntactic choices lead to preferred semantic interpretations. Without demanding additional cognitive resources, the effects form a causal chain that will benefit the interlocutor's purposes. Or, at the very least, it will be easier for them to repeat linguistic choices than to

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 808–815,
Prague, Czech Republic, June 2007.

actively discuss their terminology and keep track of each other's current knowledge of the situation in order to come to a mutual understanding.

1.2 Structural priming

The repetition effect at the center of this paper, priming, is defined as a tendency to repeat linguistic decisions. Priming has been shown to affect language production and, to a lesser extent, comprehension, at different levels of linguistic analysis. This tendency may show up in various ways, for instance in the case of lexical priming as a shorter response time in lexical decision making tasks, or as a preference for one syntactic construction over an alternative one in syntactic priming (Bock, 1986). In an experimental study (Branigan et al., 1999), subjects were primed by completing either sentence (1a) or (1b):

1a. *The racing driver showed the torn overall...*
1b. *The racing driver showed the helpful mechanic...*

Sentence (1a) was to be completed with a prepositional object ("to the helpful mechanic"), while (1b) required a double object construction ("the torn overall"). Subsequently, subjects were allowed to freely complete a sentence such as the following one, describing a picture they were shown:

2. *The patient showed ...*

Subjects were more likely to complete (2) with a double-object construction when primed with (1b), and with a prepositional object construction when primed with (1a).

In a previous corpus-study, using transcriptions of spontaneous, task-oriented and non-task-oriented dialogue, utterances were annotated with syntactic trees, which we then used to determine the phrase-structure rules that licensed production (and comprehension) of the utterances (Reitter et al., 2006b). For each rule, the time of its occurrence was noted, e.g. we noted

3. 117.9*s NP* $\rightarrow$ *AT AP NN a fenced meadow*
4. 125.5*s NP* $\rightarrow$ *AT AP NN the abandoned cottage*

In this study, we then found that the re-occurrence of a rule (as in 4) was correlated with the temporal distance to the first occurrence (3), e.g., 7.6 seconds. The shorter the distance between prime (3) and target (4), the more likely were rules to re-occur.

In a conversation, priming may lead a speaker to choose a verb over a synonym because their interlocutor has used it a few seconds before. This, in turn, will increase the likelihood of the structural form of the arguments in the governed verbal phrase–simply because lexical items have their preferences for particular syntactic structures, but also because structural priming may be stronger if lexical items are repeated (lexical boost, Pickering and Branigan (1998)). Additionally, the structural priming effects introduced above will make a previously observed or produced syntactic structure more likely to be re-used. This chain reaction leads interlocutors in dialogue to reach a common situation model. Note that the IAM, in which interlocutors automatically and cheaply build a common representation of common knowledge, is at odds with views that afford each dialogue participant an explicit and separate representation of their interlocutor's knowledge.

The connection between linguistic persistence or priming effects and the success of dialogue is crucial for the IAM. The predictions arising from this, however, have eluded testing so far. In our previous study (Reitter et al., 2006b), we found more syntactic priming in the task-oriented dialogues of the Map Task corpus than in the spontaneous conversation collected in the Switchboard corpus. However, we compared priming effects across two datasets, where participants and conversation topics differed greatly. Switchboard contains spontaneous conversation over the telephone, while the task-oriented Map Task corpus was recorded with interlocutors co-present. While the result (more priming in task-oriented dialogue) supported the predictions of IAM, cognitive load effects could not be distinguished from priming. In the current study, we examine structural repetition in task-oriented dialogue only and focus on an extrinsic measure, namely task success.

2 Related Work

Prior work on predicting task success has been done in the context of human-computer spoken dialogue systems. Features such as recognition error rates, natural language understanding confidence and context shifts, confirmations and re-prompts (dialogue management) have been used classify dia-

logues into *successful* and *problematic* ones (Walker et al., 2000). With these automatically obtainable features, an accuracy of 79% can be achieved given the first two turns of "How may I help you?" dialogues, where callers are supposed to be routed given a short statement from them about what they would like to do. From the whole interaction (very rarely more than five turns), 87% accuracy can be achieved (36% of dialogues had been hand-labeled "problematic"). However, the most predictive features, which related to automatic speech recognition errors, are neither available in the human-human dialogue we are concerned with, nor are they likely to be the cause of communication problems there.

Moreover, failures in the Map Task dialogues are due to the actual goings-on when two interlocutors engage in collaborative problem-solving to jointly reach an understanding. In such dialogues, interlocutors work over a period of about half an hour. To predict their degree of success, we will leverage the phenomenon of *persistence*, or *priming*.

In previous work, two paradigms have seen extensive use to measure repetition and priming effects. *Experimental studies* expose subjects to a particular syntactic construction, either by having them produce the construction by completing a sample sentence, or by having an experimenter or confederate interlocutor use the construction. Then, subjects are asked to describe a picture or continue with a given task, eliciting the target construction or a competing, semantically equivalent alternative. The analysis then shows an effect of the controlled condition on the subject's use of the target construction.

Observational studies use naturalistic data, such as text and dialogue found in corpora. Here, the prime construction is not controlled–but again, a correlation between primes and targets is sought. Specific competing constructions such as active/passive, verbal particle placement or *that*-deletion in English are often the object of study (Szmrecsanyi, 2005; Gries, 2005; Dubey et al., 2005; Jäger, 2006), but the effect can also be generalized to syntactic phrase-structure rules or combinatorial categories (Reitter et al., 2006a).

Church (2000) proposes adaptive language models to account for lexical adaptation. Each document is split into *prime* and *target* halves. Then, for selected words w, the model estimates

$$P(+adapt) = P(w \in target | w \in prime)$$

$P(+adapt)$ is higher than $P_{prior} = P(w \in target)$, which is not surprising, since texts are usually about a limited number of topics.

This method looks at repetition over whole document halves, independently of decay. In this paper, we apply the same technique to syntactic rules, where we expect to estimate syntactic priming effects of the long-term variety.

3 Repetition-based Success Prediction

3.1 The Success Prediction Task

In the following, we define two variants of the task and then describe a model that uses repetition effects to predict success.

Task 1: *Success is estimated* when an entire dialogue is given. All linguistic and non-linguistic information available may be used. This task reflects post-hoc analysis applications, where dialogues need to be evaluated without the actual success measure being available for each dialogue. This covers cases where, e.g., it is unclear whether a call center agent or an automated system actually responded to the call satisfactorily.

Task 2: *Success is predicted* when just the initial 5-minute portion of the dialogue is available. A dialogue system's or a call center agent's strategy may be influenced depending on such a prediction.

3.2 Method

To address the tasks described in the previous Section, we train support vector machines (SVM) to predict the task success score of a dialogue from lexical and syntactic repetition information accumulated up to a specified point in time in the dialogue.

Data

The HCRC Map Task corpus (Anderson et al., 1991) contains 128 dialogues between subjects, who were given two slightly different maps depicting the same (imaginary) landscape. One subject gives directions for a predefined route to another subject, who follows them and draws a route on their map.

The spoken interactions were recorded, transcribed and syntactically annotated with phrase-structure grammar.

The Map Task provides us with a precise measure of success, namely the deviation of the predefined and followed route. Success can be quantified by computing the inverse deviation between subjects' paths. Both subjects in each trial were asked to draw "their" respective route on the map that they were given. The deviation between the respective paths drawn by interlocutors was then determined as the area covered in between the paths (PATHDEV).

Features

Repetition is measured on a lexical and a syntactic level. To do so, we identify all constituents in the utterances as per phrase-structure analysis. *[Go [to [the [[white house] [on [the right]]]]]]* would yield 11 constituents. Each constituent is licensed by a syntactic rule, for instance *VP* $\rightarrow$ *V PP* for the topmost constituent in the above example.

For each constituent, we check whether it is a lexical or syntactic repetition, i.e. if the same words occurred before, or if the licensing rule has occurred before in the same dialogue. If so, we increment counters for lexical and/or syntactic repetitions, and increase a further counter for string repetition by the length of the phrase (in characters). The latter variable accounts for the repetition of long phrases.

We include a data point for each 10-second interval of the dialogue, with features reporting the lexical (LEXREP), syntactic (SYNREP) and character-based (CHARREP) repetitions up to that point in time. A time stamp and the total numbers of constituents and characters are also included (LENGTH). This way, the model may work with repetition proportions rather than the absolute counts.

We train a support vector machine for regression with a radial basis function kernel ($\gamma = 5$), using the features as described above and the PATHDEV score as output.

3.3 Evaluation

We cast the task as a regression problem. To predict a dialogue's score, we apply the SVM to its data points. The mean outcome is the estimated score.

A suitable evaluation measure, the classical r^2, indicates the proportion of the variance in the actual task success score that can be predicted by the model. All results reported here are produced from 10-fold cross-validated 90% training / 10% test splits of the dialogues. No full dialogue was included in both test and training sets.

	Task 1	Task 2
ALL Features	**0.17**	**0.14**
ALL w/o SYNREP	0.15	0.06
ALL w/o LEX/CHARREP	0.09	0.07
LENGTH ONLY	0.09	n/a
Baseline	0.01	0.01

Table 1: Portion of variance explained (r^2)

Task 1 was evaluated with all data, the Task 2 model was trained and tested on data points sampled from the first 5 minutes of the dialogue.

For Task 1 (full dialogues), the results (Table 1) indicate that ALL repetition features together with the LENGTH of the conversation, account for about 17% of the total score variance. The repetition features improve on the performance achieved from dialogue length alone (about 9%).

For the more difficult Task 2, ALL features together achieve 14% of the variance. (Note that LENGTH is not available.) When the syntactic repetition feature is taken out and only lexical (LEXREP) and character repetition (CHARREP) are used, we achieve 6% in explained variance.

The baseline is implemented as a model that always estimates the mean score. It should, theoretically, be close to 0.

3.4 Discussion

Obviously, linguistic information alone will not explain the majority of the task-solving abilities. Apart from subject-related factors, communicative strategies will play a role.

However, linguistic repetition serves as a good predictor of how well interlocutors will complete their joint task. The features used are relatively simple: provided there is some syntactic annotation, rule repetition can easily be detected. Even without syntactic information, lexical repetition already goes a long way.

But what kind of repetition is it that plays a role in task-oriented dialogue? Leaving out features is not an ideal method to quantify their influence–in particular, where features inter-correlate. The contribution of syntactic repetition is still unclear from the

present results: it acts as a useful predictor only over the course of the whole dialogues, but not within a 5-minute time span, where the SVM cannot incorporate its informational content.

We will therefore turn to a more detailed analysis of structural repetition, which should help us draw conclusions relating to the psycholinguistics of dialogue.

4 Long term and short term priming

In the following, we will examine syntactic (structural) priming as one of the driving forces behind alignment. We choose syntactic over lexical priming for two reasons. Lexical repetition due to priming is difficult to distinguish from repetition that is due to interlocutors attending to a particular topic of conversation, which, in coherent dialogue, means that topics are clustered. Lexical choice reflects those topics, hence we expect clusters of particular terminology. Secondly: the maps used to collect the dialogues in the Map Task corpus contained landmarks with labels. It is only natural (even if by means to cross-modal priming) that speakers will identify landmarks using the labels and show little variability in lexical choice. We will measure repetition of syntactic rules, whereby word-by-word repetition (topicality effects, parroting) is explicitly excluded.

For syntactic priming[1], two repetition effects have been identified. Classical priming effects are strong: around 10% for syntactic rules (Reitter et al., 2006b). However, they decay quickly (Branigan et al., 1999) and reach a low plateau after a few seconds, which likens to the effect to semantic (similarity) priming. What complicates matters is that there is also a different, long-term adaptation effect that is also commonly called (repetition) priming.

Adaptation has been shown to last longer, from minutes (Bock and Griffin, 2000) to several days. Lexical boost interactions, where the lexical repetition of material within the repeated structure strengthens structural priming, have been observed for short-term priming, but not for long-term priming trials where material intervened between prime and target utterances (Konopka and Bock, 2005). Thus, short- and long-term adaptation effects may well be due to separate cognitive processes, as recently argued by (Ferreira and Bock, 2006). Section 5 deals with decay-based short-term priming, Section 6 with long-term adaptation.

Pickering and Garrod (2004) do not make the type of priming supporting alignment explicit. Should we find differences in the way task success interacts with different kinds of repetition effects, then this would be a good indication about what effect supports IAM. More concretely, we could say whether alignment is due to the automatic, classical *priming* effect, or whether it is based on a long-term effect that is possibly closer to implicit learning (Chang et al., 2006).

5 Short-term priming

In this section, we attempt to detect differences in the strength of short-term priming in successful and less successful dialogues. To do so, we use the measure of priming strength established by Reitter et al. (2006b), which then allows us to test whether priming interacts with task success. Under the assumptions of IAM we would expect successful dialogues to show more priming than unsuccessful ones.

Obviously, difficulties with the task at hand may be due to a range of problems that the subjects may have, linguistic and otherwise. But given that the dialogues contain variable levels of syntactic priming, one would expect that this has at least some influence on the outcome of the task.

5.1 Method: Logistic Regression

We used mixed-effects regression models that predict a binary outcome (repetition) using a number of discrete and continuous factors.[2]

As a first step, our modeling effort tries to establish a priming effect. To do so, we can make use of the fact that the priming effect decays over time. How strong that decay is gives us an indication of how much repetition probability we see shortly after the stimulus (prime) compared to the probability of chance repetition–without ever explicitly calculating such a prior.

Thus we define the strength of priming as the decay rate of repetition probability, from shortly after

[1] in production and comprehension, which we will not distinguish further for space reasons. Our data are (off-line) production data.

[2] We use Generalized Linear Mixed Effects models fitted using GlmmPQL in the MASS R library.

the prime to 15 seconds afterward (predictor: DIST). Thus, we take several samples at varying distances (d), looking at cases of structural repetition, and cases where structure has not been repeated.

In the syntactic context, syntactic rules such as VP $\rightarrow$ VP PP reflect syntactic decisions. Priming of a syntactic construction shows up in the tendency to repeat such rules in different lexical contexts. Thus, we examine whether syntactic rules have been repeated at a distance d. For each syntactic rule that occurs at time t_1, we check a one-second time period $[t_1 - d - 0.5, t_1 - d + 0.5]$ for an occurrence of the same rule, which would constitute a prime. Thus, the model will be able to implicitly estimate the probability of repetition.

Generalized Linear Regression Models (GLMs) can then model the decay by estimating the relationship between d and the probability of rule repetition. The model is designed to predict whether repetition will occur, or, more precisely, whether there is a prime for a given target (priming). Under a no-priming null-hypothesis, we would assume that the priming probability is independent of d. If there is priming, however, increasing d will negatively influence the priming probability (decay). So, we expect a model parameter (DIST) for d that is reliably negative, and lower, if there is more priming.

With this method, we draw multiple samples from the same utterance–for different d, but also for different syntactic rules occurring in those utterances. Because these samples are inter-dependent, we use a grouping variable indicating the source utterance. Because the dataset is sparse with respect to PRIME, balanced sampling is needed to ensure an equal number of data points of priming and non-priming cases (PRIME) is included.

This method has been previously used to confirm priming effects for the general case of syntactic rules by Reitter et al. (2006b). Additionally, the GLM can take into account categorical and continuous covariates that may interact with the priming effect. In the present experiment, we use an interaction term to model the effect of task success.[3] The crucial interaction, in our case, is task success: PATHDEV is the deviation of the paths that the interlocutors drew, normalized to the range [0,1]. The core model is thus PRIME $\sim log(\text{DIST}) * \text{PATHDEV}$.

If IAM is correct, we would expect that the deviation of paths, which indicates negative task success, will negatively correlate with the priming effect.

5.2 Results

Short-term priming reliably correlated (negatively) with the distance, hence we see a decay and priming effect (DIST, $b = -0.151, p < 0.0001$, as shown in previous work).

Notably, path deviation and short-term priming did not correlate. The model showed was no such interaction (DIST:PATHDEV, $p = 0.91$).

We also tested for an interaction with an additional factor indicating whether prime and target were uttered by the same or a different speaker (comprehension-production vs. production-production priming). No such interaction approached reliability (log(DIST):PATHDEV:ROLE, $p = 0.60$).

We also tested whether priming changes over time over the course of each dialogue. It does not. There were no reliable interaction effects of centered prime/target times (log(DIST):log(STARTTIME), $p = 0.75$, log(DIST):PATHDEV:log(STARTTIME), $p = 0.63$). Reducing the model by removing unreliable interactions did not yield any reliable effects.

5.3 Discussion

We have shown that while there is a clear priming effect in the short term, the size of this priming effect does not correlate with task success. There is no reliable interaction with success.

Does this indicate that there is no strong functional component to priming in the dialogue context? There may still be an influence of cognitive load due to speakers working on the task, or an overall disposition for higher priming in task-oriented dialogue: Reitter et al. (2006b) point at stronger priming in such situations. But our results here are difficult to reconcile with the model suggested by Pickering and Garrod (2004), if we take short-term priming as the driving force behind IAM.

Short-term priming decays within a few seconds. Thus, to what extent could syntactic priming help interlocutors align their situation models? In the Map

[3] We use the $A * B$ operator in the model formulas to indicate the inclusion of main effects of the features A and B and their interactions $A : B$.

Task experiments, interlocutors need to refer to landmarks regularly–but not every few seconds. It would be sensible to expect longer-term adaptation (within minutes) to drive dialogue success.

6 Long-term adapation

Long-term adaptation is a form of priming that occurs over minutes and could, therefore, support linguistic and situation model alignment in task-oriented dialogue. IAM and the success of the SVM based method could be based on such an effect instead of short-term priming. Analogous to the the previous experiment, we hypothesize that more adaptation relates to more task success.

6.1 Method

After the initial few seconds, structural repetition shows little decay, but can be demonstrated even minutes or longer after the stimulus. To measure this type of adapation, we need a different strategy to estimate the size of this effect.

While short-term priming can be pin-pointed using the characteristic decay, for long-term priming we need to inspect whole dialogues and construct and contrast dialogues where priming is possible and ones where it is not. Factor SAMEDOC distinguishes the two situations: 1) Priming can happen in contiguous dialogues. We treat the first half of the dialogue as priming period, and the rule instances in the second half as targets. 2) The control case is when priming cannot have taken place, i.e., between unrelated dialogues. Prime period and targets stem from separate randomly sampled dialogue halves that always come from different dialogues.

Thus, our model (PRIME $\sim$ SAMEDOC $*$ PATHDEV) estimates the influence of priming on rule us. From a Bayesian perspective, we would say that the second kind of data (non-priming) allow the model to estimate a prior for rule repetitions. The goal is now to establish a correlation between SAMEDOC and the existence of repetition. If and only if there is long-term adapation would we expect such a correlation.

Analogous to the short-term priming model, we define repetition as the occurrence of a prime within the first document half (PRIME), and sample rule instances from the second document half. To exclude short-term priming effects, we drop a 10-second portion in the middle of the dialogues.

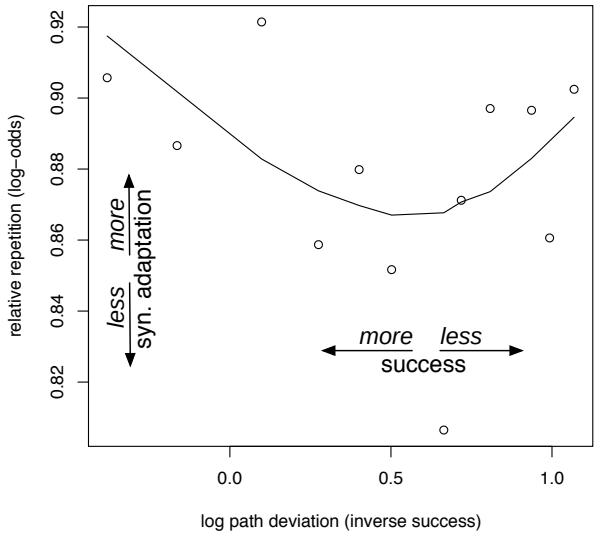

Figure 1: Relative rule repetition probability (chance repetition exluded) over (neg.) task success.

Task success is inverse path deviation PATHDEV as before, which should, under IAM assumptions, interact with the effect estimated for SAMEDOC.

6.2 Results

Long-term repetition showed a positive priming effect (SAMEDOC, $b = 3.303, p < 0.0001$). This generalizes previous experimental priming results in long-term priming.

Long-term-repetition did not interact with (normalized) rule frequency (SAMEDOC:log(RULEFREQ, $b = -0.044, p = 0.35$). The interaction was removed for all other parameters reported.[4]

The effect interacted reliably with the path deviation scores (SAMEDOC:PATHDEV, $b = -0.624, p < 0.05$). We find a reliable correlation of task success and syntactic priming. Stronger path deviations relate to weaker priming.

6.3 Discussion

The more priming we see, the better subjects perform at synchronizing their routes on the maps. This is exactly what one would expect under the assump-

[4]Such an interaction also could not be found in a reduced model with only SAMEDOC and RULEFREQ.

tion of IAM. Also, there is no evidence for stronger long-term adaptation of rare rules, which may point out a qualitative difference to short-term priming.

Of course, this correlation does not necessarily indicate a causal relationship. However, participants in Map Task did not receive an explicit indication about whether they were on the "right track". Mistakes, such as passing a landmark on its East and not on the West side, were made and went unnoticed. Thus, it is not very likely that task success caused alignment to improve at large. We suspect such a possibility, however, for very unsuccessful dialogues. A closer look at the correlation (Figure 1) reveals that while adaptation indeed decreases as task success decreases, adaptation increased again for some of the least successful dialogues. It is possible that here, miscoordination became apparent to the participants, who then tried to switch strategies. Or, simply put: too much alignment (and too little risk-taking) is unhelpful. Further, qualitative, work needs to be done to investigate this hypothesis.

From an applied perspective, the correlation shows that of the repetition effects included in our task-success prediction model, it is long-term syntactic adaptation as opposed to the more automatic short-term priming effect that contributes to prediction accuracy. We take this as an indication to include adaptation rather than just priming in a model of alignment in dialogue.

7 Conclusion

Task success in human-human dialogue is predictable–the more successfully speakers collaborate, the more they show linguistic adaptation. This confirms our initial hypothesis of IAM. In the applied model, knowledge of lexical and syntactic repetition helps to determine task success even after just a few minutes of the conversation.

We suggested two application-oriented tasks (estimating and predicting task success) and an approach to address them. They now provide an opportunity to explore and exploit other linguistic and extra-linguistic parameters.

The second contribution is a closer inspection of structural repetition, which showed that it is long-term adaptation that varies with task success, while short-term priming appears largely autonomous. Long-term adaptation may thus be a strategy that aids dialogue partners in aligning their language and their situation models.

Resolving *It, This,* and *That* in Unrestricted Multi-Party Dialog

Abstract

We present an implemented system for the resolution of *it*, *this*, and *that* in transcribed multi-party dialog. The system handles NP-anaphoric as well as discourse-deictic anaphors, i.e. pronouns with VP antecedents. Selectional preferences for NP or VP antecedents are determined on the basis of corpus counts. Our results show that the system performs significantly better than a recency-based baseline.

1 Introduction

This paper describes a fully automatic system for resolving the pronouns *it*, *this*, and *that* in unrestricted multi-party dialog. The system processes manual transcriptions from the ICSI Meeting Corpus (Janin et al., 2003). The following is a short fragment from one of these transcripts. The letters FN in the speaker tag mean that the speaker is a female non-native speaker of English. The brackets and subscript numbers are not part of the original transcript.

FN083: Maybe you can also read through the - all the text which is on the web pages cuz I'd like to change the text a bit cuz sometimes $[\text{it}]_1$'s too long, sometimes $[\text{it}]_2$'s too short, *inbreath* maybe the English is not that good, so *inbreath* um, but anyways - So I tried to do $[\text{this}]_3$ today and if you could do $[\text{it}]_4$ afterwards $[\text{it}]_5$ would be really nice cuz I'm quite sure that I can't find every, like, orthographic mistake in $[\text{it}]_6$ or something. (Bns003)

For each of the six 3rd-person pronouns in the example, the task is to automatically identify its referent, i.e. the entity (if any) to which the speaker makes reference. Once a referent has been identified, the pronoun is resolved by linking it to one of its antecedents, i.e. one of the referent's earlier mentions. For humans, identification of a pronoun's referent is often easy: it_1, it_2, and it_6 are probably used to refer to the text on the web pages, while it_4 is probably used to refer to *reading* this text. Humans also have no problem determining that it_5 is not a normal pronoun at all. In other cases, resolving a pronoun is difficult even for humans: this_3 could be used to refer to either *reading* or *changing* the text on the web pages. The pronoun is ambiguous because evidence for more than one interpretation can be found. Ambiguous pronouns are common in spoken dialog (Poesio & Artstein, 2005), a fact that has to be taken into account when building a spoken dialog pronoun resolution system. Our system is intended as a component in an extractive dialog summarization system. There are several ways in which coreference information can be integrated into extractive summarization. Kabadjov et al. (2005) e.g. obtained their best extraction results by specifying for each sentence whether it contained a mention of a particular anaphoric chain. Apart from improving the extraction itself, coreference information can also be used to substitute anaphors with their antecedents, thus improving the readability of a summary by minimizing the number of dangling anaphors, i.e. anaphors whose antecedents occur in utterances that are not part of the summary. The paper is structured as follows: Section 2 outlines the most important challenges and the state of the art in spoken dialog pronoun resolution. Section 3 describes our annotation experiments, and Section 4 describes the automatic

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 816–823,
Prague, Czech Republic, June 2007.

dialog preprocessing. Resolution experiments and results can be found in Section 5.

2 Pronoun Resolution in Spoken Dialog

Spoken language poses some challenges for pronoun resolution. Some of these arise from nonreferential resp. nonresolvable pronouns, which are important to identify because failure to do so can harm pronoun resolution precision. One common type of nonreferential pronoun is pleonastic *it*. Another cause of nonreferentiality that only applies to spoken language is that the pronoun is *discarded*, i.e. it is part of an incomplete or abandoned utterance. Discarded pronouns occur in utterances that are abandoned altogether.

ME010: Yeah. Yeah. No, no. There was a whole co- There was a little contract signed. It was - Yeah. (Bed017)

If the utterance contains a speech repair (Heeman & Allen, 1999), a pronoun in the *reparandum* part is also treated as discarded because it is not part of the final utterance.

ME10: That's - that's - so that's a - that's a very good question, then - now that it - I understand it. (Bro004)

In the corpus of task-oriented TRAINS dialogs described in Byron (2004), the rate of discarded pronouns is 7 out of 57 (12.3%) for *it* and 7 out of 100 (7.0%) for *that*. Schiffman (1985) reports that in her corpus of career-counseling interviews, 164 out of 838 (19.57%) instances of *it* and 80 out of 582 (13.75%) instances of *that* occur in abandoned utterances.

There is a third class of pronouns which is referential but nonetheless unresolvable: *vague* pronouns (Eckert & Strube, 2000) are characterized by having no clearly defined textual antecedent. Rather, vague pronouns are often used to refer to the topic of the current (sub-)dialog as a whole.

Finally, in spoken language the pronouns *it*, *this*, and *that* are often discourse deictic (Webber, 1991), i.e. they are used to refer to an *abstract object* (Asher, 1993). We treat as abstract objects all referents of VP antecedents, and do not distinguish between VP and S antecedents.

ME013: Well, I mean there's this Cyber Transcriber service, right?

ME025: Yeah, that's true, that's true. (Bmr001)

Discourse deixis is very frequent in spoken dialog: The rate of discourse deictic expressions reported in Eckert & Strube (2000) is 11.8% for pronouns and as much as 70.9% for demonstratives.

2.1 State of the Art

Pronoun resolution in spoken dialog has not received much attention yet, and a major limitation of the few implemented systems is that they are not fully automatic. Instead, they depend on manual removal of unresolvable pronouns like pleonastic *it* and discarded and vague pronouns, which are thus prevented from triggering a resolution attempt. This eliminates a major source of error, but it renders the systems inapplicable in a real-world setting where no such manual preprocessing is feasible.

One of the earliest empirically based works adressing (discourse deictic) pronoun resolution in spoken dialog is Eckert & Strube (2000). The authors outline two algorithms for identifying the antecedents of personal and demonstrative pronouns in two-party telephone conversations from the Switchboard corpus. The algorithms depend on two nontrivial types of information: the incompatibility of a given pronoun with either concrete or abstract antecedents, and the structure of the dialog in terms of dialog acts. The algorithms are not implemented, and Eckert & Strube (2000) report results of the manual application to a set of three dialogs (199 expressions, including other pronouns than *it*, *this*, and *that*). Precision and recall are 66.2 resp. 68.2 for pronouns and 63.6 resp. 70.0 for demonstratives.

An implemented system for resolving personal and demonstrative pronouns in task-oriented TRAINS dialogs is described in Byron (2004). The system uses an explicit representation of domain-dependent semantic category restrictions for predicate argument positions, and achieves a precision of 75.0 and a recall of 65.0 for *it* (50 instances) and a precision of 67.0 and a recall of 62.0 for *that* (93 instances) if all available restrictions are used. Precision drops to 52.0 for *it* and 43.0 for *that* when only domain-independent restrictions are used.

To our knowledge, there is only one implemented system so far that resolves normal and discourse deictic pronouns in unrestricted spoken dialog (Strube & Müller, 2003). The system runs on dialogs from the Switchboard portion of the Penn Treebank. For

it, *this* and *that*, the authors report 40.41 precision and 12.64 recall. The recall does not reflect the actual pronoun resolution performance as it is calculated against all coreferential links in the corpus, not just those with pronominal anaphors. The system draws some non-trivial information from the Penn Treebank, including correct NP chunks, grammatical function tags (subject, object, etc.) and discarded pronouns (based on the `-UNF`-tag). The treebank information is also used for determining the accessibility of potential candidates for discourse deictic pronouns.

In contrast to these approaches, the work described in the following is fully automatic, using only information from the raw, transcribed corpus. No manual preprocessing is performed, so that during testing, the system is exposed to the full range of discarded, pleonastic, and other unresolvable pronouns.

3 Data Collection

The ICSI Meeting Corpus (Janin et al., 2003) is a collection of 75 manually transcribed group discussions of about one hour each, involving three to ten speakers. A considerable number of participants are non-native speakers of English, whose proficiency is sometimes poor, resulting in disfluent or incomprehensible speech. The discussions are real, unstaged meetings on various, technical topics. Most of the discussions are regular weekly meetings of a quite informal conversational style, containing many interrupts, asides, and jokes (Janin, 2002). The corpus features a semi-automatically generated segmentation in which each segment is associated with a speaker tag and a start and end time stamp. Time stamps on the word level are not available. The transcription contains capitalization and punctuation, and it also explicitly records *interruption points* and *word fragments* (Heeman & Allen, 1999), but not the extent of the related disfluencies.

3.1 Annotation

The annotation was done by naive project-external annotators, two non-native and two native speakers of English, with the annotation tool MMAX2[1] on five randomly selected dialogs[2]. The annotation instructions were deliberately kept simple, explaining and illustrating the basic notions of anaphora and discourse deixis, and describing how markables were to be created and linked in the annotation tool. This practice of using a higher number of naive – rather than fewer, highly trained – annotators was motivated by our intention to elicit as many plausible interpretations as possible in the presence of ambiguity. It was inspired by the annotation experiments of Poesio & Artstein (2005) and Artstein & Poesio (2006). Their experiments employed up to 20 annotators, and they allowed for the explicit annotation of ambiguity. In contrast, our annotators were instructed to choose the single most plausible interpretation in case of perceived ambiguity. The annotation covered the pronouns *it*, *this*, and *that* only. Markables for these tokens were created automatically. From among the pronominal[3] instances, the annotators then identified normal, vague, and nonreferential pronouns. For normal pronouns, they also marked the most recent antecedent using the annotation tool's coreference annotation function. Markables for antecedents other than *it*, *this*, and *that* had to be created by the annotators by dragging the mouse over the respective words in the tool's GUI. Nominal antecedents could be either noun phrases (NP) or pronouns (PRO). VP antecedents (for discourse deictic pronouns) spanned only the verb phrase *head*, i.e. the verb, not the entire phrase. By this, we tried to reduce the number of disagreements caused by differing markable demarcations. The annotation of discourse deixis was limited to cases where the antecedent was a finite or infinite verb phrase expressing a proposition, event type, etc.[4]

3.2 Reliability

Inter-annotator agreement was checked by computing the variant of Krippendorff's α described in Passonneau (2004). This metric requires all annotations to contain the same set of markables, a condition that is not met in our case. Therefore, we report α values computed on the *intersection* of the com-

[1] http://mmax.eml-research.de

[2] Bed017, Bmr001, Bns003, Bro004, and Bro005.

[3] The automatically created markables included all instances of *this* and *that*, i.e. also relative pronouns, determiners, complementizers, etc.

[4] Arbitrary spans of text could not serve as antecedents for discourse deictic pronouns. The respective pronouns were to be treated as vague, due to lack of a well-defined antecedent.

pared annotations, i.e. on those markables that can be found in all four annotations. Only a subset of the markables in each annotation is relevant for the determination of inter-annotator agreement: all non-pronominal markables, i.e. all antecedent markables manually created by the annotators, and all referential instances of *it*, *this*, and *that*. The second column in Table 1 contains the cardinality of the union of all four annotators' markables, i.e. the number of all distinct relevant markables in all four annotations. The third and fourth column contain the cardinality and the relative size of the intersection of these four markable sets. The fifth column contains α calculated on the markables in the intersection only. The four annotators only agreed in the identification of markables in approx. 28% of cases. α in the five dialogs ranges from $.43$ to $.52$.

	$\lvert 1 \cup 2 \cup 3 \cup 4 \rvert$	$\lvert 1 \cap 2 \cap 3 \cap 4 \rvert$		α
Bed017	397	109	27.46 %	.47
Bmr001	619	195	31.50 %	.43
Bns003	529	131	24.76 %	.45
Bro004	703	142	20.20 %	.45
Bro005	530	132	24.91 %	.52

Table 1: Krippendorff's α for four annotators.

3.3 Data Subsets

In view of the subjectivity of the annotation task, which is partly reflected in the low agreement even on markable *identification*, the manual creation of a consensus-based gold standard data set did not seem feasible. Instead, we created *core* data sets from all four annotations by means of majority decisions. The core data sets were generated by automatically collecting in each dialog those anaphor-antecedent pairs that at least three annotators identified independently of each other. The rationale for this approach was that an anaphoric link is the more plausible the more annotators identify it. Such a data set certainly contains some spurious or dubious links, while lacking some correct but more difficult ones. However, we argue that it constitutes a plausible subset of anaphoric links that are useful to resolve.

Table 2 shows the number and lengths of anaphoric chains in the core data set, broken down according to the type of the chain-initial antecedent. The rare type OTHER mainly contains adjectival antecedents. More than 75% of all chains consist of two elements only. More than 33% begin with a pronoun. From the perspective of extractive summarization, the resolution of these latter chains is not helpful since there is no non-pronominal antecedent that it can be linked to or substituted with.

4 Automatic Preprocessing

Data preprocessing was done fully automatically, using only information from the manual transcription. Punctuation signs and some heuristics were used to split each dialog into a sequence of graphemic sentences. Then, a shallow disfluency detection and removal method was applied, which removed direct repetitions, nonlexicalized filled pauses like *uh*, *um*, interruption points, and word fragments. Each sentence was then matched against a list of potential discourse markers (*actually*, *like*, *you know*, *I mean*, etc.) If a sentence contained one or more matches, string variants were created in which the respective words were deleted. Each of these variants was then submitted to a parser trained on written text (Charniak, 2000). The variant with the highest probability (as determined by the parser) was chosen. NP chunk markables were created for all non-recursive NP constituents identi-

fied by the parser. Then, VP chunk markables were created. Complex verbal constructions like MD + INFINITIVE were modelled by creating markables for the individual expressions, and attaching them to each other with labelled relations like INFINITIVE_COMP. NP chunks were also attached, using relations like SUBJECT, OBJECT, etc.

5 Automatic Pronoun Resolution

We model pronoun resolution as binary classification, i.e. as the mapping of anaphoric mentions to previous mentions of the same referent. This method is not incremental, i.e. it cannot take into account earlier resolution decisions or any other information beyond that which is conveyed by the two mentions. Since more than 75% of the anaphoric chains in our data set would not benefit from incremental processing because they contain one anaphor only, we see this limitation as acceptable. In addition, incremental processing bears the risk of system degradation due to error propagation.

5.1 Features

In the binary classification model, a pronoun is resolved by creating a set of candidate antecedents and searching this set for a matching one. This search process is mainly influenced by two factors: exclusion of candidates due to *constraints*, and selection of candidates due to *preferences* (Mitkov, 2002). Our features encode information relevant to these two factors, plus more generally descriptive factors like distance etc. Computation of all features was fully automatic.

Shallow constraints for nominal antecedents include number, gender and person incompatibility, embedding of the anaphor into the antecedent, and coargumenthood (i.e. the antecedent and anaphor must not be governed by the same verb). For VP antecedents, a common shallow constraint is that the anaphor must not be governed by the VP antecedent (so-called *argumenthood*). Preferences, on the other hand, define conditions under which a candidate probably is the correct antecedent for a given pronoun. A common shallow preference for nominal antecedents is the parallel function preference, which states that a pronoun with a particular grammatical function (i.e. subject or object) preferably has an antecedent with a similar function. The subject preference, in contrast, states that subject antecedents are generally preferred over those with less salient functions, independent of the grammatical function of the anaphor. Some of our features encode this functional and structural parallelism, including identity of form (for PRO antecedents) and identity of grammatical function or governing verb.

A more sophisticated constraint on NP antecedents is what Eckert & Strube (2000) call *I-Incompatibility*, i.e. the semantic incompatibility of a pronoun with an individual (i.e. NP) antecedent. As Eckert & Strube (2000) note, subject pronouns in copula constructions with adjectives that can only modify abstract entities (like e.g. *true*, *correct*, *right*) are incompatible with concrete antecedents like *car*. We postulate that the preference of an adjective to modify an abstract entity (in the sense of Eckert & Strube (2000)) can be operationalized as the conditional probability of the adjective to appear with a *to*-infinitive resp. a *that*-sentence complement, and introduce two features which calculate the respective preference on the basis of corpus[5] counts. For the first feature, the following query is used:

$$\frac{\text{\# it (’s|is|was|were) ADJ to}}{\text{\# it (’s|is|was|were) ADJ}}$$

According to Eckert & Strube (2000), pronouns that are objects of verbs which mainly take sentence complements (like *assume*, *say*) exhibit a similar incompatibility with NP antecedents, and we capture this with a similar feature. Constraints for VPs include the following: VPs are inaccessible for discourse deictic reference if they fail to meet the *right frontier* condition (Webber, 1991). We use a feature which is similar to that used by Strube & Müller (2003) in that it approximates the *right frontier* on the basis of syntactic (rather than discourse structural) relations. Another constraint is *A-Incompatibility*, i.e. the incompatibility of a pronoun with an abstract (i.e. VP) antecedent. According to Eckert & Strube (2000), subject pronouns in copula constructions with adjectives that can only modify concrete entities (like e.g. *expensive*, *tasty*) are incompatible with abstract antecedents, i.e. they

[5] Based on the approx. 250,000,000 word TIPSTER corpus (Harman & Liberman, 1994).

cannot be discourse deictic. The function of this constraint is already covered by the two corpus-based features described above in the context of *I-Incompatibility*. Another feature, based on Yang et al. (2005), encodes the semantic compatibility of anaphor and NP antecedent. We operationalize the concept of semantic compatibility by substituting the anaphor with the antecedent head and performing corpus queries. E.g., if the anaphor is object, the following query[6] is used:

$$\frac{\#\,(\text{V}|\text{Vs}|\text{Ved}|\text{Ving})\ (\varnothing|\text{a}|\text{an}|\text{the}|\text{this}|\text{that})\ \text{ANTE}+}{\#\,(\text{V}|\text{Vs}|\text{Ved}|\text{Ving})\ (\varnothing|\text{the}|\text{these}|\text{those})\ \text{ANTES}}$$
$$\#\,(\text{ANTE}|\text{ANTES})$$

If the anaphor is the subject in an adjective copula construction, we use the following corpus count to quantify the compatibility between the predicated adjective and the NP antecedent (Lapata et al., 1999):

$$\frac{\#\ \text{ADJ}\ (\text{ANTE}|\text{ANTES}) + \#\ \text{ANTE}\ (\text{is}|\text{was})\ \text{ADJ}+}{\#\ \text{ANTES}\ (\text{are}|\text{were})\ \text{ADJ}}$$
$$\#\ \text{ADJ}$$

A third class of more general properties of the potential anaphor-antecedent pair includes the type of anaphor (personal vs. demonstrative), type of antecedent (definite vs. indefinite noun phrase, pronoun, finite vs. infinite verb phrase, etc.). Special features for the identification of discarded expressions include the distance (in words) to the closest preceeding resp. following disfluency (indicated in the transcription as an interruption point, word fragment, or *uh* resp. *um*). The relation between potential anaphor and (any type of) antecedent is described in terms of distance in seconds[7] and words. For VP antecedents, the distance is calculated from the *last* word in the entire phrase, not from the phrase *head*. Another feature which is relevant for dialog encodes whether both expressions are uttered by the same speaker.

[6] V is the verb governing the anaphor. Correct inflected forms were also generated for irregular verbs. ANTE resp. ANTES is the singular resp. plural head of the antecedent.

[7] Since the data does not contain word-level time stamps, this distance is determined on the basis of a simple forced alignment. For this, we estimated the number of syllables in each word on the basis of its vowel clusters, and simply distributed the known duration of the segment evenly on all words it contains.

5.2 Data Representation and Generation

Machine learning data for training and testing was created by pairing each anaphor with each of its compatible potential antecedents within a certain temporal distance (9 seconds for NP and 7 seconds for VP antecedents), and labelling the resulting data instance as *positive* resp. *negative*. VP antecedent candidates were created only if the anaphor was either *that*[8] or the object of a form of *do*.

Our core data set does not contain any nonreferential pronouns, though the classifier is exposed to the full range of pronouns, including discarded and otherwise nonreferential ones, during testing. We try to make the classifier robust against nonreferential pronouns in the following way: From the manual annotations, we select instances of *it*, *this*, and *that* that at least three annotators identified as nonreferential. For each of these, we add the full range of all-negative instances to the training data, applying the constraints mentioned above.

5.3 Evaluation Measure

As Bagga & Baldwin (1998) point out, in an application-oriented setting, not all anaphoric links are equally important: If a pronoun is resolved to an anaphoric chain that contains only pronouns, this resolution can be treated as neutral because it has no application-level effect. The common coreference evaluation measure described in Vilain et al. (1995) is inappropriate in this setting. We calculate precision, recall and F-measure on the basis of the following definitions: A pronoun is resolved correctly resp. incorrectly only if it is linked (directly or transitively) to the correct resp. incorrect *non-pronominal* antecedent. Likewise, the number of maximally resolvable pronouns in the core data set (i.e. the evaluation *key*) is determined by considering only pronouns in those chains that do not begin with a pronoun. Note that our definition of precision is stricter (and yields lower figures) than that applied in the ACE context, as the latter ignores incorrect links between two expressions in the *response*

[8] It is a common observation that demonstratives (in particular *that*) are preferred over *it* for discourse deictic reference (Schiffman, 1985; Webber, 1991; Asher, 1993; Eckert & Strube, 2000; Byron, 2004; Poesio & Artstein, 2005). This preference can also be observed in our core data set: 44 out of 59 VP antecedents (69.49%) are anaphorically referred to by *that*.

if these expressions happen to be unannotated in the *key*, while we treat them as precision errors unless the antecedent is a pronoun. The same is true for links in the *response* that were identified by less than three annotators in the *key*. While it is practical to treat those links as wrong, it is also simplistic because it does not do justice to ambiguous pronouns (cf. Section 6).

5.4 Experiments and Results

Our best machine learning results were obtained with the Weka[9] Logistic Regression classifier.[10] All experiments were performed with dialog-wise cross-validation. For each run, training data was created from the manually annotated markables in four dialogs from the core data set, while testing was performed on the automatically detected chunks in the remaining fifth dialog. For training and testing, the person, number[11], gender, and (co-)argument constraints were used. If an anaphor gave rise to a positive instance, no negative training instances were created beyond that instance. If a referential anaphor did not give rise to a positive training instance (because its antecedent fell outside the search scope or because it was removed by a constraint), no instances were created for that anaphor. Instances for nonreferential pronouns were added to the training data as described in Section 5.2.

During testing, we select for each potential anaphor the positive antecedent with the highest overall confidence. Testing parameters include `it-filter`, which switches on and off the module for the detection of nonreferential *it* described in Müller (2006). When evaluated alone, this module yields a precision of 80.0 and a recall of 60.9 for the detection of pleonastic and discarded *it* in the five ICSI dialogs. For training, this module was always on. We also vary the parameter `tipster`, which controls whether or not the corpus frequency features are used. If `tipster` is off, we ignore the corpus frequency features both during training and testing.

We first ran a simple baseline system which resolved pronouns to their most recent compatible antecedent, applying the same settings and constraints as for testing (cf. above). The results can be found in the first part of Table 3. Precision, recall and F-measure are provided for ALL and for NP and VP antecedents individually. The parameter `tipster` is not available for the baseline system. The best baseline performance is precision 4.88, recall 20.06 and F-measure 7.85 in the setting with `it-filter` on. As expected, this filter yields an increase in precision and a decrease in recall. The negative effect is outweighed by the positive effect, leading to a small but insignificant[12] increase in F-measure for all types of antecedents.

Setting		Ante	Baseline P	Baseline R	Baseline F	Logistic Regression P	Logistic Regression R	Logistic Regression F
-it-filter	-tipster	NP	4.62	27.12	7.90	18.53	20.34	19.39*
		VP	1.72	2.63	2.08	13.79	10.53	11.94
		ALL	4.40	20.69	7.25	17.67	17.56	17.61*
	+tipster	NP	-	-	-	19.33	22.03	20.59***
		VP	-	-	-	13.43	11.84	12.59
		ALL	-	-	-	18.16	19.12	18.63**
+it-filter	-tipster	NP	5.18	26.27	8.65	17.87	17.80	17.83*
		VP	1.77	2.63	2.12	13.12	10.53	11.68
		ALL	4.88	20.06	7.85	16.89	15.67	16.26*
	+tipster	NP	-	-	-	20.82	21.61	21.21**
		VP	-	-	-	11.27	10.53	10.88
		ALL	-	-	-	18.67	18.50	18.58**

Table 3: Resolution results.

The second part of Table 3 shows the results of the Logistic Regression classifier. When compared to the best baseline, the F-measures are consistently better for NP, VP, and ALL. The improvement is (sometimes highly) significant for NP and ALL, but never for VP. The best F-measure for ALL is 18.63, yielded by the setting with `it-filter` off and `tipster` on. This setting also yields the best F-measure for VP and the second best for NP. The contribution of the it-filter is disappointing: In both `tipster` settings, the it-filter causes F-measure for ALL to go down. The contribution of the corpus features, on the other hand, is somewhat inconclusive: In both `it-filter` settings, they cause an increase in F-measure for ALL. In the first setting, this increase is accompanied by an increase in F-measure for VP, while in the second setting, F-measure for VP goes down. It has to be noted, however, that none of the improvements brought about by the it-filter or the tipster corpus features is statistically significant. This also confirms some of the findings of Kehler et al. (2004), who found features similar to

[9] http://www.cs.waikato.ac.nz/ml/weka/

[10] The full set of experiments is described in Müller (2007).

[11] The *number* constraint applies to *it* only, as *this* and *that* can have both singular and plural antecedents (Byron, 2004).

[12] Significance of improvement in F-measure is tested using a paired one-tailed t-test and $p <= 0.05$ (*), $p <= 0.01$ (**), and $p <= 0.005$ (***).

our tipster corpus features not to be significant for NP-anaphoric pronoun resolution in written text.

6 Conclusions and Future Work

The system described in this paper is – to our knowledge – the first attempt towards fully automatic resolution of NP-anaphoric and discourse deictic pronouns (*it*, *this*, and *that*) in multi-party dialog. Unlike other implemented systems, it is usable in a realistic setting because it does not depend on manual pronoun preselection or non-trivial discourse structure or domain knowledge. The downside is that, at least in our strict evaluation scheme, the performance is rather low, especially when compared to that of state-of-the-art systems for pronoun resolution in written text. In future work, it might be worthwhile to consider less rigorous and thus more appropriate evaluation schemes in which links are weighted according to how many annotators identified them.

In its current state, the system only processes manual dialog transcripts, but it also needs to be evaluated on the output of an automatic speech recognizer. While this will add more noise, it will also give access to useful prosodic features like stress.

Finally, the system also needs to be evaluated extrinsically, i.e. with respect to its contribution to dialog summarization. It might turn out that our system already has a positive effect on extractive summarization, even though its performance is low in absolute terms.

Abstract

This paper presents a comparative study of five parameter estimation algorithms on four NLP tasks. Three of the five algorithms are well-known in the computational linguistics community: Maximum Entropy (ME) estimation with L_2 regularization, the Averaged Perceptron (AP), and Boosting. We also investigate ME estimation with L_1 regularization using a novel optimization algorithm, and BLasso, which is a version of Boosting with Lasso (L_1) regularization. We first investigate all of our estimators on two re-ranking tasks: a parse selection task and a language model (LM) adaptation task. Then we apply the best of these estimators to two additional tasks involving conditional sequence models: a Conditional Markov Model (CMM) for part of speech tagging and a Conditional Random Field (CRF) for Chinese word segmentation. Our experiments show that across tasks, three of the estimators — ME estimation with L_1 or L_2 regularization, and AP — are in a near statistical tie for first place.

1 Introduction

Parameter estimation is fundamental to many statistical approaches to NLP. Because of the high-dimensional nature of natural language, it is often easy to generate an extremely large number of features. The challenge of parameter estimation is to find a combination of the typically noisy, redundant features that accurately predicts the target output variable and avoids overfitting. Intuitively, this can be achieved either by selecting a small number of highly-effective features and ignoring the others, or by averaging over a large number of weakly informative features. The first intuition motivates feature selection methods such as Boosting and BLasso (e.g., Collins 2000; Zhao and Yu, 2004), which usually work best when many features are completely irrelevant. L_1 or Lasso regularization of linear models, introduced by Tibshirani (1996), embeds feature selection into regularization so that both an assessment of the reliability of a feature and the decision about whether to remove it are done in the same framework, and has generated a large amount of interest in the NLP community recently (e.g., Goodman 2003; Riezler and Vasserman 2004). If on the other hand most features are noisy but at least weakly correlated with the target, it may be reasonable to attempt to reduce noise by averaging over all of the features. ME estimators with L_2 regularization, which have been widely used in NLP tasks (e.g., Chen and Rosenfeld 2000; Charniak and Johnson 2005; Johnson et al. 1999), tend to produce models that have this property. In addition, the perceptron algorithm and its variants, e.g., the voted or averaged perceptron, is becoming increasingly popular due to their competitive performance, simplicity in implementation and low computational cost in training (e.g., Collins 2002).

While recent studies claim advantages for L_1 regularization, this study is the first of which we are aware to systematically compare it to a range of estimators on a diverse set of NLP tasks. Gao et al. (2006) showed that BLasso, due to its explicit use of L_1 regularization, outperformed Boosting in the LM adaptation task. Ng (2004) showed that for logistic regression, L_1 regularization outperforms L_2 regularization on artificial datasets which contain many completely irrelevant features. Goodman (2003) showed that in two out of three tasks, an ME estimator with a one-sided Laplacian prior (i.e., L_1 regularization with the constraint that all feature weights are positive) outperformed a comparable estimator using a Gaussian prior (i.e., L_2 regularization). Riezler and Vasserman (2004) showed that an L_1-regularized ME estimator outperformed an L_2-regularized estimator for ranking the parses of a stochastic unification-based grammar.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 824–831,
Prague, Czech Republic, June 2007.

While these individual estimators are well described in the literature, little is known about the relative performance of these methods because the published results are generally not directly comparable. For example, in the parse re-ranking task, one cannot tell whether the L_2- regularized ME approach used by Charniak and Johnson (2005) significantly outperforms the Boosting method by Collins (2000) because different feature sets and *n*-best parses were used in the evaluations of these methods.

This paper conducts a much-needed comparative study of these five parameter estimation algorithms on four NLP tasks: ME estimation with L_1 and L_2 regularization, the Averaged Perceptron (AP), Boosting, and BLasso, a version of Boosting with Lasso (L_1) regularization. We first investigate all of our estimators on two re-ranking tasks: a parse selection task and a language model adaptation task. Then we apply the best of these estimators to two additional tasks involving conditional sequence models: a CMM for POS tagging and a CRF for Chinese word segmentation. Our results show that ME estimation with L_2 regularization achieves the best performing estimators in all of the tasks, and AP achieves almost as well and requires much less training time. L_1 (Lasso) regularization also performs well and leads to sparser models.

2 Estimators

All the four NLP tasks studied in this paper are based on linear models (Collins 2000) which require learning a mapping from inputs $x \in X$ to outputs $y \in Y$. We are given:

- Training samples (x_i, y_i) for $i = 1 \ldots N$,
- A procedure $\boldsymbol{GEN}$ to generate a set of candidates $\boldsymbol{GEN}(x)$ for an input *x*,
- A feature mapping $\Phi: X \times Y \mapsto \mathbb{R}^D$ to map each (x, y) to a vector of feature values, and
- A parameter vector $\boldsymbol{w} \in \mathbb{R}^D$, which assigns a real-valued weight to each feature.

For all models except the CMM sequence model for POS tagging, the components $\boldsymbol{GEN}$, Φ and $\boldsymbol{w}$ directly define a mapping from an input x to an output $F(x)$ as follows:

$$F(x) = \arg\max_{y \in \boldsymbol{GEN}(X)} \Phi(x, y) \cdot \boldsymbol{w}. \quad (1)$$

In the CMM sequence classifier, locally normalized linear models to predict the tag of each word token are chained together to arrive at a probability estimate for the entire tag sequence, resulting in a slightly different decision rule.

Linear models, though simple, can capture very complex dependencies because the features can be arbitrary functions of the input/output pair. For example, we can define a feature to be the log conditional probability of the output as estimated by some other model, which may in turn depend on arbitrarily complex interactions of 'basic' features. In practice, with an appropriate feature set, linear models achieve very good empirical results on various NLP tasks. The focus of this paper however is not on feature definition (which requires domain knowledge and varies from task to task), but on parameter estimation (which is generic across tasks). We assume we are given fixed feature templates from which a large number of features are generated. The task of the estimator is to use the training samples to choose a parameter vector $\boldsymbol{w}$, such that the mapping $F(x)$ is capable of correctly classifying unseen examples. We will describe the five estimators in our study individually.

2.1 ME estimation with L_2 regularization

Like many linear models, the ME estimator chooses $\boldsymbol{w}$ to minimize the sum of the empirical loss on the training set and a regularization term:

$$\widehat{\boldsymbol{w}} = \arg\min_{\boldsymbol{w}} \{L(\boldsymbol{w}) + R(\boldsymbol{w})\}. \quad (2)$$

In this case, the loss term $L(\mathbf{w})$ is the negative conditional log-likelihood of the training data,

$$L(\boldsymbol{w}) = -\sum_{i=1}^{n} \log P(y_i|x_i), \text{ where}$$

$$P(y|x) = \frac{\exp(\Phi(x, y) \cdot \boldsymbol{w})}{\sum_{y' \in GEN(x)} \exp(\Phi(x, y') \cdot \boldsymbol{w})}$$

and the regularizer term $R(\boldsymbol{w}) = \alpha \sum_j w_j^2$ is the weighted squared L_2 norm of the parameters. Here, α is a parameter that controls the amount of regularization, optimized on held-out data.

This is one of the most popular estimators, largely due to its appealing computational properties: both $L(\boldsymbol{w})$ and $R(\boldsymbol{w})$ are convex and differentiable, so gradient-based numerical algorithms can be used to find the global minimum efficiently.

In our experiments, we used the *limited memory quasi-Newton* algorithm (or L-BFGS, Nocedal and Wright 1999) to find the optimal $\boldsymbol{w}$ because this method has been shown to be substantially faster than other methods such as Generalized Iterative Scaling (Malouf 2002).

Because for some sentences there are multiple best parses (i.e., parses with the same F-Score), we used the variant of ME estimator described in Riezler et al. (2002), where $L(\boldsymbol{w})$ is defined as the likelihood of the best parses $y \in Y(x)$ relative to the *n*-best parser output $\boldsymbol{GEN}(x)$, (i.e., $Y(x) \sqsubseteq \boldsymbol{GEN}(x)$): $L(\boldsymbol{w}) = -\sum_{i=1}^{n} \log \sum_{y_i \in Y(x_i)} P(y_i|x_i)$.

We applied this variant in our experiments of parse re-ranking and LM adaptation, and found that on both tasks it leads to a significant improvement in performance for the L_2-regularied ME estimator but not for the L_1-regularied ME estimator.

2.2 ME estimation with L_1 regularization

This estimator also minimizes the negative conditional log-likelihood, but uses an L_1 (or Lasso) penalty. That is, $R(\boldsymbol{w})$ in Equation (2) is defined according to $R(\boldsymbol{w}) = \alpha \sum_j |w_j|$. L_1 regularization typically leads to sparse solutions in which many feature weights are exactly zero, so it is a natural candidate when feature selection is desirable. By contrast, L_2 regularization produces solutions in which most weights are small but non-zero.

Optimizing the L_1-regularized objective function is challenging because its gradient is discontinuous whenever some parameter equals zero. Kazama and Tsujii (2003) described an estimation method that constructs an equivalent constrained optimization problem with twice the number of variables. However, we found that this method is impractically slow for large-scale NLP tasks. In this work we use the *orthant-wise limited-memory quasi-Newton* algorithm (OWL-QN), which is a modification of L-BFGS that allows it to effectively handle the discontinuity of the gradient (Andrew and Gao 2007). We provide here a high-level description of the algorithm.

A quasi-Newton method such as L-BFGS uses first order information at each iterate to build an approximation to the Hessian matrix, $\boldsymbol{H}$, thus modeling the local curvature of the function. At each step, a search direction is chosen by minimizing a quadratic approximation to the function:

$$Q(x) = \frac{1}{2}(x - x_0)'\boldsymbol{H}(x - x_0) + g_0'(x - x_0)$$

where x_0 is the current iterate, and g_0 is the function gradient at x_0. If $\boldsymbol{H}$ is positive definite, the minimizing value of x can be computed analytically according to: $x^* = x_0 - \boldsymbol{H}^{-1} g_0$.

L-BFGS maintains vectors of the change in gradient $g_k - g_{k-1}$ from the most recent iterations, and uses them to construct an estimate of the inverse Hessian $\boldsymbol{H}^{-1}$. Furthermore, it does so in such a way that $\boldsymbol{H}^{-1} g_0$ can be computed without expanding out the full matrix, which is typically unmanageably large. The computation requires a number of operations linear in the number of variables.

OWL-QN is based on the observation that when restricted to a single orthant, the L_1 regularizer *is* differentiable, and is in fact a linear function of $\boldsymbol{w}$. Thus, so long as each coordinate of any two consecutive search points does not pass through zero, $R(\boldsymbol{w})$ does not contribute at all to the curvature of the function on the segment joining them. Therefore, we can use L-BFGS to approximate the Hessian of $L(\boldsymbol{w})$ alone, and use it to build an approximation to the full regularized objective that is valid on a given orthant. To ensure that the next point is in the valid region, we project each point during the line search back onto the chosen orthant.[1] At each iteration, we choose the orthant containing the current point and into which the direction giving the greatest local rate of function decrease points.

This algorithm, although only a simple modification of L-BFGS, works quite well in practice. It typically reaches convergence in even fewer iterations than standard L-BFGS takes on the analogous L_2-regularized objective (which translates to less training time, since the time per iteration is only negligibly higher, and total time is dominated by function evaluations). We describe OWL-QN more fully in (Andrew and Gao 2007). We also show that it is significantly faster than Kazama and Tsujii's algorithm for L_1 regularization and prove that it is guaranteed converge to a parameter vector that globally optimizes the L_1-regularized objective.

2.3 Boosting

The Boosting algorithm we used is based on Collins (2000). It optimizes the pairwise *exponential loss* (ExpLoss) function (rather than the logarithmic loss optimized by ME). Given a training sample (x_i, y_i), for each possible output $y_j \in \boldsymbol{GEN}(x_i)$, we

[1] This projection just entails zeroing-out any coordinates that change sign. Note that it is possible for a variable to change sign in two iterations, by moving from a negative value to zero, and on a the next iteration moving from zero to a positive value.

1 Set w_0 = argmin$_{w0}$ExpLoss(w); and w_d = 0 for d=1…D
2 Select a feature f_{k^*} which has largest estimated impact on reducing ExpLoss of Equation (3)
3 Update $\lambda_{k^*} \leftarrow \lambda_{k^*} + \delta^*$, and return to Step 2

Figure 1: The boosting algorithm

define the margin of the pair (y_i, y_j) with respect to $\boldsymbol{w}$ as $M(y_i, y_j) = \Phi(x_i, y_i) \cdot \boldsymbol{w} - \Phi(x_i, y_j) \cdot \boldsymbol{w}$.

Then ExpLoss is defined as

$$\text{ExpLoss}(\boldsymbol{w}) = \sum_i \sum_{y_j \in \boldsymbol{GEN}(x_i)} \exp\left(-\text{M}(\text{y}_\text{i}, \text{y}_\text{j})\right) \quad (3)$$

Figure 1 summarizes the Boosting algorithm we used. It is an incremental feature selection procedure. After initialization, Steps 2 and 3 are repeated T times; at each iteration, a feature is chosen and its weight is updated as follows.

First, we define $\text{Upd}(\boldsymbol{w}, k, \delta)$ as an updated model, with the same parameter values as w with the exception of w_k, which is incremented by δ:

$$\text{Upd}(\boldsymbol{w}, k, \delta) = (w_1, \ldots, w_k + \delta, \ldots, w_D)$$

Then, Steps 2 and 3 in Figure 1 can be rewritten as Equations (4) and (5), respectively.

$$(k^*, \delta^*) = \arg\min_{k,\delta} \text{ExpLoss}(\text{Upd}(\boldsymbol{w}, k, \delta)) \quad (4)$$

$$\boldsymbol{w}^t = \text{Upd}(\boldsymbol{w}^{t-1}, k^*, \delta^*) \quad (5)$$

Because Boosting can overfit we update the weight of f_{k^*} by a small fixed step size ε, as in Equation (6), following the FSLR algorithm (Hastie et al. 2001).

$$\boldsymbol{w}^t = \text{Upd}(\boldsymbol{w}^{t-1}, k^*, \epsilon \times \text{sign}(\delta^*)) \quad (6)$$

By taking such small steps, Boosting imposes a kind of implicit regularization, and can closely approximate the effect of L_1 regularization in a local sense (Hastie et al. 2001). Empirically, smaller values of ϵ lead to smaller numbers of test errors.

2.4 Boosted Lasso

The Boosted Lasso (BLasso) algorithm was originally proposed in Zhao and Yu (2004), and was adapted for language modeling by Gao et al. (2006). BLasso can be viewed as a version of Boosting with L_1 regularization. It optimizes an L_1-regularized ExpLoss function:

$$\text{LassoLoss}(\boldsymbol{w}) = \text{ExpLoss}(\boldsymbol{w}) + R(\boldsymbol{w}) \quad (7)$$

where $R(\boldsymbol{w}) = \alpha \sum_j |w_j|$.

BLasso also uses an incremental feature selection procedure to learn parameter vector $\boldsymbol{w}$, just as Boosting does. Due to the explicit use of the regularization term $R(\boldsymbol{w})$, however, there are two major differences from Boosting.

At each iteration, BLasso takes either a *forward step* or a *backward step*. Similar to Boosting, at each forward step, a feature is selected and its weight is updated according to Eq. (8) and (9).

$$(k^*, \delta^*) = arg \min_{k,\delta=\pm\epsilon} \text{ExpLoss}(\text{Upd}(\boldsymbol{w}, k, \delta)) \quad (8)$$

$$\boldsymbol{w}^t = \text{Upd}(\boldsymbol{w}^{t-1}, k^*, \epsilon \times \text{sign}(\delta^*)) \quad (9)$$

There is a small but important difference between Equations (8) and (4). In Boosting, as shown in Equation (4), a feature is selected by its impact on reducing the loss with its optimal update δ^*. By contrast, in BLasso, as shown in Equation (8), rather than optimizing over δ for each feature, the loss is calculated with an update of either $+\epsilon$ or $-\epsilon$, i.e., grid search is used for feature weight estimation. We found in our experiments that this modification brings a consistent improvement.

The backward step is unique to BLasso. At each iteration, a feature is selected and the absolute value of its weight is reduced by ϵ if and only if it leads to a decrease of the LassoLoss, as shown in Equations (10) and (11), where θ is a tolerance parameter.

$$k^* = \arg\min_{k:w_k \neq 0} \text{ExpLoss}(\text{Upd}(\boldsymbol{w}, k, -\epsilon\text{sign}(w_k)) \quad (10)$$

$$\boldsymbol{w}^t = \text{Upd}(\boldsymbol{w}^{t-1}, k^*, \text{sign}(w_{k^*}) \times \epsilon) \quad (11)$$

$$\text{if } \text{LassoLoss}(\boldsymbol{w}^{t-1}, \alpha^{t-1}) - \text{LassoLoss}(\boldsymbol{w}^t, \alpha^t) > \theta$$

Figure 2 summarizes the BLasso algorithm we used. After initialization, Steps 4 and 5 are repeated T times; at each iteration, a feature is chosen and its weight is updated either backward or forward by a fixed amount ϵ. Notice that the value of α is adaptively chosen according to the reduction of ExpLoss during training. The algorithm starts with a large initial α, and then at each forward step the value of α decreases until ExpLoss stops decreasing. This is intuitively desirable: it is expected that most highly effective features are selected in early stages of training, so the reduction of ExpLoss at each step in early stages are more substantial than in later stages. These early steps coincide with the Boosting steps most of the time. In other words, the effect of backward steps is more visible at later stages. It can be proved that for a finite number of features and θ=0, the BLasso algorithm shown in Figure 2 converges to the Lasso solution when $\epsilon \to 0$. See Gao et al. (2006) for implementation details, and Zhao and Yu (2004) for a theoretical justification for BLasso.

1 Initialize w^0: set $w_0 = \text{argmin}_{w0}\text{ExpLoss}(w)$, and $w_d = 0$ for d=1…D.
2 Take a forward step according to Eq. (8) and (9), and the updated model is denoted by w^1
3 Initialize $\alpha = (\text{ExpLoss}(w^0)-\text{ExpLoss}(w^1))/\varepsilon$
4 Take a backward step if and only if it leads to a decrease of LassoLoss according to Eq. (10) and (11), where $\theta = 0$; otherwise
5 Take a forward step according to Eq. (8) and (9); update $\alpha = \min(\alpha, (\text{ExpLoss}(w^{t-1})-\text{ExpLoss}(w^t))/\varepsilon)$; and return to Step 4.

Figure 2: The BLasso algorithm

1 Set $w_0 = 1$ and $w_d = 0$ for d=1…D
2 For t = 1…T (T = the total number of iterations)
3 For each training sample (x_i, y_i), i = 1…N
4 Choose the best candidate z_i from GEN(x_i) using the current model w,

$$z_i = \arg\max_{z \in GEN(x\_i)} \Phi(x_i, z) \cdot w$$

5 w = w + $\eta(\Phi(x_i, y_i) - \Phi(x_i, z_i))$, where η is the size of learning step, optimized on held-out data.

Figure 3: The perceptron algorithm

2.5 Averaged Perceptron

The perceptron algorithm can be viewed as a form of incremental training procedure (e.g., using stochastic approximation) that optimizes a *minimum square error* (MSE) loss function (Mitchell, 1997). As shown in Figure 3**,** it starts with an initial parameter setting and updates it for each training example. In our experiments, we used the Averaged Perceptron algorithm of Freund and Schapire (1999), a variation that has been shown to be more effective than the standard algorithm (Collins 2002). Let $\boldsymbol{w}^{t,i}$ be the parameter vector after the i^{th} training sample has been processed in pass t over the training data. The average parameters are defined as $\bar{\boldsymbol{w}} = \frac{1}{TN}\sum_t \sum_i \boldsymbol{w}^{t,i}$ where T is the number of epochs, and N is the number of training samples.

3 Evaluations

From the four tasks we consider, parsing and language model adaptation are both examples of re-ranking. In these tasks, we assume that we have been given a list of candidates $\boldsymbol{GEN}(x)$ for each training or test sample (x, y), generated using a *baseline* model. Then, a linear model of the form in Equation (1) is used to discriminatively re-rank the candidate list using additional features which may or may not be included in the baseline model. Since the mapping from x to y by the linear model may make use of arbitrary global features of the output and is performed "all at once", we call such a linear model a *global model*.

In the other two tasks (i.e., Chinese word segmentation and POS tagging), there is no explicit enumeration of $\boldsymbol{GEN}(x)$. The mapping from x to y is determined by a sequence model which aggregates the decisions of local linear models via a dynamic program. In the CMM, the local linear models are trained independently, while in the CRF model, the local models are trained jointly. We call these two linear models *local models* because they dynamically combine the output of models that use only local features.

While it is straightforward to apply the five estimators to global models in the re-ranking framework, the application of some estimators to the local models is problematic. Boosting and BLasso are too computationally expensive to be applied to CRF training and we compared the other three better performing estimation methods for this model. The CMM is a probabilistic sequence model and the log-loss used by ME estimation is most natural for it; thus we limit the comparison to the two kinds of ME models for CMMs. Note that our goal is not to compare locally trained models to globally trained ones; for a study which focuses on this issue, see (Punyakanok et al. 2005).

In each task we compared the performance of different estimators using task-specific measures. We used the Wilcoxon signed rank test to test the statistical significance of the difference among the competing estimators. We also report other results such as number of non-zero features after estimation, number of training iterations, and computation time (in minutes of elapsed time on an XEON™ MP 3.6GHz machine).

3.1 Parse re-ranking

We follow the experimental paradigm of parse re-ranking outlined in Charniak and Johnson (2005), and fed the features extracted by their program to the five rerankers we developed. Each uses a linear model trained using one of the five estimators. These rerankers attempt to select the best parse y for a sentence x from the 50-best list of possible parses $\boldsymbol{GEN}(x)$ for the sentence. The linear model combines the log probability calculated by the Charniak (2000) parser as a feature with 1,219,272 additional features. We trained the fea-

	F-Score	# features	time (min)	# train iter
Baseline	0.8986			
ME/L2	0.9176	1,211,026	62	129
ME/L1	0.9165	19,121	37	174
AP	0.9164	939,248	2	8
Boosting	0.9131	6,714	495	92,600
BLasso	0.9133	8,085	239	56,500

Table 1: Performance summary of estimators on parsing re-ranking (ME/L2: ME with L_2 regularization; ME/L1: ME with L_1 regularization)

	ME/L2	ME/L1	AP	Boost	BLasso

ture weights **w** on Sections 2-19 of the Penn Treebank, adjusted the regularizer constant α to maximize the F-Score on Sections 20-21 of the Treebank, and evaluated the rerankers on Section 22. The results are presented in Tables 1[2] and 2, where **Baseline** results were obtained using the parser by Charniak (2000).

The ME estimation with L_2 regularization outperforms all of the other estimators significantly except for the AP, which performs almost as well and requires an order of magnitude less time in training. Boosting and BLasso are feature selection methods in nature, so they achieve the sparsest models, but at the cost of slightly lower performance and much longer training time. The L_1-regularized ME estimator also produces a relatively sparse solution whereas the Averaged Perceptron and the L_2-regularized ME estimator assign almost all features a non-zero weight.

3.2 Language model adaptation

Our experiments with LM adaptation are based on the work described in Gao et al. (2006). The variously trained language models were evaluated according to their impact on Japanese text input accuracy, where input phonetic symbols x are mapped into a word string y. Performance of the application is measured in terms of character error rate (CER), which is the number of characters wrongly converted from x divided by the number of characters in the correct transcript.

	CER	# features	time (min)	#train iter
Baseline	10.24%			
MAP	7.98%			
ME/L2	6.99%	295,337	27	665
ME/L1	7.01%	53,342	25	864
AP	7.23%	167,591	6	56
Boost	7.54%	32,994	175	71,000
BLasso	7.20%	33,126	238	250,000

Table 3. Performance summary of estimators (lower is better) on language model adaptation

ME/L1	~		>>	>>	>>
AP	<<	<<		>>	~
Boost	<<	<<	<<		<<
BLasso	<<	<<	~	>>	

Table 4. Statistical significance test results.

Again we evaluated five linear rerankers, one for each estimator. These rerankers attempt to select the best conversions y for an input phonetic string x from a 100-best list $\boldsymbol{GEN}(x)$ of possible conversions proposed by a baseline system. The linear model combines the log probability under a trigram language model as base feature and additional 865,190 word uni/bi-gram features. These uni/bi-gram features were already included in the trigram model which was trained on a *background* domain corpus (Nikkei Newspaper). But in the linear model their feature weights were trained discriminatively on an *adaptation* domain corpus (Encarta Encyclopedia). Thus, this forms a cross domain adaptation paradigm. This also implies that the portion of redundant features in this task could be much larger than that in the parse re-ranking task, especially because the background domain is reasonably similar to the adaptation domain.

We divided the Encarta corpus into three sets that do not overlap. A 72K-sentences set was used as training data, a 5K-sentence set as development data, and another 5K-sentence set as testing data. The results are presented in Tables 3 and 4, where **Baseline** is the word-based trigram model trained on background domain corpus, and **MAP** (maximum *a posteriori*) is a traditional model adaptation method, where the parameters of the background model are adjusted so as to maximize the likelihood of the adaptation data.

[2] The result of ME/L2 is better than that reported in Andrew and Gao (2007) due to the use of the variant of L_2-regularized ME estimator, as described in Section 2.1.

	Test F_1	# features	# train iter
ME/L2	0.9719	8,084,086	713
ME/L1	0.9713	317,146	201
AP	0.9703	1,965,719	162

Table 5. Performance summary of estimators on CWS

The results are more or less similar to those in the parsing task with one visible difference: L_1 regularization achieved relatively better performance in this task. For example, while in the parsing task ME with L_2 regularization significantly outperforms ME with L_1 regularization, their performance difference is not significant in this task. While in the parsing task the performance difference between BLasso and Boosting is not significant, BLasso outperforms Boosting significantly in this task. Considering that a much higher proportion of the features are redundant in this task than the parsing task, the results seem to corroborate the observation that L_1 regularization is robust to the presence of many redundant features.

3.3 Chinese word segmentation

Our third task is Chinese word segmentation (CWS). The goal of CWS is to determine the boundaries between words in a section of Chinese text. The model we used is the hybrid Markov/semi- Markov CRF described by Andrew (2006), which was shown to have state-of-the-art accuracy. We tested models trained with the various estimation methods on the Microsoft Research Asia corpus from the Second International Chinese Word Segmentation, and we used the same train/test split used in the competition. The model and experimental setup is identical with that of Andrew (2006) except for two differences. First, we extracted features from both positive and negative training examples, while Andrew (2006) uses only features that occur in some positive training example. Second, we used the last 4K sentences of the training data to select the weight of the regularizers and to determine when to stop perceptron training.

We compared three of the best performing estimation procedures on this task: ME with L_2 regularization, ME with L_1 regularization, and the Averaged Perceptron. In this case, ME refers to minimizing the negative log-probability of the correct segmentation, which is globally normalized, while the perceptron is trained using at each iteration the exact maximum-scoring segmentation with the current weights. We observed the same pattern as in the other tasks: the three algorithms have nearly identical performance, while L_1 uses only 6% of the features, and the Averaged Perceptron requires significantly fewer training iterations. In this case, L_1 was also several times faster than L_2. The results are summarized in Table 5.[3]

We note that all three algorithms performed slightly better than the model used by Andrew (2006), which also used L_2 regularization (96.84 F_1). We believe the difference is due to the use of features derived from negative training examples.

3.4 POS tagging

Finally we studied the impact of the regularization methods on a Maximum Entropy conditional Markov Model (MEMM, McCallum et al. 2000) for POS tagging. MEMMs decompose the conditional probability of a tag sequence given a word sequence as follows:

$$P(t_1 \dots t_n | w_1 \dots w_n) = \prod_{i=1}^{n} P(t_i | t_{i-1} \dots t_{i-k}, w_1 \dots w_n)$$

where the probability distributions for each tag given its context are ME models. Following previous work (Ratnaparkhi, 1996), we assume that the tag of a word is independent of the tags of all preceding words given the tags of the previous two words (i.e., $k=2$ in the equation above). The local models at each position include features of the current word, the previous word, the next word, and features of the previous two tags. In addition to lexical identity of the words, we used features of word suffixes, capitalization, and number/special character signatures of the words.

We used the standard splits of the Penn Treebank from the tagging literature (Toutanova et al. 2003) for training, development and test sets. The training set comprises Sections 0-18, the development set — Sections 19-21, and the test set — Sections 22-24. We compared training the ME models using L_1 and L_2 regularization. For each of the two types of regularization we selected the best value of the regularization constant using grid search to optimize the accuracy on the development set. We report final accuracy measures on the test set in Table 6.

The results on this task confirm the trends we have seen so far. There is almost no difference in

[3] Only the L2 vs. AP comparison is significant at a 0.05 level according to the Wilcoxon signed rank test.

	Accuracy (%)	# features	# train iter
MEMM/L2	96.39	926,350	467
MEMM/L1	96.41	84,070	85

Table 6. Performance summary of estimators on POS tagging

accuracy of the two kinds of regularizations, and indeed the differences were not statistically significant. Estimation with L_1 regularization required considerably less time than estimation with L_2, and resulted in a model which is more than ten times smaller.

4 Conclusions

We compared five of the most competitive parameter estimation methods on four NLP tasks employing a variety of models, and the results were remarkably consistent across tasks. Three of the methods — ME estimation with L_2 regularization, ME estimation with L_1 regularization, and the Averaged Perceptron — were nearly indistinguishable in terms of test set accuracy, with ME estimation with L_2 regularization perhaps enjoying a slight lead. Meanwhile, ME estimation with L_1 regularization achieves the same level of performance while at the same time producing sparse models, and the Averaged Perceptron provides an excellent compromise of high performance and fast training.

These results suggest that when deciding which type of parameter estimation to use on these or similar NLP tasks, one may choose any of these three popular methods and expect to achieve comparable performance. The choice of which to implement should come down to other considerations: if model sparsity is desired, choose ME estimation with L_1 regularization (or feature selection methods such as BLasso); if quick implementation and training is necessary, use the Averaged Perceptron; and ME estimation with L_2 regularization may be used if it is important to achieve the highest obtainable level of performance.

Abstract

We propose a new language learning model that learns a syntactic-semantic grammar from a small number of natural language strings annotated with their semantics, along with basic assumptions about natural language syntax. We show that the search space for grammar induction is a complete grammar lattice, which guarantees the uniqueness of the learned grammar.

1 Introduction

There is considerable interest in learning computational grammars.[1] While much attention has focused on learning syntactic grammars either in a supervised or unsupervised manner, recently there is a growing interest toward learning grammars/parsers that capture semantics as well (Bos et al., 2004; Zettlemoyer and Collins, 2005; Ge and Mooney, 2005).

Learning both syntax and semantics is arguably more difficult than learning syntax alone. In formal grammar learning theory it has been shown that learning from "good examples," or representative examples, is more powerful than learning from all the examples (Freivalds et al., 1993). Haghighi and Klein (2006) show that using a handful of "prototypes" significantly improves over a fully unsupervised PCFG induction model (their prototypes were formed by sequences of POS tags; for example, prototypical NPs were DT NN, JJ NN).

In this paper, we present a new grammar formalism and a new learning method which together address the problem of learning a syntactic-semantic grammar in the presence of a representative sample of strings annotated with their semantics, along with minimal assumptions about syntax (such as syntactic categories). The semantic representation is an ontology-based semantic representation. The annotation of the representative examples does not include the entire derivation, unlike most of the existing syntactic treebanks. The aim of the paper is to present the formal aspects of our grammar induction model.

In Section 2, we present a new grammar formalism, called *Lexicalized Well-Founded Grammars*, a type of constraint-based grammars that combine syntax and semantics. We then turn to the two main results of this paper. In Section 3 we show that our grammars can always be learned from a set of positive representative examples (with no negative examples), and the search space for grammar induction is a complete grammar lattice, which guarantees the uniqueness of the learned grammar. In Section 4, we propose a new computationally efficient model for grammar induction from pairs of utterances and their semantic representations, called *Grammar Approximation by Representative Sublanguage (GARS)*. Section 5 discusses the practical use of our model and Section 6 states our conclusions and future work.

2 Lexicalized Well-Founded Grammars

Lexicalized Well-Founded Grammars (LWFGs) are a type of Definite Clause Grammars (Pereira and Warren, 1980) where: (1) the Context-Free Grammar backbone is extended by introducing a partial ordering relation among nonterminals (well-founded) 2) each string is associated with a syntactic-semantic representation called *semantic molecule*; 3) grammar rules have two types of constraints: one for semantic composition and one for ontology-based semantic interpretation.

The partial ordering among nonterminals allows the ordering of the grammar rules, and thus facilitates the bottom-up induction of these grammars.

The *semantic molecule* is a syntactic-semantic representation of natural language strings $w' = \binom{h}{b}$ where h *(head)* encodes the information required for semantic composition, and b *(body)* is the actual semantic representation of the string. Figure 1 shows examples of semantic molecules for an adjective, a noun and a noun phrase. The representations associated with the lexical items are called *elementary semantic molecules* (I), while the representations built by the combination of others are called *derived semantic molecules* (II). The head of the semantic molecule is a flat feature structure, having at least two attributes encoding the syntactic category of the associated string, cat, and the head of the string, head. The set of attributes is finite and known a priori for each syntactic category. The body of the semantic molecule is a flat, ontology-based semantic representation. It is a logical form, built as a conjunction of atomic predicates $\langle concept \rangle.\langle attr \rangle = \langle concept \rangle$, where variables are either concept or slot identifiers in an ontology. For example, the adjective *major* is represented as $\langle X_1.isa = major, X_2.Y = X_1 \rangle$, which says that the meaning of an adjective is a concept ($X_1.isa = major$), which is a value of a property of another concept ($X_2.Y = X_1$) in the ontology.

The grammar nonterminals are augmented with pairs of strings and their semantic molecules. These pairs are called syntagmas, and are denoted by $\sigma = (w, w') = (w, \binom{h}{b})$. There are two types of constraints at the grammar rule level — one for *semantic composition* (defines how the meaning of a natural language expression is composed from the meaning of its parts) and one for *ontology-based semantic interpretation*. An example of a LWFG rule is given in Figure 1(III). The composition constraints Φ_{comp} applied to the heads of the semantic molecules, form a system of equations that is a simplified version of "path equations" (Shieber et al., 1983), because the heads are flat feature structures. These constraints are learned together with the grammar rules. The ontology-based constraints represent the validation on the ontology, and are applied to the body of the semantic molecule associated with the left-hand side nonterminal. They are not learned. Currently, Φ_{onto} is a predicate which can succeed or fail. When it succeeds, it instantiates the variables of the semantic representation with concepts/slots in the ontology. For example, given the phrase *major damage*, Φ_{onto} succeeds and returns (X_1=MAJOR, X=DAMAGE, Y=DEGREE), while given the phrase *major birth* it fails. We leave the discussion of the ontology constraints for a future paper, since it is not needed for the main result of this paper.

We give below the formal definition of Lexical-

I. Elementary Semantic Molecules

(major/adj)′ = $\begin{pmatrix} \begin{bmatrix} \text{cat} & \text{adj} \\ \text{head} & X_1 \\ \text{mod} & X_2 \end{bmatrix} \\ h_1 \\ b_1 \left\langle X_1.\text{isa} = \text{major},\ X_2.\text{Y}=X_1 \right\rangle \end{pmatrix}$

(damage/noun)′ = $\begin{pmatrix} \begin{bmatrix} \text{cat} & \text{noun} \\ \text{nr} & \text{sg} \\ \text{head} & X_3 \end{bmatrix} \\ h_3 \\ b_3 \left\langle X_3.\text{isa} = \text{damage} \right\rangle \end{pmatrix}$

II. Derived Semantic Molecule

(major damage)′ = $\begin{pmatrix} \begin{bmatrix} \text{cat} & \text{n} \\ \text{nr} & \text{sg} \\ \text{head} & \text{X} \end{bmatrix} \\ h \\ b \left\langle X_1.\text{isa} = \text{major},\ \text{X.Y}=X_1,\ \text{X.isa}=\text{damage} \right\rangle \end{pmatrix}$

III. Constraint Grammar Rule

$N(w, \binom{h}{b}) \rightarrow Adj(w_1, \binom{h_1}{b_1}), N(w_2, \binom{h_2}{b_2}) : \Phi_{comp}, \Phi_{onto}(b)$

$\Phi_{comp}(h, h_1, h_2) = \{h.cat = n, h.head = h_1.mod,$
$h.head = h_2.head, h.nr = h_2.nr, h_1.cat = adj, h_2.cat = n\}$

$\Phi_{onto}(b)$ returns X_1=MAJOR, X=DAMAGE, Y=DEGREE from ontology

Figure 1: Examples of two elementary semantic molecules (I), a derived semantic molecule (II) obtained by combining them, and a constraint grammar rule together with the constraints Φ_{comp}, Φ_{onto} (III) .

ized Well-Founded Grammars, except that we do not define formally the constraints due to lack of space (see (Muresan, 2006) for details).

Definition 1. A *Lexicalized Well-Founded Grammar (LWFG)* is a 6-tuple, $G = \langle \Sigma, \Sigma', N_G, \succeq, P_G, S \rangle$, where:

1. Σ is a finite set of terminal symbols.
2. Σ' is a finite set of elementary semantic molecules corresponding to the set of terminal symbols.
3. N_G is a finite set of nonterminal symbols.
4. $\succeq$ is a partial ordering relation among the nonterminals.
5. P_G is a set of constraint rules. A constraint rule is written $A(\sigma) \rightarrow B_1(\sigma_1), \ldots, B_n(\sigma_n)\colon \Phi(\bar{\sigma})$, where $\bar{\sigma} = (\sigma, \sigma_1, ..., \sigma_n)$ such that $\sigma = (w, w'), \sigma_i = (w_i, w_i'), 1 \leq i \leq n, w = w_1 \cdots w_n, w' = w_1' \circ \cdots \circ w_n'$, and $\circ$ is the semantic composition operator. For brevity, we denote a rule by $A \rightarrow \beta\colon \Phi$, where $A \in N_G, \beta \in N_G^+$. For the rules whose left-hand side are preterminals, $A(\sigma) \rightarrow$, we use the notation $A \rightarrow \sigma$. There are three types of rules: ordered non-recursive, ordered recursive, and non-ordered rules. A grammar rule $A(\sigma) \rightarrow B_1(\sigma_1), \ldots, B_n(\sigma_n)\colon \Phi(\bar{\sigma})$, is an *ordered rule*, if for all B_i, we have $A \succeq B_i$. In LWFGs, each nonterminal symbol is a left-hand side in at least one ordered non-recursive rule and the empty string cannot be derived from any nonterminal symbol.
6. $S \in N_G$ is the start nonterminal symbol, and $\forall A \in N_G, S \succeq A$ (we use the same notation for the reflexive, transitive closure of $\succeq$).

The relation $\succeq$ is a partial ordering only among nonterminals, and it should not be confused with information ordering derived from the flat feature structures. This relation makes the set of nonterminals well-founded, which allows the ordering of the grammar rules, as well as the ordering of the syntagmas generated by LWFGs.

Definition 2. Given a LWFG, G, the *ground syntagma derivation* relation, $\stackrel{*G}{\Rightarrow}$,[2] is defined as: $\frac{A \rightarrow \sigma}{A \stackrel{*G}{\Rightarrow} \sigma}$ (if $\sigma = (w, w'), w \in \Sigma, w' \in \Sigma'$, i.e., A is a preterminal), and $\frac{B_i \stackrel{*G}{\Rightarrow} \sigma_i,\ i=1,\ldots,n, \quad A(\sigma) \rightarrow B_1(\sigma_1), \ldots, B_n(\sigma_n)\colon \Phi(\bar{\sigma})}{A \stackrel{*G}{\Rightarrow} \sigma}$.

In LWFGs all syntagmas $\sigma = (w, w')$, derived from a nonterminal A have the same category of their semantic molecules w'.[3]

The language of a grammar G is the set of all syntagmas generated from the start symbol S, i.e., $L(G) = \{\sigma | \sigma = (w, w'), w \in \Sigma^+, S \stackrel{*G}{\Rightarrow} \sigma\}$. The *set of all syntagmas* generated by *a grammar* G is $L_\sigma(G) = \{\sigma | \sigma = (w, w'), w \in \Sigma^+, \exists A \in N_G, A \stackrel{*G}{\Rightarrow} \sigma\}$. Given a LWFG G we call a set $E_\sigma \subseteq L_\sigma(G)$ a sublanguage of G. Extending the notation, given a LWFG G, the set of syntagmas generated by a *rule* $(A \rightarrow \beta\colon \Phi) \in P_G$ is $L_\sigma(A \rightarrow \beta\colon \Phi) = \{\sigma | \sigma = (w, w'), w \in \Sigma^+, (A \rightarrow \beta\colon \Phi) \stackrel{*G}{\Rightarrow} \sigma\}$, where $(A \rightarrow \beta\colon \Phi) \stackrel{*G}{\Rightarrow} \sigma$ denotes the ground derivation $A \stackrel{*G}{\Rightarrow} \sigma$ obtained using the rule $A \rightarrow \beta\colon \Phi$ in the last derivation step (we have bottom-up derivation). We will use the short notation $L_\sigma(r)$, where r is a grammar rule.

Given a LWFG G and a sublanguage E_σ (not necessarily of G) we denote by $\mathbb{S}(G) = L_\sigma(G) \cap E_\sigma$, the set of syntagmas generated by G *reduced to the sublanguage* E_σ. Given a grammar rule $r \in P_G$, we call $\mathbb{S}(r) = L_\sigma(r) \cap E_\sigma$ the set of syntagmas generated by r *reduced to the sublanguage* E_σ.

As we have previously mentioned, the partial ordering among grammar nonterminals allows the ordering of the syntagmas generated by the grammar, which allows us to define the *representative examples* of a LWFG.

Representative Examples. Informally, the representative examples E_R of a LWFG, G, are the simplest syntagmas ground-derived by the grammar G, i.e., for each grammar rule there exist a syntagma which is ground-derived from it in the minimum number of steps. Thus, the size of the representative example set is equal with the size of the set of grammar rules, $|E_R| = |P_G|$.

This set of representative examples is used by the grammar learning model to generate the candidate hypotheses. For generalization, a larger sublanguage $E_\sigma \supseteq E_R$ is used, which we call representative sublanguage.

[2] The ground derivation ("reduction" in (Wintner, 1999)) can be viewed as the bottom-up counterpart of the usual derivation.

[3] This property is used for determining the lhs nonterminal of the learned rule.

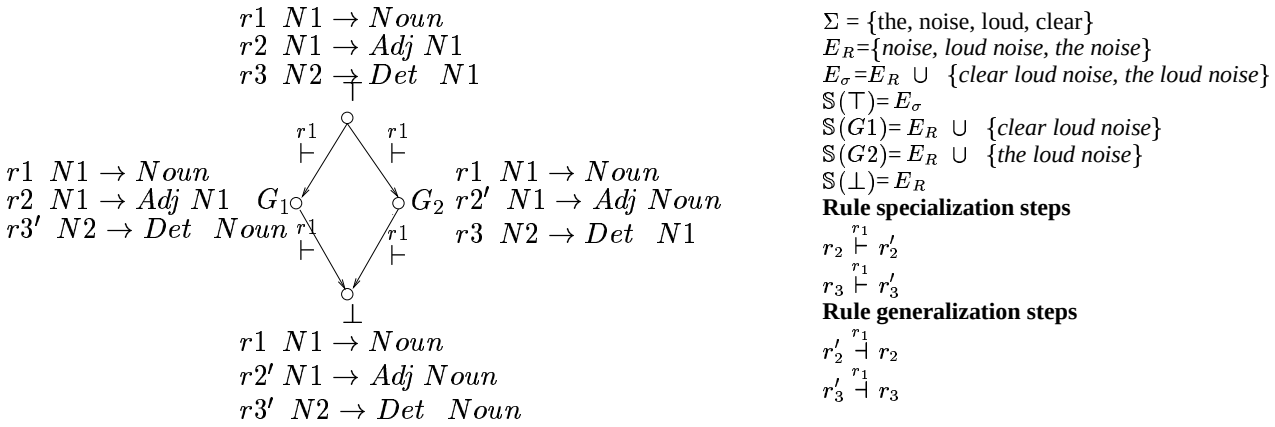

Figure 2: Example of a simple grammar lattice. All grammars generate E_R, and only $\top$ generates E_σ (Σ is a common lexicon for all the grammars)

3 A Grammar Lattice as a Search Space for Grammar Induction

In this section we present a class of Lexicalized Well-Founded Grammars that form a complete lattice. This grammar lattice is the search space for our grammar induction model, which we present in Section 4. An example of a grammar lattice is given in Figure 2, where for simplicity, we only show the context-free backbone of the grammar rules, and only strings, not syntagmas. Intuitively, the grammars found lower in the lattice are more specialized than the ones higher in the lattice. For learning, E_R is used to generate the most specific hypotheses (grammar rules), and thus all the grammars should be able to generate those examples. The sublanguage E_σ is used during generalization, thus only the most general grammar, $\top$, is able to generate the entire sublanguage. In other words, the generalization process is bounded by E_σ, that is why our model is called Grammar Approximation by Representative Sublanguage.

There are two properties that LWFGs should have in order to form a complete lattice: 1) they should be unambiguous, and 2) they should preserve the parsing of the representative example set, E_R. We define these two properties in turn.

Definition 3. A LWFG, G, is *unambiguous* w.r.t. a sublanguage $E_\sigma \subseteq L_\sigma(G)$ if $\forall \sigma \in E_\sigma$ there is one and only one rule that derives σ.

Since the unambiguity is relative to a set of syntagmas (pairs of strings and their semantic molecules) and not to a set of natural language strings, the requirement is compatible with modeling natural language. For example, an ambiguous string such as *John saw the man with the telescope* corresponds to two unambiguous syntagmas.

In order to define the second property, we need to define *the rule specialization step* and *the rule generalization step* of unambiguous LWFGs, such that they are *E_R-parsing-preserving* and are the inverse of each other. The property of E_R-parsing-preserving means that both the initial and the specialized/generalized rules ground-derive the same syntagma, $\sigma_A \in E_R$.

Definition 4. The *rule specialization step*:

$$\frac{A(\sigma_A)\rightarrow\alpha B(\sigma_B^*)\gamma\colon \Phi_A \qquad B(\sigma_B)\rightarrow\beta\colon \Phi_B}{A(\sigma_A)\rightarrow\alpha\beta\gamma\colon \Phi'_A}$$

is *E_R-parsing-preserving*, if there exists $\sigma_A \in E_R$ and $r_{gen} \overset{*G}{\Rightarrow} \sigma_A$ and $r_{spec} \overset{*G'}{\Rightarrow} \sigma_A$, where $r_{gen} = A(\sigma_A) \rightarrow \alpha B(\sigma_B^*)\gamma\colon \Phi_A$, $r_B = B(\sigma_B) \rightarrow \beta\colon \Phi_B$, and $r_{spec} = A(\sigma_A) \rightarrow \alpha\beta\gamma\colon \Phi'_A$. We write $r_{gen} \overset{r_B}{\vdash} r_{spec}$.

The *rule generalization step* :

$$\frac{A(\sigma_A)\rightarrow\alpha\beta\gamma\colon \Phi'_A \qquad B(\sigma_B)\rightarrow\beta\colon \Phi_B}{A(\sigma_A)\rightarrow\alpha B(\sigma_B^*)\gamma\colon \Phi_A}$$

is *E_R-parsing-preserving*, if there exists $\sigma_A \in E_R$ and $r_{spec} \overset{*G'}{\Rightarrow} \sigma_A$ and $r_{gen} \overset{*G}{\Rightarrow} \sigma_A$. We write $r_{spec} \overset{r_B}{\dashv} r_{gen}$.

Since σ_A is a representative example, it is derived in the minimum number of derivation steps, and thus the rule r_B is always an ordered, non-recursive rule.

The goal of the rule specialization step is to obtain a new target grammar G' from G by modifying a rule of G. Similarly, the goal of the rule generalization step is to obtain a new target grammar G from G' by modifying a rule of G'. They are not to be taken as the derivation/reduction concepts in parsing. The specialization/generalization steps are the inverse of each other. From both the specialization and the generalization step we have that: $L_\sigma(r_{gen}) \supseteq L_\sigma(r_{spec})$.

In Figure 2, the specialization step $r_2 \overset{r_1}{\vdash} r_2'$ is E_R-parsing-preserving, because the rule r_2' ground-derives the syntagma *loud noise*. If instead we would have a specialization step $r_2 \overset{r_2}{\vdash} r_2''$ ($r_2'' = N1 \rightarrow Adj\ Adj\ N1$), it would not be E_R-parsing-preserving since the syntagma *loud noise* could no longer be ground-derived from the rule r_2'' (which requires two adjectives).

Definition 5. A grammar G' is *one-step specialized* from a grammar G, $G \overset{r_1}{\vdash} G'$, if $\exists r, r_1 \in P_G$ and $\exists r', r_1 \in P_{G'}$, s.t. $r \overset{r_1}{\vdash} r'$, and $\forall q \neq r, q \in P_G$ iff $q \in P_{G'}$. A grammar G' is *specialized* from a grammar G, $G \overset{*}{\vdash} G'$, if it is obtained from G in n-specialization steps: $G \overset{r_1}{\vdash} \cdots \overset{r_n}{\vdash} G'$, where n is finite. We extend the notation so that we have $G \overset{*}{\vdash} G$. Similarly, we define the concept of a grammar G *g*eneralized from a grammar G', $G' \overset{*}{\dashv} G$ using the rule generalization step.

In Figure 2, the grammar $\perp$ is one-step specialized from the grammar G_1, i.e., $G_1 \overset{r_1}{\vdash} \perp$, since $\perp$ preserve the parsing of the representative examples E_R. A grammar which contains the rule $r_2'' = N1 \rightarrow Adj\ Adj N1$ instead of r_2' is not specialized from the grammar G_1 since it does not preserve the parsing of the representative example set, E_R. Such grammars will not be in the lattice.

In order to define the grammar lattice we need to introduce one more concept: a *normalized* grammar w.r.t. a sublanguage.

Definition 6. A LWFG G is called *normalized* w.r.t. a sublanguage E_σ (not necessarily of G), if none of the grammar rules r_{spec} of G can be further generalized to a rule r_{gen} by the rule generalization step such that $\mathbb{S}(r_{spec}) \subset \mathbb{S}(r_{gen})$.

In Figure 2, grammar $\top$ is normalized w.r.t. E_σ, while $\perp$, G_1 and G_2 are not.

We now define a grammar lattice $\mathfrak{L}$ which will be the search space for our grammar learning model. We first define the set of lattice elements $\mathcal{L}$.

Let $\top$ be a LWFG, normalized and unambiguous w.r.t. a sublanguage $E_\sigma \subseteq L_\sigma(\top)$ which includes the representative example set E_R of the grammar $\top$ ($E_\sigma \supseteq E_R$). Let $\mathcal{L} = \{G | \top \overset{*}{\vdash} G\}$ be the set of grammars specialized from $\top$. We call $\top$ the *top element* of $\mathcal{L}$, and $\perp$ the *bottom element* of $\mathcal{L}$, if $\forall G \in \mathcal{L}, \top \overset{*}{\vdash} G \wedge G \overset{*}{\vdash} \perp$. The bottom element, $\perp$, is the grammar specialized from $\top$, such that the right-hand side of all grammar rules contains only preterminals. We have $\mathbb{S}(\top) = E_\sigma$ and $\mathbb{S}(\perp) \supseteq E_R$.

The grammars in $\mathcal{L}$ have the following two properties (Muresan, 2006):

- For two grammars G and G', we have that G' is specialized from G if and only if G is generalized from G', with $L_\sigma(G) \supseteq L_\sigma(G')$.
- All grammars in $\mathcal{L}$ preserve the parsing of the representative example set E_R.

Note that we have that for $G, G' \in \mathcal{L}$, if $G \overset{*}{\vdash} G'$ then $\mathbb{S}(G) \supseteq \mathbb{S}(G')$.

The system $\mathfrak{L} = \langle \mathcal{L}, \overset{*}{\vdash} \rangle$ is a complete grammar lattice (see (Muresan, 2006) for the full formal proof). In Figure 2 the grammars G_1, G_2, $\top$, $\perp$ preserve the parsing of the representative examples E_R. We have that $\top \overset{r_1}{\vdash} G_1$, $\top \overset{r_1}{\vdash} G_2$, $G_2 \overset{r_1}{\vdash} \perp$, $G_1 \overset{r_1}{\vdash} \perp$ and $\top \overset{*}{\vdash} \perp$. Due to space limitation we do not define here the *least upper bound* (lub), $\curlyvee$ and the *greatest lower bound* (glb), $\curlywedge$ operators, but in this example $\top = G_1 \curlyvee G_2$, $\perp = G_1 \curlywedge G_2$.

In oder to give a learnability theorem we need to show that $\perp$ and $\top$ elements of the lattice can be built. First, an assumption in our learning model is that the rules corresponding to the grammar preterminals are given. Thus, for a given set of representative examples, E_R, we can build the grammar $\perp$ using a bottom-up robust parser, which returns partial analyses (chunks) if it cannot return a full parse. In order to soundly build the $\top$ element of the grammar lattice from the $\perp$ grammar through generalization, we must give the definition of a grammar G *conformal* w.r.t. E_σ.

Definition 7. A LWFG G is *conformal* w.r.t. a sublanguage $E_\sigma \subseteq L_\sigma(G)$ iff G is normalized and unambiguous w.r.t. E_σ and the rule specialization step guarantees that $\mathbb{S}(r_{gen}) \supset \mathbb{S}(r_{spec})$ for all grammars specialized from G.

The only rule generalization steps allowed in the grammar induction process are those which guarantee the same relation $\mathbb{S}(r_{spec}) \subset \mathbb{S}(r_{gen})$, which ensures that all the generalized grammars belong to the grammar lattice.

In Figure 2, $\top$ is conformal to the given sublanguage E_σ. If the sublanguage were $E^*_\sigma = E_R \cup \{$*clear loud noise*$\}$ then $\top$ would not be conformal to E^*_σ since $\mathbb{S}(\top) = \mathbb{S}(G_1) = E^*_\sigma$ and thus the specialization step would not satisfy the relation $\mathbb{S}(N2 \rightarrow Det\ N1) \supset \mathbb{S}(N2 \rightarrow Det\ Noun)$. During learning, the generalization step cannot generalize from grammar G_1 to $\top$.

Theorem 1 (Learnability Theorem). *If E_R is the set of representative examples associated with a LWFG G conformal w.r.t. a sublanguage $E_\sigma \supseteq E_R$, then G can always be learned from E_R and E_σ as the grammar lattice top element ($\top = G$).*

The proof is given in (Muresan, 2006).

If the hypothesis of Theorem 1 holds, then any grammar induction algorithm that uses the complete lattice search space can converge to the lattice top element, using different search strategies. In the next section we present our new model of grammar learning which relies on the property of the search space as grammar lattice.

4 Grammar Induction Model

Based on the theoretical foundation of the hypothesis search space for LWFG learning given in the previous section, we define our grammar induction model. First, we present the LWFG induction as an Inductive Logic Programming problem. Second, we present our new relational learning model for LWFG induction, called *Grammar Approximation by Representative Sublanguage (GARS)*.

4.1 Grammar Induction Problem in ILP-setting

Inductive Logic Programming (ILP) is a class of relational learning methods concerned with inducing first-order Horn clauses from examples and background knowledge. Kietz and Džeroski (1994) have formally defined the *ILP-learning problem* as the tuple $\langle \vdash, LB, LE, LH \rangle$, where $\vdash$ is the provability relation (also called the generalization model), LB is the language of the background knowledge, LE is the language of the (positive and negative) examples, and LH is the hypothesis language. The general ILP-learning problem is undecidable. Possible choices to restrict the ILP-problem are: the provability relation, $\vdash$, the background knowledge and the hypothesis language. Research in ILP has presented positive results only for very limited subclasses of first-order logic (Kietz and Džeroski, 1994; Cohen, 1995), which are not appropriate to model natural language grammars.

Our grammar induction problem can be formulated as an ILP-learning problem $\langle \vdash, LB, LE, LH \rangle$ as follows:

- The provability relation, $\vdash$, is given by robust parsing, and we denote it by $\vdash_{rp}$. We use the "parsing as deduction" technique (Shieber et al., 1995). For all syntagmas we can say in polynomial time whether they belong or not to the grammar language. Thus, using the $\vdash_{rp}$ as generalization model, our grammar induction problem is decidable.

- The language of background knowledge, LB, is the set of LWFG rules that are already learned together with elementary syntagmas (i.e., corresponding to the lexicon), which are ground atoms (the variables are made constants).

- The language of examples, LE are syntagmas of the representative sublanguage, which are ground atoms. We only have positive examples.

- The hypothesis language, LH, is a LWFG lattice whose top element is a conformal grammar, and which preserve the parsing of representative examples.

4.2 Grammar Approximation by Representative Sublanguage Model

We have formulated the grammar induction problem in the ILP-setting. The theoretical learning model,

called *Grammar Approximation by Representative Sublanguage (GARS)*, can be formulated as follows:
Given:

- a representative example set E_R, lexically consistent (i.e., it allows the construction of the grammar lattice $\perp$ element)
- a finite sublanguage E_σ, conformal and thus unambiguous, which includes the representative example set, $E_\sigma \supseteq E_R$. We called this sublanguage, the *representative sublanguage*

Learn a grammar G, using the above ILP-learning setting, such that G is unique and $E_\sigma \subseteq L_\sigma(G)$.

The hypothesis space is a complete grammar lattice, and thus the uniqueness property of the learned grammar is guaranteed by the learnability theorem (i.e., the learned grammar is the lattice top element). This learnability result extends significantly the class of problems learnable by ILP methods.

The GARS model uses two polynomial algorithms for LWFG learning. In the first algorithm, the learner is presented with an ordered set of representative examples (syntagmas), i.e., the examples are ordered from the simplest to the most complex. The reader should remember that for a LWFG G, there exists a partial ordering among the grammar nonterminals, which allows a total ordering of the representative examples of the grammar G. Thus, in this algorithm, the learner has access to the ordered representative syntagmas when learning the grammar. However, in practice it might be difficult to provide the learner with the "true" order of examples, especially when modeling complex language phenomena. The second algorithm is an iterative algorithm that learns starting from a random order of the representative example set. Due to the property of the search space, both algorithms converge to the same target grammar.

Using ILP and theory revision terminology (Greiner, 1999), we can establish the following analogy: syntagmas (examples) are "labeled queries", the LWFG lattice is the "space of theories", and a LWFG in the lattice is "a theory." The first algorithm learns from an "empty theory", while the second algorithm is an instance of "theory revision", since the grammar ("theory") learned during the first iteration, is then revised, by deleting and adding rules.

Both of these algorithms are cover set algorithms. In the first step the most specific grammar rule is generated from the current representative example. The category name annotated in the representative example gives the name of the lhs nonterminal (predicate invention in ILP terminology), while the robust parser returns the minimum number of chunks that cover the representative example. In the second step this most specific rule is generalized using as performance criterion the number of the examples in E_σ that can be parsed using the candidate grammar rule (hypothesis) together with the previous learned rules. For the full details for these two algorithms, and the proof of their polynomial efficiency, we refer the reader to (Muresan, 2006).

5 Discussion

A practical advantage of our GARS model is that instead of writing syntactic-semantic grammars by hand (both rules and constraints), we construct just a small annotated treebank - utterances and their semantic molecules. If the grammar needs to be refined, or enhanced, we only refine, or enhance the representative examples/sublanguage, and not the grammar rules and constraints, which would be a more difficult task.

We have built a framework to test whether our GARS model can learn diverse and complex linguistic phenomena. We have primarily analyzed a set of definitional-type sentences in the medical domain. The phenomena covered by our learned grammar includes complex noun phrases (including noun compounds, nominalization), prepositional phrases, relative clauses and reduced relative clauses, finite and non-finite verbal constructions (including, tense, aspect, negation, and subject-verb agreement), copula *to be*, and raising and control constructions. We also learned rules for wh-questions (including long-distance dependencies). In Figure 3 we show the ontology-level representation of a definition-type sentence obtained using our learned grammar. It includes the treatment of reduced relative clauses, raising construction (*tends to persist*, where *virus* is not the argument of *tends* but the argument of *persist*), and noun compounds. The learned grammar together with a semantic interpreter targeted to terminological knowledge has been used in an acquisition-query experiment, where the answers are at the concept level (the querying is a graph

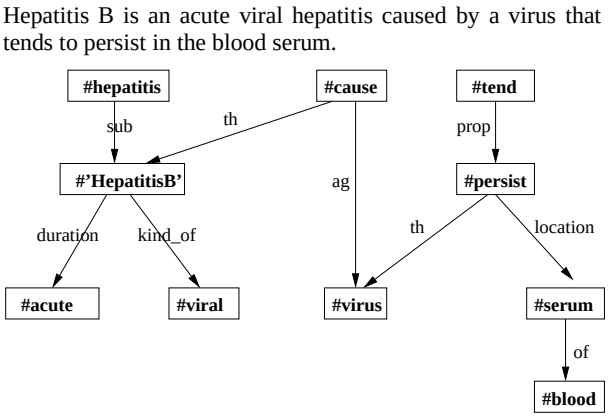

Figure 3: A definition-type sentence and its ontology-based representation obtained using our learned LWFG

matching problem where the "wh-word" matches the answer concept). A detailed discussion of the linguistic phenomena covered by our learned grammar using the GARS model, as well as the use of this grammar for terminological knowledge acquisition, is given in (Muresan, 2006).

To learn the grammar used in these experiments we annotated 151 representative examples and 448 examples used as a representative sublanguage for generalization. Annotating these examples requires knowledge about categories and their attributes. We used 31 categories (nonterminals) and 37 attributes (e.g., category, head, number, person). In this experiment, we chose the representative examples guided by the type of phenomena we wanted to modeled and which occurred in our corpus. We also used 13 lexical categories (i.e., parts of speech). The learned grammar contains 151 rules and 151 constraints.

6 Conclusion

We have presented Lexicalized Well-Founded Grammars, a type of constraint-based grammars for natural language specifically designed to enable learning from representative examples annotated with semantics. We have presented a new grammar learning model and showed that the search space is a complete grammar lattice that guarantees the uniqueness of the learned grammar. Starting from these fundamental theoretical results, there are several directions into which to take this research. A first obvious extension is to have probabilistic-LWFGs. For example, the ontology constraints might not be "hard" constraints, but "soft" ones (because language expressions are more or less likely to be used in a certain context). Investigating where to add probabilities (ontology, grammar rules, or both) is part of our planned future work. Another future extension of this work is to investigate how to automatically select the representative examples from an existing treebank.

Abstract

Standard approaches to Chinese word segmentation treat the problem as a tagging task, assigning labels to the characters in the sequence indicating whether the character marks a word boundary. Discriminatively trained models based on local character features are used to make the tagging decisions, with Viterbi decoding finding the highest scoring segmentation. In this paper we propose an alternative, word-based segmentor, which uses features based on complete words and word sequences. The generalized perceptron algorithm is used for discriminative training, and we use a beam-search decoder. Closed tests on the first and second SIGHAN bakeoffs show that our system is competitive with the best in the literature, achieving the highest reported F-scores for a number of corpora.

1 Introduction

Words are the basic units to process for most NLP tasks. The problem of Chinese word segmentation (CWS) is to find these basic units for a given sentence, which is written as a continuous sequence of characters. It is the initial step for most Chinese processing applications.

Chinese character sequences are ambiguous, often requiring knowledge from a variety of sources for disambiguation. Out-of-vocabulary (OOV) words are a major source of ambiguity. For example, a difficult case occurs when an OOV word consists of characters which have themselves been seen as words; here an automatic segmentor may split the OOV word into individual single-character words. Typical examples of unseen words include Chinese names, translated foreign names and idioms.

The segmentation of known words can also be ambiguous. For example, "这里面" should be "这 里 (here) 面 (flour)" in the sentence "这里面和米很贵" (flour and rice are expensive here) or "这 (here) 里面 (inside)" in the sentence "这里面很冷" (it's cold inside here). The ambiguity can be resolved with information about the neighboring words. In comparison, for the sentences "洽谈会很成功", possible segmentations include "洽谈 (the discussion) 会 (will) 很 (very) 成功 (be successful)" and "洽谈会 (the discussion meeting) 很 (very) 成功 (be successful)". The ambiguity can only be resolved with contextual information outside the sentence. Human readers often use semantics, contextual information about the document and world knowledge to resolve segmentation ambiguities.

There is no fixed standard for Chinese word segmentation. Experiments have shown that there is only about 75% agreement among native speakers regarding the correct word segmentation (Sproat et al., 1996). Also, specific NLP tasks may require different segmentation criteria. For example, "北京银行" could be treated as a single word (Bank of Beijing) for machine translation, while it is more naturally segmented into "北京 (Beijing) 银行 (bank)" for tasks such as text-to-speech synthesis. Therefore, supervised learning with specifically defined training data has become the dominant approach.

Following Xue (2003), the standard approach to

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 840–847,
Prague, Czech Republic, June 2007.

supervised learning for CWS is to treat it as a tagging task. Tags are assigned to each character in the sentence, indicating whether the character is a single-character word or the start, middle or end of a multi-character word. The features are usually confined to a five-character window with the current character in the middle. In this way, dynamic programming algorithms such as the Viterbi algorithm can be used for decoding.

Several discriminatively trained models have recently been applied to the CWS problem. Examples include Xue (2003), Peng et al. (2004) and Shi and Wang (2007); these use maximum entropy (ME) and conditional random field (CRF) models (Ratnaparkhi, 1998; Lafferty et al., 2001). An advantage of these models is their flexibility in allowing knowledge from various sources to be encoded as features.

Contextual information plays an important role in word segmentation decisions; especially useful is information about surrounding words. Consider the sentence "中国外企业", which can be from "其中 (among which) 国外 (foreign) 企业 (companies)", or "中国 (in China) 外企 (foreign companies) 业务 (business)". Note that the five-character window surrounding "外" is the same in both cases, making the tagging decision for that character difficult given the local window. However, the correct decision can be made by comparison of the two three-word windows containing this character.

In order to explore the potential of word-based models, we adapt the perceptron discriminative learning algorithm to the CWS problem. Collins (2002) proposed the perceptron as an alternative to the CRF method for HMM-style taggers. However, our model does not map the segmentation problem to a tag sequence learning problem, but defines features on segmented sentences directly. Hence we use a beam-search decoder during training and testing; our idea is similar to that of Collins and Roark (2004) who used a beam-search decoder as part of a perceptron parsing model. Our work can also be seen as part of the recent move towards *search-based* learning methods which do not rely on dynamic programming and are thus able to exploit larger parts of the context for making decisions (Daume III, 2006).

We study several factors that influence the performance of the perceptron word segmentor, including the averaged perceptron method, the size of the beam and the importance of word-based features. We compare the accuracy of our final system to the state-of-the-art CWS systems in the literature using the first and second SIGHAN bakeoff data. Our system is competitive with the best systems, obtaining the highest reported F-scores on a number of the bakeoff corpora. These results demonstrate the importance of word-based features for CWS. Furthermore, our approach provides an example of the potential of search-based discriminative training methods for NLP tasks.

2 The Perceptron Training Algorithm

We formulate the CWS problem as finding a mapping from an input sentence $x \in X$ to an output sentence $y \in Y$, where X is the set of possible raw sentences and Y is the set of possible segmented sentences. Given an input sentence x, the correct output segmentation $F(x)$ satisfies:

$$F(x) = \arg\max_{y \in \text{GEN}(x)} \text{Score}(y)$$

where $\text{GEN}(x)$ denotes the set of possible segmentations for an input sentence x, consistent with notation from Collins (2002).

The score for a segmented sentence is computed by first mapping it into a set of features. A feature is an indicator of the occurrence of a certain pattern in a segmented sentence. For example, it can be the occurrence of "里面" as a single word, or the occurrence of "里" separated from "面" in two adjacent words. By defining features, a segmented sentence is mapped into a global feature vector, in which each dimension represents the count of a particular feature in the sentence. The term "global" feature vector is used by Collins (2002) to distinguish between feature count vectors for whole sequences and the "local" feature vectors in ME tagging models, which are Boolean valued vectors containing the indicator features for one element in the sequence.

Denote the global feature vector for segmented sentence y with $\Phi(y) \in R^d$, where d is the total number of features in the model; then $\text{Score}(y)$ is computed by the dot product of vector $\Phi(y)$ and a parameter vector $\overline{\alpha} \in R^d$, where α_i is the weight for the ith feature:

$$\text{Score}(y) = \Phi(y) \cdot \overline{\alpha}$$

Inputs: training examples (x_i, y_i)
Initialization: set $\overline{\alpha} = 0$
Algorithm:
  for $t = 1..T$, $i = 1..N$
    calculate $z_i = \arg\max_{y \in \text{GEN}(x_i)} \Phi(y) \cdot \overline{\alpha}$
    if $z_i \neq y_i$
      $\overline{\alpha} = \overline{\alpha} + \Phi(y_i) - \Phi(z_i)$
Outputs: $\overline{\alpha}$

Figure 1: the perceptron learning algorithm, adapted from Collins (2002)

The perceptron training algorithm is used to determine the weight values $\overline{\alpha}$.

The training algorithm initializes the parameter vector as all zeros, and updates the vector by decoding the training examples. Each training sentence is turned into the raw input form, and then decoded with the current parameter vector. The output segmented sentence is compared with the original training example. If the output is incorrect, the parameter vector is updated by adding the global feature vector of the training example and subtracting the global feature vector of the decoder output. The algorithm can perform multiple passes over the same training sentences. Figure 1 gives the algorithm, where N is the number of training sentences and T is the number of passes over the data.

Note that the algorithm from Collins (2002) was designed for discriminatively training an HMM-style tagger. Features are extracted from an input sequence x and its corresponding tag sequence y:

$$\text{Score}(x, y) = \Phi(x, y) \cdot \overline{\alpha}$$

Our algorithm is not based on an HMM. For a given input sequence x, even the length of different candidates y (the number of words) is not fixed. Because the output sequence y (the segmented sentence) contains all the information from the input sequence x (the raw sentence), the global feature vector $\Phi(x, y)$ is replaced with $\Phi(y)$, which is extracted from the candidate segmented sentences directly.

Despite the above differences, since the theorems of convergence and their proof (Collins, 2002) are only dependent on the feature vectors, and not on the source of the feature definitions, the perceptron algorithm is applicable to the training of our CWS model.

2.1 The averaged perceptron

The averaged perceptron algorithm (Collins, 2002) was proposed as a way of reducing overfitting on the training data. It was motivated by the voted-perceptron algorithm (Freund and Schapire, 1999) and has been shown to give improved accuracy over the non-averaged perceptron on a number of tasks. Let N be the number of training sentences, T the number of training iterations, and $\overline{\alpha}^{n,t}$ the parameter vector immediately after the nth sentence in the tth iteration. The averaged parameter vector $\overline{\gamma} \in R^d$ is defined as:

$$\overline{\gamma} = \frac{1}{NT} \sum_{n=1..N, t=1..T} \overline{\alpha}^{n,t}$$

To compute the averaged parameters $\overline{\gamma}$, the training algorithm in Figure 1 can be modified by keeping a total parameter vector $\overline{\sigma}^{n,t} = \sum \overline{\alpha}^{n,t}$, which is updated using $\overline{\alpha}$ after each training example. After the final iteration, $\overline{\gamma}$ is computed as $\overline{\sigma}^{n,t}/NT$. In the averaged perceptron algorithm, $\overline{\gamma}$ is used instead of $\overline{\alpha}$ as the final parameter vector.

With a large number of features, calculating the total parameter vector $\overline{\sigma}^{n,t}$ after each training example is expensive. Since the number of changed dimensions in the parameter vector $\overline{\alpha}$ after each training example is a small proportion of the total vector, we use a lazy update optimization for the training process.[1] Define an update vector $\overline{\tau}$ to record the number of the training sentence n and iteration t when each dimension of the averaged parameter vector was last updated. Then after each training sentence is processed, only update the dimensions of the total parameter vector corresponding to the features in the sentence. (Except for the last example in the last iteration, when each dimension of $\overline{\tau}$ is updated, no matter whether the decoder output is correct or not).

Denote the sth dimension in each vector before processing the nth example in the tth iteration as $\alpha_s^{n-1,t}$, $\sigma_s^{n-1,t}$ and $\tau_s^{n-1,t} = (n_{\tau,s}, t_{\tau,s})$. Suppose that the decoder output $z_{n,t}$ is different from the training example y_n. Now $\alpha_s^{n,t}$, $\sigma_s^{n,t}$ and $\tau_s^{n,t}$ can

[1] Daume III (2006) describes a similar algorithm.

be updated in the following way:

$$\sigma_s^{n,t} = \sigma_s^{n-1,t} + \alpha_s^{n-1,t} \times (tN + n - t_{\tau,s}N - n_{\tau,s})$$
$$\alpha_s^{n,t} = \alpha_s^{n-1,t} + \Phi(y_n) - \Phi(z_{n,t})$$
$$\sigma_s^{n,t} = \sigma_s^{n,t} + \Phi(y_n) - \Phi(z_{n,t})$$
$$\tau_s^{n,t} = (n, t)$$

We found that this lazy update method was significantly faster than the naive method.

3 The Beam-Search Decoder

The decoder reads characters from the input sentence one at a time, and generates candidate segmentations incrementally. At each stage, the next incoming character is combined with an existing candidate in two different ways to generate new candidates: it is either appended to the last word in the candidate, or taken as the start of a new word. This method guarantees exhaustive generation of possible segmentations for any input sentence.

Two agendas are used: the source agenda and the target agenda. Initially the source agenda contains an empty sentence and the target agenda is empty. At each processing stage, the decoder reads in a character from the input sentence, combines it with each candidate in the source agenda and puts the generated candidates onto the target agenda. After each character is processed, the items in the target agenda are copied to the source agenda, and then the target agenda is cleaned, so that the newly generated candidates can be combined with the next incoming character to generate new candidates. After the last character is processed, the decoder returns the candidate with the best score in the source agenda. Figure 2 gives the decoding algorithm.

For a sentence with length l, there are 2^{l-1} different possible segmentations. To guarantee reasonable running speed, the size of the target agenda is limited, keeping only the B best candidates.

4 Feature templates

The feature templates are shown in Table 1. Features 1 and 2 contain only word information, 3 to 5 contain character and length information, 6 and 7 contain only character information, 8 to 12 contain word and character information, while 13 and 14 contain

Input: raw sentence $sent$ – a list of characters
Initialization: set agendas $src = [[]]$, $tgt = []$
Variables: candidate sentence $item$ – a list of words
Algorithm:
  for $index = 0..sent$.length-1:
    var $char = sent[index]$
    foreach $item$ in src:
      // append as a new word to the candidate
      var $item_1 = item$
      $item_1$.append($char$.toWord())
      tgt.insert($item_1$)
      // append the character to the last word
      if $item$.length > 1:
        var $item_2 = item$
        $item_2[item_2$.length$-1]$.append($char$)
        tgt.insert($item_2$)
    $src = tgt$
    $tgt = []$
Outputs: src.best_item

Figure 2: The decoding algorithm

word and length information. Any segmented sentence is mapped to a global feature vector according to these templates. There are $356,337$ features with non-zero values after 6 training iterations using the development data.

For this particular feature set, the longest range features are word bigrams. Therefore, among partial candidates ending with the same bigram, the best one will also be in the best final candidate. The decoder can be optimized accordingly: when an incoming character is combined with candidate items as a new word, only the best candidate is kept among those having the same last word.

5 Comparison with Previous Work

Among the character-tagging CWS models, Li et al. (2005) uses an uneven margin alteration of the traditional perceptron classifier (Li et al., 2002). Each character is classified independently, using information in the neighboring five-character window. Liang (2005) uses the discriminative perceptron algorithm (Collins, 2002) to score whole character tag sequences, finding the best candidate by the global score. It can be seen as an alternative to the ME and CRF models (Xue, 2003; Peng et al., 2004), which

1	word w
2	word bigram w_1w_2
3	single-character word w
4	a word starting with character c and having length l
5	a word ending with character c and having length l
6	space-separated characters c_1 and c_2
7	character bigram c_1c_2 in any word
8	the first and last characters c_1 and c_2 of any word
9	word w immediately before character c
10	character c immediately before word w
11	the starting characters c_1 and c_2 of two consecutive words
12	the ending characters c_1 and c_2 of two consecutive words
13	a word of length l and the previous word w
14	a word of length l and the next word w

Table 1: feature templates

do not involve word information. Wang et al. (2006) incorporates an N-gram language model in ME tagging, making use of word information to improve the character tagging model. The key difference between our model and the above models is the word-based nature of our system.

One existing method that is based on sub-word information, Zhang et al. (2006), combines a CRF and a rule-based model. Unlike the character-tagging models, the CRF submodel assigns tags to sub-words, which include single-character words and the most frequent multiple-character words from the training corpus. Thus it can be seen as a step towards a word-based model. However, sub-words do not necessarily contain full word information. Moreover, sub-word extraction is performed separately from feature extraction. Another difference from our model is the rule-based submodel, which uses a dictionary-based forward maximum match method described by Sproat et al. (1996).

6 Experiments

Two sets of experiments were conducted. The first, used for development, was based on the part of Chinese Treebank 4 that is not in Chinese Treebank 3 (since CTB3 was used as part of the first bakeoff). This corpus contains 240K characters (150K words and 4798 sentences). 80% of the sentences (3813) were randomly chosen for training and the rest (985 sentences) were used as development testing data. The accuracies and learning curves for the non-averaged and averaged perceptron were compared. The influence of particular features and the agenda size were also studied.

The second set of experiments used training and testing sets from the first and second international Chinese word segmentation bakeoffs (Sproat and Emerson, 2003; Emerson, 2005). The accuracies are compared to other models in the literature.

F-measure is used as the accuracy measure. Define precision p as the percentage of words in the decoder output that are segmented correctly, and recall r as the percentage of gold standard output words that are correctly segmented by the decoder. The (balanced) F-measure is $2pr/(p+r)$.

CWS systems are evaluated by two types of tests. The *closed* tests require that the system is trained only with a designated training corpus. Any extra knowledge is not allowed, including common surnames, Chinese and Arabic numbers, European letters, lexicons, part-of-speech, semantics and so on. The *open* tests do not impose such restrictions.

Open tests measure a model's capability to utilize extra information and domain knowledge, which can lead to improved performance, but since this extra information is not standardized, direct comparison between open test results is less informative.

In this paper, we focus only on the closed test. However, the perceptron model allows a wide range of features, and so future work will consider how to integrate open resources into our system.

6.1 Learning curve

In this experiment, the agenda size was set to 16, for both training and testing. Table 2 shows the precision, recall and F-measure for the development set after 1 to 10 training iterations, as well as the number of mistakes made in each iteration. The corresponding learning curves for both the non-averaged and averaged perceptron are given in Figure 3.

The table shows that the number of mistakes made in each iteration decreases, reflecting the convergence of the learning algorithm. The averaged per-

Iteration	1	2	3	4	5	6	7	8	9	10
P (non-avg)	89.0	91.6	92.0	92.3	92.5	92.5	92.5	92.7	92.6	92.6

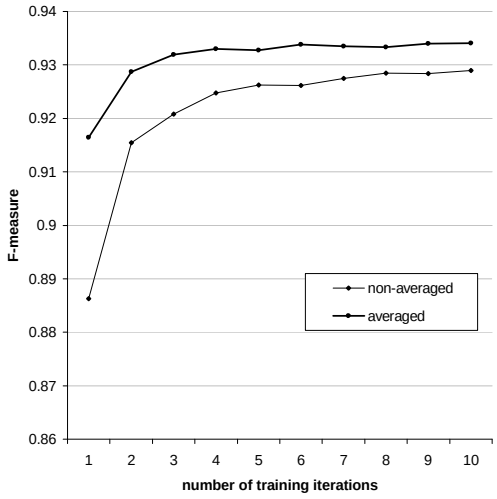

Figure 3: learning curves of the averaged and non-averaged perceptron algorithms

ceptron algorithm improves the segmentation accuracy at each iteration, compared with the non-averaged perceptron. The learning curve was used to fix the number of training iterations at 6 for the remaining experiments.

6.2 The influence of agenda size

Reducing the agenda size increases the decoding speed, but it could cause loss of accuracy by eliminating potentially good candidates. The agenda size also affects the training time, and resulting model, since the perceptron training algorithm uses the decoder output to adjust the model parameters. Table 3 shows the accuracies with ten different agenda sizes, each used for both training and testing.

Accuracy does not increase beyond $B = 16$. Moreover, the accuracy is quite competitive even with B as low as 4. This reflects the fact that the best segmentation is often within the current top few candidates in the agenda.[2] Since the training and testing time generally increases as N increases, the agenda size is fixed to 16 for the remaining experiments.

6.3 The influence of particular features

Our CWS model is highly dependent upon word information. Most of the features in Table 1 are related to words. Table 4 shows the accuracy with various features from the model removed.

Among the features, vocabulary words (feature 1) and length prediction by characters (features 3 to 5) showed strong influence on the accuracy, while word bigrams (feature 2) and special characters in them (features 11 and 12) showed comparatively weak influence.

[2]The optimization in Section 4, which has a pruning effect, was applied to this experiment. Similar observations were made in separate experiments without such optimization.

Features	F	Features	F

w/o 11, 12	93.38	w/o 13, 14	93.23

Table 4: the influence of features. (F: F-measure. Feature numbers are from Table 1)

6.4 Closed test on the SIGHAN bakeoffs

Four training and testing corpora were used in the first bakeoff (Sproat and Emerson, 2003), including the Academia Sinica Corpus (AS), the Penn Chinese Treebank Corpus (CTB), the Hong Kong City University Corpus (CU) and the Peking University Corpus (PU). However, because the testing data from the Penn Chinese Treebank Corpus is currently unavailable, we excluded this corpus. The corpora are encoded in GB (PU, CTB) and BIG5 (AS, CU). In order to test them consistently in our system, they are all converted to UTF8 without loss of information.

The results are shown in Table 5. We follow the format from Peng et al. (2004). Each row represents a CWS model. The first eight rows represent models from Sproat and Emerson (2003) that participated in at least one closed test from the table, row "Peng" represents the CRF model from Peng et al. (2004), and the last row represents our model. The first three columns represent tests with the AS, CU and PU corpora, respectively. The best score in each column is shown in bold. The last two columns represent the average accuracy of each model over the tests it participated in (SAV), and our average over the same tests (OAV), respectively. For each row the best average is shown in bold.

We achieved the best accuracy in two of the three corpora, and better overall accuracy than the majority of the other models. The average score of S10 is 0.7% higher than our model, but S10 only participated in the HK test.

Four training and testing corpora were used in the second bakeoff (Emerson, 2005), including the Academia Sinica corpus (AS), the Hong Kong City University Corpus (CU), the Peking University Corpus (PK) and the Microsoft Research Corpus (MR).

	AS	CU	PU	SAV	OAV
S01	93.8	90.1	**95.1**	93.0	**95.0**
S04			93.9	93.9	**94.0**
S05	94.2		89.4	91.8	**95.3**
S06	94.5	92.4	92.4	93.1	**95.0**
S08		90.4	93.6	92.0	**94.3**
S09	96.1		94.6	**95.4**	95.3
S10			94.7	**94.7**	94.0
S12	95.9	91.6		93.8	**95.6**
Peng	95.6	92.8	94.1	94.2	**95.0**
	96.5	**94.6**	94.0		

Table 5: the accuracies over the first SIGHAN bakeoff data.

	AS	CU	PK	MR	SAV	OAV
S14	94.7	94.3	95.0	96.4	95.1	**95.4**
S15b	**95.2**	94.1	94.1	95.8	94.8	**95.4**
S27	94.5	94.0	95.0	96.0	94.9	**95.4**
Zh-a	94.7	94.6	94.5	96.4	95.1	**95.4**
Zh-b	95.1	**95.1**	**95.1**	97.1	**95.6**	95.4
	94.6	**95.1**	94.5	**97.2**		

Table 6: the accuracies over the second SIGHAN bakeoff data.

Different encodings were provided, and the UTF8 data for all four corpora were used in this experiment.

Following the format of Table 5, the results for this bakeoff are shown in Table 6. We chose the three models that achieved at least one best score in the closed tests from Emerson (2005), as well as the sub-word-based model of Zhang et al. (2006) for comparison. Row "Zh-a" and "Zh-b" represent the pure sub-word CRF model and the confidence-based combination of the CRF and rule-based models, respectively.

Again, our model achieved better overall accuracy than the majority of the other models. One system to achieve comparable accuracy with our system is Zh-b, which improves upon the sub-word CRF model (Zh-a) by combining it with an independent dictionary-based submodel and improving the accuracy of known words. In comparison, our system is based on a single perceptron model.

In summary, closed tests for both the first and the second bakeoff showed competitive results for our

system compared with the best results in the literature. Our word-based system achieved the best F-measures over the AS (96.5%) and CU (94.6%) corpora in the first bakeoff, and the CU (95.1%) and MR (97.2%) corpora in the second bakeoff.

7 Conclusions and Future Work

We proposed a word-based CWS model using the discriminative perceptron learning algorithm. This model is an alternative to the existing character-based tagging models, and allows word information to be used as features. One attractive feature of the perceptron training algorithm is its simplicity, consisting of only a decoder and a trivial update process. We use a beam-search decoder, which places our work in the context of recent proposals for search-based discriminative learning algorithms. Closed tests using the first and second SIGHAN CWS bakeoff data demonstrated our system to be competitive with the best in the literature.

Open features, such as knowledge of numbers and European letters, and relationships from semantic networks (Shi and Wang, 2007), have been reported to improve accuracy. Therefore, given the flexibility of the feature-based perceptron model, an obvious next step is the study of open features in the segmentor.

Also, we wish to explore the possibility of incorporating POS tagging and parsing features into the discriminative model, leading to joint decoding. The advantage is two-fold: higher level syntactic information can be used in word segmentation, while joint decoding helps to prevent bottom-up error propagation among the different processing steps.

Unsupervised Coreference Resolution in a Nonparametric Bayesian Model

Aria Haghighi and Dan Klein
Computer Science Division
UC Berkeley
{aria42, klein}@cs.berkeley.edu

Abstract

We present an unsupervised, nonparametric Bayesian approach to coreference resolution which models both global entity identity across a corpus as well as the sequential anaphoric structure within each document. While most existing coreference work is driven by pairwise decisions, our model is fully generative, producing each mention from a combination of global entity properties and local attentional state. Despite being unsupervised, our system achieves a 70.3 MUC F_1 measure on the MUC-6 test set, broadly in the range of some recent supervised results.

1 Introduction

Referring to an entity in natural language can broadly be decomposed into two processes. First, speakers directly introduce new entities into discourse, entities which may be shared across discourses. This initial reference is typically accomplished with proper or nominal expressions. Second, speakers refer back to entities already introduced. This anaphoric reference is canonically, though of course not always, accomplished with pronouns, and is governed by linguistic and cognitive constraints. In this paper, we present a nonparametric generative model of a document corpus which naturally connects these two processes.

Most recent coreference resolution work has focused on the task of deciding which *mentions* (noun phrases) in a document are coreferent. The dominant approach is to decompose the task into a collection of pairwise coreference decisions. One then applies discriminative learning methods to pairs of mentions, using features which encode properties such as distance, syntactic environment, and so on (Soon et al., 2001; Ng and Cardie, 2002). Although such approaches have been successful, they have several liabilities. First, rich features require plentiful labeled data, which we do not have for coreference tasks in most domains and languages. Second, coreference is inherently a clustering or partitioning task. Naive pairwise methods can and do fail to produce coherent partitions. One classic solution is to make greedy left-to-right linkage decisions. Recent work has addressed this issue in more global ways. McCallum and Wellner (2004) use graph partioning in order to reconcile pairwise scores into a final coherent clustering. Nonetheless, all these systems crucially rely on pairwise models because cluster-level models are much harder to work with, combinatorially, in discriminative approaches.

Another thread of coreference work has focused on the problem of identifying matches between documents (Milch et al., 2005; Bhattacharya and Getoor, 2006; Daume and Marcu, 2005). These methods ignore the sequential anaphoric structure inside documents, but construct models of how and when entities are shared between them.[1] These models, as ours, are generative ones, since the focus is on cluster discovery and the data is generally unlabeled.

In this paper, we present a novel, fully generative, nonparametric Bayesian model of mentions in a document corpus. Our model captures both within- and cross-document coreference. At the top, a hierarchical Dirichlet process (Teh et al., 2006) cap-

[1] Milch et al. (2005) works with citations rather than discourses and does model the linear structure of the citations.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 848–855,
Prague, Czech Republic, June 2007.

tures cross-document entity (and parameter) sharing, while, at the bottom, a sequential model of salience captures within-document sequential structure. As a joint model of several kinds of discourse variables, it can be used to make predictions about either kind of coreference, though we focus experimentally on within-document measures. To the best of our ability to compare, our model achieves the best unsupervised coreference performance.

2 Experimental Setup

We adopt the terminology of the Automatic Context Extraction (ACE) task (NIST, 2004). For this paper, we assume that each document in a corpus consists of a set of *mentions*, typically noun phrases. Each mention is a *reference* to some entity in the domain of discourse. The coreference resolution task is to partition the mentions according to referent. Mentions can be divided into three categories, *proper* mentions (names), *nominal* mentions (descriptions), and *pronominal* mentions (pronouns).

In section 3, we present a sequence of increasingly enriched models, motivating each from shortcomings of the previous. As we go, we will indicate the performance of each model on data from ACE 2004 (NIST, 2004). In particular, we used as our development corpus the English translations of the Arabic and Chinese treebanks, comprising 95 documents and about 3,905 mentions. This data was used heavily for model design and hyperparameter selection. In section 5, we present final results for new test data from MUC-6 on which no tuning or development was performed. This test data will form our basis for comparison to previous work.

In all experiments, as is common, we will assume that we have been given as part of our input the true mention boundaries, the head word of each mention and the mention type (proper, nominal, or pronominal). For the ACE data sets, the head and mention type are given as part of the mention annotation. For the MUC data, the head was crudely chosen to be the rightmost mention token, and the mention type was automatically detected. We will not assume any other information to be present in the data beyond the text itself. In particular, unlike much related work, we do not assume gold named entity recognition (NER) labels; indeed we do not assume observed NER labels or POS tags at all. Our primary performance metric will be the MUC F_1 measure (Vilain et al., 1995), commonly used to evaluate coreference systems on a within-document basis. Since our system relies on sampling, all results are averaged over five random runs.

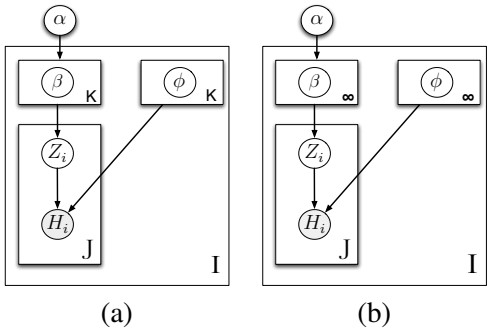

Figure 1: Graphical model depiction of document level entity models described in sections 3.1 and 3.2 respectively. The shaded nodes indicate observed variables.

3 Coreference Resolution Models

In this section, we present a sequence of generative coreference resolution models for document corpora. All are essentially mixture models, where the mixture components correspond to entities. As far as notation, we assume a collection of I documents, each with J_i mentions. We use random variables Z to refer to (indices of) entities. We will use ϕ_z to denote the parameters for an entity z, and $\boldsymbol{\phi}$ to refer to the concatenation of all such ϕ_z. X will refer somewhat loosely to the collection of variables associated with a mention in our model (such as the head or gender). We will be explicit about X and ϕ_z shortly.

Our goal will be to find the setting of the entity indices which maximize the posterior probability:

$$\begin{aligned}\mathbf{Z}^* &= \arg\max_{\mathbf{Z}} P(\mathbf{Z}|\mathbf{X}) = \arg\max_{\mathbf{Z}} P(\mathbf{Z},\mathbf{X}) \\ &= \arg\max_{\mathbf{Z}} \int P(\mathbf{Z},\mathbf{X},\boldsymbol{\phi})\, dP(\boldsymbol{\phi})\end{aligned}$$

where $\mathbf{Z}$, $\mathbf{X}$, and $\boldsymbol{\phi}$ denote all the entity indices, observed values, and parameters of the model. Note that we take a Bayesian approach in which all parameters are integrated out (or sampled). The inference task is thus primarily a search problem over the index labels $\mathbf{Z}$.

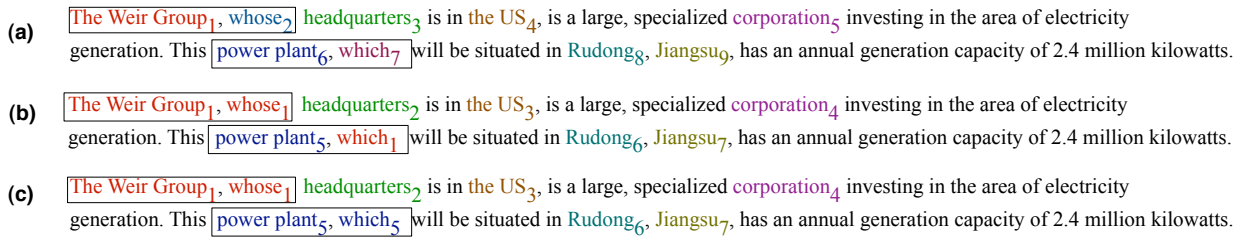

Figure 2: Example output from various models. The output from (a) is from the infinite mixture model of section 3.2. It incorrectly labels both boxed cases of anaphora. The output from (b) uses the pronoun head model of section 3.3. It correctly labels the first case of anaphora but incorrectly labels the second pronominal as being coreferent with the dominant document entity *The Weir Group*. This error is fixed by adding the salience feature component from section 3.4 as can be seen in (c).

3.1 A Finite Mixture Model

Our first, overly simplistic, corpus model is the standard finite mixture of multinomials shown in figure 1(a). In this model, each document is independent save for some global hyperparameters. Inside each document, there is a finite mixture model with a fixed number K of components. The distribution β over components (entities) is a draw from a symmetric Dirichlet distribution with concentration α. For each mention in the document, we choose a component (an entity index) z from β. Entity z is then associated with a multinomial emission distribution over head words with parameters ϕ_Z^h, which are drawn from a symmetric Dirichlet over possible mention heads with concentration λ_H.[2] Note that here the X for a mention consists only of the mention head H.

As we enrich our models, we simultaneously develop an accompanying Gibbs sampling procedure to obtain samples from $P(\mathbf{Z}|\mathbf{X})$.[3] For now, all heads H are observed and all parameters (β and $\boldsymbol{\phi}$) can be integrated out analytically: for details see Teh et al. (2006). The only sampling is for the values of $Z_{i,j}$, the entity index of mention j in document i. The relevant conditional distribution is:[4]

$$P(Z_{i,j}|\mathbf{Z}^{-i,j}, \mathbf{H}) \propto P(Z_{i,j}|\mathbf{Z}^{-i,j})P(H_{i,j}|\mathbf{Z}, \mathbf{H}^{-i,j})$$

where $H_{i,j}$ is the head of mention j in document i. Expanding each term, we have the contribution of the prior:

$$P(Z_{i,j} = z|\mathbf{Z}^{-i,j}) \propto n_z + \alpha$$

where n_z is the number of elements of $\mathbf{Z}^{-i,j}$ with entity index z. Similarly we have for the contribution of the emissions:

$$P(H_{i,j} = h|\mathbf{Z}, \mathbf{H}^{-i,j}) \propto n_{h,z} + \lambda_H$$

where $n_{h,z}$ is the number of times we have seen head h associated with entity index z in $(\mathbf{Z}, \mathbf{H}^{-i,j})$.

3.2 An Infinite Mixture Model

A clear drawback of the finite mixture model is the requirement that we specify a priori a number of entities K for a document. We would like our model to select K in an effective, principled way. A mechanism for doing so is to replace the finite Dirichlet prior on β with the non-parametric Dirichlet process (DP) prior (Ferguson, 1973).[5] Doing so gives the model in figure 1(b). Note that we now list an infinite number of mixture components in this model since there can be an unbounded number of entities. Rather than a finite β with a symmetric Dirichlet distribution, in which draws tend to have balanced clusters, we now have an infinite β. However, most draws will have weights which decay exponentially quickly in the prior (though not necessarily in the posterior). Therefore, there is a natural penalty for each cluster which is actually used.

With $\mathbf{Z}$ observed during sampling, we can integrate out β and calculate $P(Z_{i,j}|\mathbf{Z}^{-i,j})$ analytically, using the Chinese restaurant process representation:

$$P(Z_{i,j} = z|\mathbf{Z}^{-i,j}) \propto \begin{cases} \alpha, & \text{if } z = z_{new} \\ n_z, & \text{otherwise} \end{cases} \quad (1)$$

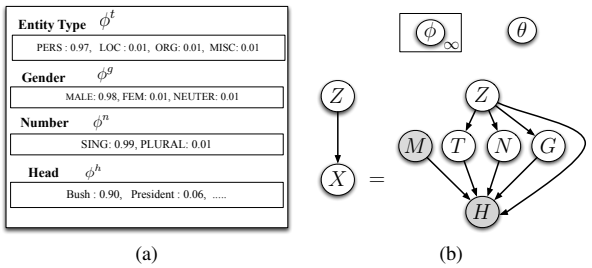
where z_{new} is a new entity index not used in $\mathbf{Z}^{-i,j}$ and n_z is the number of mentions that have entity index z. Aside from this change, sampling is identical

[2] In general, we will use a subscripted λ to indicate concentration for finite Dirichlet distributions. Unless otherwise specified, λ concentration parameters will be set to e^{-4} and omitted from diagrams.

[3] One could use the EM algorithm with this model, but EM will not extend effectively to the subsequent models.

[4] Here, $\mathbf{Z}^{-i,j}$ denotes $\mathbf{Z} - \{Z_{i,j}\}$

[5] We do not give a detailed presentation of the Dirichlet process here, but see Teh et al. (2006) for a presentation.



(a) (b)

Figure 3: (a) An entity and its parameters. (b)The head model described in section 3.3. The shaded nodes indicate observed variables. The mention type determines which set of parents are used. The dependence of mention variable on entity parameters $\boldsymbol{\phi}$ and pronoun head model $\boldsymbol{\theta}$ is omitted.

to the finite mixture case, though with the number of clusters actually occupied in each sample drifting upwards or downwards.

This model yielded a 54.5 F_1 on our development data.[6] This model is, however, hopelessly crude, capturing nothing of the structure of coreference. Its largest empirical problem is that, unsurprisingly, pronoun mentions such as *he* are given their own clusters, not labeled as coreferent with any non-pronominal mention (see figure 2(a)).

3.3 Pronoun Head Model

While an entity-specific multinomial distribution over heads makes sense for proper, and some nominal, mention heads, it does not make sense to generate pronominal mentions this same way. I.e., all entities can be referred to by generic pronouns, the choice of which depends on entity properties such as gender, not the specific entity.

We therefore enrich an entity's parameters ϕ to contain not only a distribution over lexical heads ϕ^h, but also distributions (ϕ^t, ϕ^g, ϕ^n) over properties, where ϕ^t parametrizes a distribution over entity types (PER, LOC, ORG, MISC), and ϕ^g for gender (MALE, FEMALE, NEUTER), and ϕ^n for number (SG, PL).[7] We assume each of these property distributions is drawn from a symmetric Dirichlet distribution with small concentration parameter in order to encourage a peaked posterior distribution.

[6] See section 4 for inference details.

[7] It might seem that entities should simply have, for example, a gender g rather than a distribution over genders ϕ^g. There are two reasons to adopt the softer approach. First, one can rationalize it in principle, for entities like cars or ships whose grammatical gender is not deterministic. However, the real reason is that inference is simplified. In any event, we found these property distributions to be highly determinized in the posterior.

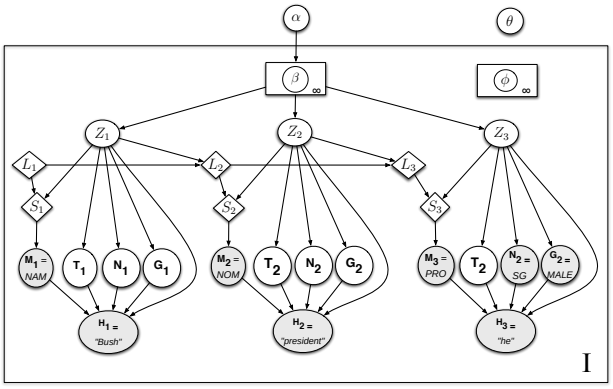


Figure 4: Coreference model at the document level with entity properties as well salience lists used for mention type distributions. The diamond nodes indicate deterministic functions. Shaded nodes indicate observed variables. Although it appears that each mention head node has many parents, for a given mention type, the mention head depends on only a small subset. Dependencies involving parameters $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$ are omitted.

Previously, when an entity z generated a mention, it drew a head word from ϕ^h_z. It now undergoes a more complex and structured process. It first draws an entity type T, a gender G, a number N from the distributions ϕ^t, ϕ^g, and ϕ^n, respectively. Once the properties are fetched, a mention type M is chosen (*proper*, *nominal*, *pronoun*), according to a global multinomial (again with a symmetric Dirichlet prior and parameter λ_M). This corresponds to the (temporary) assumption that the speaker makes a random i.i.d. choice for the type of each mention.

Our head model will then generate a head, conditioning on the entity, its properties, and the mention type, as shown in figure 3(b). If M is not a pronoun, the head is drawn directly from the entity head multinomial with parameters ϕ^h_z. Otherwise, it is drawn based on a global pronoun head distribution, conditioning on the entity properties and parametrized by $\boldsymbol{\theta}$. Formally, it is given by:

$$P(H|Z,T,G,N,M,\boldsymbol{\phi},\boldsymbol{\theta}) = \begin{cases} P(H|T,G,N,\boldsymbol{\theta}), & \text{if } M = \text{PRO} \\ P(H|\phi^h_Z), & \text{otherwise} \end{cases}$$

Although we can observe the number and gender draws for some mentions, like personal pronouns, there are some for which properties aren't observed (e.g., *it*). Because the entity property draws are not (all) observed, we must now sample the unobserved ones as well as the entity indices Z. For instance, we could sample

Salience Feature	Pronoun	Proper	Nominal
TOP	0.75	0.17	0.08
HIGH	0.55	0.28	0.17
MID	0.39	0.40	0.21
LOW	0.20	0.45	0.35
NONE	0.00	0.88	0.12

Table 1: Posterior distribution of mention type given salience by bucketing entity activation rank. Pronouns are preferred for entities which have high salience and non-pronominal mentions are preferred for inactive entities.

$T_{i,j}$, the entity type of pronominal mention j in document i, using, $P(T_{i,j}|\mathbf{Z}, \mathbf{N}, \mathbf{G}, \mathbf{H}, \mathbf{T}^{-i,j}) \propto P(T_{i,j}|\mathbf{Z})P(H_{i,j}|\mathbf{T}, \mathbf{N}, \mathbf{G}, \mathbf{H})$, where the posterior distributions on the right hand side are straightforward because the parameter priors are all finite Dirichlet. Sampling G and N are identical.

Of course we have prior knowledge about the relationship between entity type and pronoun head choice. For example, we expect that *he* is used for mentions with $T = \text{PERSON}$. In general, we assume that for each pronominal head we have a list of compatible entity types, which we encode via the prior on $\boldsymbol{\theta}$. We assume $\boldsymbol{\theta}$ is drawn from a Dirichlet distribution where each pronoun head is given a synthetic count of $(1 + \lambda_P)$ for each (t, g, n) where t is compatible with the pronoun and given λ_P otherwise. So, while it will be possible in the posterior to use *he* to refer to a non-person, it will be biased towards being used with persons.

This model gives substantially improved predictions: 64.1 F_1 on our development data. As can be seen in figure 2(b), this model does correct the systematic problem of pronouns being considered their own entities. However, it still does not have a preference for associating pronominal references to entities which are in any way local.

3.4 Adding Salience

We would like our model to capture how mention types are generated for a given entity in a robust and somewhat language independent way. The choice of entities may reasonably be considered to be independent given the mixing weights β, but how we *realize* an entity is strongly dependent on context (Ge et al., 1998).

In order to capture this in our model, we enrich it as shown in figure 4. As we proceed through a document, generating entities and their mentions, we maintain a list of the active entities and their *saliences*, or activity scores. Every time an entity is mentioned, we increment its activity score by 1, and every time we move to generate the next mention, all activity scores decay by a constant factor of 0.5. This gives rise to an ordered list of entity activations, L, where the rank of an entity decays exponentially as new mentions are generated. We call this list a *salience list*. Given a salience list, L, each possible entity z has some rank on this list. We discretize these ranks into five buckets S: TOP (1), HIGH (2-3), MID (4-6), LOW (7+), and NONE. Given the entity choices $\mathbf{Z}$, both the list L and buckets S are deterministic (see figure 4). We assume that the mention type M is conditioned on S as shown in figure 4.

We note that correctly sampling an entity now requires that we incorporate terms for how a change will affect all future salience values. This changes our sampling equation for existing entities:

$$P(Z_{i,j} = z|\mathbf{Z}^{-i,j}) \propto n_z \prod_{j' \geq j} P(M_{i,j'}|S_{i,j'}, \mathbf{Z}) \quad (2)$$

where the product ranges over future mentions in the document and $S_{i,j'}$ is the value of future salience feature given the setting of all entities, including setting the current entity $Z_{i,j}$ to z. A similar equation holds for sampling a new entity. Note that, as discussed below, this full product can be truncated as an approximation.

This model gives a 71.5 F_1 on our development data. Table 1 shows the posterior distribution of the mention type given the salience feature. This model fixes many anaphora errors and in particular fixes the second anaphora error in figure 2(c).

3.5 Cross Document Coreference

One advantage of a fully generative approach is that we can allow entities to be shared between documents in a principled way, giving us the capacity to do cross-document coreference. Moreover, sharing across documents pools information about the properties of an entity across documents.

We can easily link entities across a corpus by assuming that the pool of entities is global, with global mixing weights β_0 drawn from a DP prior with concentration parameter γ. Each document uses

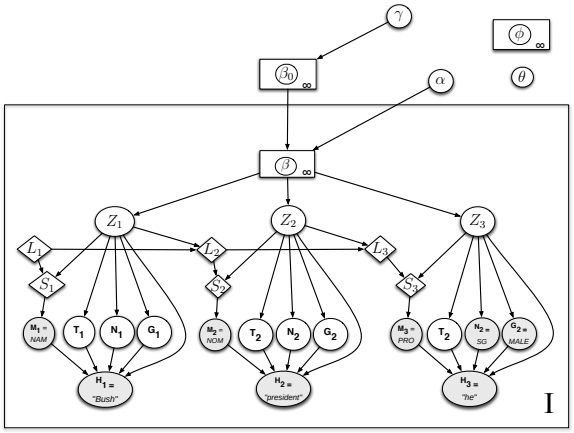

Figure 5: Graphical depiction of the HDP coreference model described in section 3.5. The dependencies between the global entity parameters ϕ and pronoun head parameters θ on the mention observations are not depicted.

the same global entities, but each has a document-specific distribution β_i drawn from a DP centered on β_0 with concentration parameter α. Up to the point where entities are chosen, this formulation follows the basic hierarchical Dirichlet process prior of Teh et al. (2006). Once the entities are chosen, our model for the realization of the mentions is as before. This model is depicted graphically in figure 5.

Although it is possible to integrate out β_0 as we did the individual β_i, we instead choose for efficiency and simplicity to sample the global mixture distribution β_0 from the posterior distribution $P(\beta_0|\mathbf{Z})$.[8] The mention generation terms in the model and sampler are unchanged.

In the full hierarchical model, our equation (1) for sampling entities, ignoring the salience component of section 3.4, becomes:

$$P(Z_{i,j} = z|\mathbf{Z}^{-i,j}, \beta_0) \propto \begin{cases} \alpha\beta_0^u, & \text{if } z = z_{new} \\ n_z + \alpha\beta_0^z, & \text{otherwise} \end{cases}$$

where β_0^z is the probability of the entity z under the sampled global entity distribution and β_0^u is the unknown component mass of this distribution.

The HDP layer of sharing improves the model's predictions to 72.5 F_1 on our development data. We should emphasize that our evaluation is of course per-document and does not reflect cross-document coreference decisions, only the gains through cross-document sharing (see section 6.2).

[8] We do not give the details here; see Teh et al. (2006) for details on how to implement this component of the sampler (called "direct assignment" in that reference).

4 Inference Details

Up until now, we've discussed Gibbs sampling, but we are not interested in sampling from the posterior $P(\mathbf{Z}|\mathbf{X})$, but in finding its mode. Instead of sampling directly from the posterior distribution, we instead sample entities proportionally to exponentiated entity posteriors. The exponent is given by $\exp \frac{ci}{k-1}$, where i is the current round number (starting at $i = 0$), $c = 1.5$ and $k = 20$ is the total number of sampling epochs. This slowly raises the posterior exponent from 1.0 to e^c. In our experiments, we found this procedure to outperform simulated annealing. We also found sampling the T, G, and N variables to be particularly inefficient, so instead we maintain soft counts over each of these variables and use these in place of a hard sampling scheme. We also found that correctly accounting for the future impact of salience changes to be particularly inefficient. However, ignoring those terms entirely made negligible difference in final accuracy.[9]

5 Final Experiments

We present our final experiments using the full model developed in section 3. As in section 3, we use true mention boundaries and evaluate using the MUC F_1 measure (Vilain et al., 1995). All hyperparameters were tuned on the development set only. The document concentration parameter α was set by taking a constant proportion of the average number of *mentions* in a document across the corpus. This number was chosen to minimize the squared error between the number of proposed entities and true entities in a document. It was not tuned to maximize the F_1 measure. A coefficient of 0.4 was chosen. The global concentration coefficient γ was chosen to be a constant proportion of αM, where M is the number of *documents* in the corpus. We found 0.15 to be a good value using the same least-square procedure. The values for these coefficients were not changed for the experiments on the test sets.

5.1 MUC-6

Our main evaluation is on the standard MUC-6 formal test set.[10] The standard experimental setup for

[9] This corresponds to truncating equation (2) at $j' = j$.

[10] Since the MUC data is not annotated with mention types, we automatically detect this information in the same way as Luo

Dataset	Num Docs.	Prec.	Recall	F_1
MUC-6	60	80.8	52.8	63.9
+DRYRUN-TRAIN	251	79.1	59.7	68.0
+ENGLISH-NWIRE	381	80.4	62.4	70.3

(a)

Dataset	Prec.	Recall	F_1
ENGLISH-NWIRE	66.7	62.3	64.2
ENGLISH-BNEWS	63.2	61.3	62.3
CHINESE-NWIRE	71.6	63.3	67.2
CHINESE-BNEWS	71.2	61.8	66.2

(b)

Table 2: Formal Results: Our system evaluated using the MUC model theoretic measure Vilain et al. (1995). The table in (a) is our performance on the thirty document MUC-6 formal test set with increasing amounts of training data. In all cases for the table, we are evaluating on the same thirty document test set which is included in our training set, since our system in unsupervised. The table in (b) is our performance on the ACE 2004 training sets.

this data is a 30/30 document train/test split. Training our system on all 60 documents of the training and test set (as this is in an unsupervised system, the unlabeled test documents are present at training time), but evaluating only on the test documents, gave 63.9 F_1 and is labeled MUC-6 in table 2(a).

One advantage of an unsupervised approach is that we can easily utilize more data when learning a model. We demonstrate the effectiveness of this fact by evaluating on the MUC-6 test documents with increasing amounts of unannotated training data. We first added the 191 documents from the MUC-6 dryrun training set (which were not part of the training data for official MUC-6 evaluation). This model gave 68.0 F_1 and is labeled +DRYRUN-TRAIN in table 2(a). We then added the ACE ENGLISH-NWIRE training data, which is from a different corpora than the MUC-6 test set and from a different time period. This model gave 70.3 F_1 and is labeled +ENGLISH-NWIRE in table 2(a).

Our results on this test set are surprisingly comparable to, though slightly lower than, some recent supervised systems. McCallum and Wellner (2004) report 73.4 F_1 on the formal MUC-6 test set, which is reasonably close to our best MUC-6 number of 70.3 F_1. McCallum and Wellner (2004) also report a much lower 91.6 F_1 on only proper nouns mentions. Our system achieves a 89.8 F_1 when evaluation is restricted to only proper mentions.[11] The

HEAD	ENT TYPE	GENDER	NUMBER
Bush: 1.0	PERS	MALE	SG
AP: 1.0	ORG	NEUTER	PL
viacom: 0.64, *company*: 0.36	ORG	NEUTER	SG
teamsters: 0.22, *union*: 0.78,	MISC	NEUTER	PL

Table 3: Frequent entities occurring across documents along with head distribution and mode of property distributions.

closest comparable unsupervised system is Cardie and Wagstaff (1999) who use pairwise NP distances to cluster document mentions. They report a 53.6 F_1 on MUC6 when tuning distance metric weights to maximize F_1 on the development set.

5.2 ACE 2004

We also performed experiments on ACE 2004 data. Due to licensing restrictions, we did not have access to the ACE 2004 formal development and test sets, and so the results presented are on the training sets.

We report results on the newswire section (NWIRE in table 2b) and the broadcast news section (BNEWS in table 2b). These datasets include the *prenominal* mention type, which is not present in the MUC-6 data. We treated prenominals analogously to the treatment of proper and nominal mentions.

We also tested our system on the Chinese newswire and broadcast news sections of the ACE 2004 training sets. Our relatively higher performance on Chinese compared to English is perhaps due to the lack of prenominal mentions in the Chinese data, as well as the presence of fewer pronouns compared to English.

Our ACE results are difficult to compare exactly to previous work because we did not have access to the restricted formal test set. However, we can perform a rough comparison between our results on the training data (without coreference annotation) to supervised work which has used the same training data (with coreference annotation) and evaluated on the formal test set. Denis and Baldridge (2007) re-

et al. (2004). A mention is proper if it is annotated with NER information. It is a pronoun if the head is on the list of English pronouns. Otherwise, it is a nominal mention. Note we do not use the NER information for any purpose but determining whether the mention is proper.

[11] The best results we know on the MUC-6 test set using the standard setting are due to Luo et al. (2004) who report a 81.3 F_1 (much higher than others). However, it is not clear this is a comparable number, due to the apparent use of gold NER features, which provide a strong clue to coreference. Regardless, it is unsurprising that their system, which has many rich features, would outperform ours.

port 67.1 F_1 and 69.2 F_1 on the English NWIRE and BNEWS respectively using true mention boundaries. While our system underperforms the supervised systems, its accuracy is nonetheless promising.

6 Discussion

6.1 Error Analysis

The largest source of error in our system is between coreferent proper and nominal mentions. The most common examples of this kind of error are appositive usages e.g. *George W. Bush, president of the US, visited Idaho.* Another error of this sort can be seen in figure 2, where the *corporation* mention is not labeled coreferent with the *The Weir Group* mention. Examples such as these illustrate the regular (at least in newswire) phenomenon that nominal mentions are used with informative intent, even when the entity is salient and a pronoun could have been used unambiguously. This aspect of nominal mentions is entirely unmodeled in our system.

6.2 Global Coreference

Since we do not have labeled cross-document coreference data, we cannot evaluate our system's cross-document performance quantitatively. However, in addition to observing the within-document gains from sharing shown in section 3, we can manually inspect the most frequently occurring entities in our corpora. Table 3 shows some of the most frequently occurring entities across the English ACE NWIRE corpus. Note that *Bush* is the most frequent entity, though his (and others') nominal cluster *president* is mistakenly its own entity. Merging of proper and nominal clusters does occur as can be seen in table 3.

6.3 Unsupervised NER

We can use our model to for unsupervised NER tagging: for each proper mention, assign the mode of the generating entity's distribution over entity types. Note that in our model the only way an entity becomes associated with an entity type is by the pronouns used to refer to it.[12] If we evaluate our system as an unsupervised NER tagger for the proper mentions in the MUC-6 test set, it yields a per-label accuracy of 61.2% (on MUC labels). Although nowhere near the performance of state-of-the-art systems, this result beats a simple baseline of always guessing PERSON (the most common entity type), which yields 46.4%. This result is interesting given that the model was not developed for the purpose of inferring entity types whatsoever.

[12] Ge et al. (1998) exploit a similar idea to assign gender to proper mentions.

7 Conclusion

We have presented a novel, unsupervised approach to coreference resolution: global entities are shared across documents, the number of entities is determined by the model, and mentions are generated by a sequential salience model and a model of pronoun-entity association. Although our system does not perform quite as well as state-of-the-art supervised systems, its performance is in the same general range, despite the system being unsupervised.

Abstract

This paper proposes a novel method for phrase-based statistical machine translation by using pivot language. To conduct translation between languages L_f and L_e with a small bilingual corpus, we bring in a third language L_p, which is named the *pivot* language. For L_f-L_p and L_p-L_e, there exist large bilingual corpora. Using only L_f-L_p and L_p-L_e bilingual corpora, we can build a translation model for L_f-L_e. The advantage of this method lies in that we can perform translation between L_f and L_e even if there is no bilingual corpus available for this language pair. Using BLEU as a metric, our pivot language method achieves an absolute improvement of 0.06 (22.13% relative) as compared with the model directly trained with 5,000 L_f-L_e sentence pairs for French-Spanish translation. Moreover, with a small L_f-L_e bilingual corpus available, our method can further improve the translation quality by using the additional L_f-L_p and L_p-L_e bilingual corpora.

1 Introduction

For statistical machine translation (SMT), phrase-based methods (Koehn et al., 2003; Och and Ney, 2004) and syntax-based methods (Wu, 1997; Alshawi et al. 2000; Yamada and Knignt, 2001; Melamed, 2004; Chiang, 2005; Quick et al., 2005; Mellebeek et al., 2006) outperform word-based methods (Brown et al., 1993). These methods need large bilingual corpora. However, for some languages pairs, only a small bilingual corpus is available, which will degrade the performance of statistical translation systems.

To solve this problem, this paper proposes a novel method for phrase-based SMT by using a pivot language. To perform translation between languages L_f and L_e, we bring in a pivot language L_p, for which there exist large bilingual corpora for language pairs L_f-L_p and L_p-L_e. With the L_f-L_p and L_p-L_e bilingual corpora, we can build a translation model for L_f-L_e by using L_p as the pivot language. We name the translation model *pivot* model. The advantage of this method lies in that we can conduct translation between L_f and L_e even if there is no bilingual corpus available for this language pair. Moreover, if a small corpus is available for L_f-L_e, we build another translation model, which is named *standard* model. Then, we build an *interpolated* model by performing linear interpolation on the standard model and the pivot model. Thus, the interpolated model can employ both the small L_f-L_e corpus and the large L_f-L_p and L_p-L_e corpora.

We perform experiments on the Europarl corpus (Koehn, 2005). Using BLEU (Papineni et al., 2002) as a metric, our method achieves an absolute improvement of 0.06 (22.13% relative) as compared with the standard model trained with 5,000 L_f-L_e sentence pairs for French-Spanish translation. The translation quality is comparable with that of the model trained with a bilingual corpus of 30,000 L_f-L_e sentence pairs. Moreover, translation quality is further boosted by using both the small L_f-L_e bilingual corpus and the large L_f-L_p and L_p-L_e corpora.

Experimental results on Chinese-Japanese translation also indicate that our method achieves satisfactory results using English as the pivot language.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 856–863,
Prague, Czech Republic, June 2007.

The remainder of this paper is organized as follows. In section 2, we describe the related work. Section 3 briefly introduces phrase-based SMT. Section 4 and Section 5 describes our method for phrase-based SMT using pivot language. We describe the experimental results in sections 6 and 7. Lastly, we conclude in section 8.

2 Related Work

Our method is mainly related to two kinds of methods: those using pivot language and those using a small bilingual corpus or scarce resources.

For the first kind, pivot languages are employed to translate queries in cross-language information retrieval (CLIR) (Gollins and Sanderson, 2001; Kishida and Kando, 2003). These methods only used the available dictionaries to perform word by word translation. In addition, NTCIR 4 workshop organized a shared task for CLIR using pivot language. Machine translation systems are used to translate queries into pivot language sentences, and then into target sentences (Sakai et al., 2004).

Callison-Burch et al. (2006) used pivot languages for paraphrase extraction to handle the unseen phrases for phrase-based SMT. Borin (2000) and Wang et al. (2006) used pivot languages to improve word alignment. Borin (2000) used multilingual corpora to increase alignment coverage. Wang et al. (2006) induced alignment models by using two additional bilingual corpora to improve word alignment quality. Pivot Language methods were also used for translation dictionary induction (Schafer and Yarowsky, 2002), word sense disambiguation (Diab and Resnik, 2002), and so on.

For the second kind, Niessen and Ney (2004) used morpho-syntactic information for translation between language pairs with scarce resources. Vandeghinste et al. (2006) used translation dictionaries and shallow analysis tools for translation between the language pair with low resources. A shared task on word alignment was organized as part of the ACL 2005 Workshop on Building and Using Parallel Texts (Martin et al., 2005). This task focused on languages with scarce resources. For the subtask of unlimited resources, some researchers (Aswani and Gaizauskas, 2005; Lopez and Resnik, 2005; Tufis et al., 2005) used language-dependent resources such as dictionary, thesaurus, and dependency parser to improve word alignment results.

In this paper, we address the translation problem for language pairs with scarce resources by bringing in a pivot language, via which we can make use of large bilingual corpora. Our method does not need language-dependent resources or deep linguistic processing. Thus, the method is easy to be adapted to any language pair where a pivot language and corresponding large bilingual corpora are available.

3 Phrase-Based SMT

According to the translation model presented in (Koehn et al., 2003), given a source sentence $\mathbf{f}$, the best target translation $\mathbf{e}_{\text{best}}$ can be obtained according to the following model

$$\begin{aligned}\mathbf{e}_{\text{best}} &= \arg\max_{\mathbf{e}} p(\mathbf{e}|\mathbf{f}) \\ &= \arg\max_{\mathbf{e}} p(\mathbf{f}|\mathbf{e}) p_{\text{LM}}(\mathbf{e}) \omega^{\text{length}(\mathbf{e})}\end{aligned} \quad (1)$$

Where the translation model $p(\mathbf{f}|\mathbf{e})$ can be decomposed into

$$\begin{aligned}&p(\bar{f}_1^I | \bar{e}_1^I) \\ &= \prod_{i=1}^{I} \phi(\bar{f}_i | \bar{e}_i) d(a_i - b_{i-1}) p_{\text{w}}(\bar{f}_i | \bar{e}_i, a)^{\lambda}\end{aligned} \quad (2)$$

Where $\phi(\bar{f}_i | \bar{e}_i)$ and $d(a_i - b_{i-1})$ denote phrase translation probability and distortion probability, respectively. $p_{\text{w}}(\bar{f}_i | \bar{e}_i, a)$ is the lexical weight, and λ is the strength of the lexical weight.

4 Phrase-Based SMT Via Pivot Language

This section will introduce the method that performs phrase-based SMT for the language pair L_f-L_e by using the two bilingual corpora of L_f-L_p and L_p-L_e. With the two additional bilingual corpora, we train two translation models for L_f-L_p and L_p-L_e, respectively. Based on these two models, we build a pivot translation model for L_f-L_e, with L_p as a pivot language.

According to equation (2), the phrase translation probability and the lexical weight are language dependent. We will introduce them in sections 4.1 and 4.2, respectively.

4.1 Phrase Translation Probability

Using the L_f-L_p and L_p-L_e bilingual corpora, we train two phrase translation probabilities

$\phi(\bar{f}_i \mid \bar{p}_i)$ and $\phi(\bar{p}_i \mid \bar{e}_i)$, where $\bar{p}_i$ is the phrase in the pivot language L_p. Given the phrase translation probabilities $\phi(\bar{f}_i \mid \bar{p}_i)$ and $\phi(\bar{p}_i \mid \bar{e}_i)$, we obtain the phrase translation probability $\phi(\bar{f}_i \mid \bar{e}_i)$ according to the following model.

$$\phi(\bar{f}_i \mid \bar{e}_i) = \sum_{\bar{p}_i} \phi(\bar{f}_i \mid \bar{p}_i, \bar{e}_i)\phi(\bar{p}_i \mid \bar{e}_i) \quad (3)$$

The phrase translation probability $\phi(\bar{f}_i \mid \bar{p}_i, \bar{e}_i)$ does not depend on the phase $\bar{e}_i$ in the language L_e, since it is estimated from the L_f-L_p bilingual corpus. Thus, equation (3) can be rewritten as

$$\phi(\bar{f}_i \mid \bar{e}_i) = \sum_{\bar{p}_i} \phi(\bar{f}_i \mid \bar{p}_i)\phi(\bar{p}_i \mid \bar{e}_i) \quad (4)$$

4.2 Lexical Weight

Given a phrase pair $(\bar{f}, \bar{e})$ and a word alignment a between the source word positions $i = 1,...,n$ and the target word positions $j = 1,...,m$, the lexical weight can be estimated according to the following method (Koehn et al., 2003).

$$p_w(\bar{f} \mid \bar{e}, a) = \prod_{i=1}^{n} \frac{1}{|j \mid (i,j) \in a|} \sum_{\forall (i,j) \in a} w(f_i \mid e_j) \quad (5)$$

In order to estimate the lexical weight, we first need to obtain the alignment information a between the two phrases $\bar{f}$ and $\bar{e}$, and then estimate the lexical translation probability $w(f \mid e)$ according to the alignment information. The alignment information of the phrase pair $(\bar{f}, \bar{e})$ can be induced from the two phrase pairs $(\bar{f}, \bar{p})$ and $(\bar{p}, \bar{e})$.

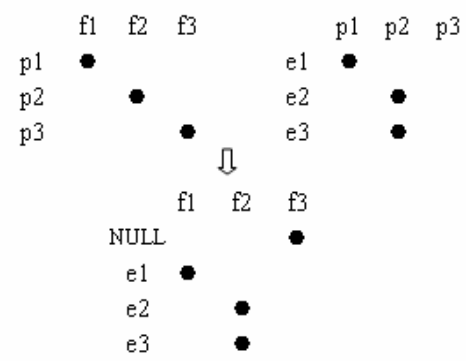

Figure 1. Alignment Information Induction

Let a_1 and a_2 represent the word alignment information inside the phrase pairs $(\bar{f}, \bar{p})$ and $(\bar{p}, \bar{e})$ respectively, then the alignment information a inside $(\bar{f}, \bar{e})$ can be obtained as shown in (6). An example is shown in Figure 1.

$$a = \{(f, e) \mid \exists p : (f, p) \in a_1 \ \& \ (p, e) \in a_2\} \quad (6)$$

With the induced alignment information, this paper proposes a method to estimate the probability directly from the induced phrase pairs. We name this method *phrase* method. If we use K to denote the number of the induced phrase pairs, we estimate the co-occurring frequency of the word pair (f, e) according to the following model.

$$count(f, e) = \sum_{k=1}^{K} \phi_k(\bar{f} \mid \bar{e}) \sum_{i=1}^{n} \delta(f, f_i)\delta(e, e_{a_i}) \quad (7)$$

Where $\phi_k(\bar{f} \mid \bar{e})$ is the phrase translation probability for phrase pair k. $\delta(x, y) = 1$ if $x = y$; otherwise, $\delta(x, y) = 0$. Thus, lexical translation probability can be estimated as in (8).

$$w(f \mid e) = \frac{count(f, e)}{\sum_{f'} count(f', e)} \quad (8)$$

We also estimate the lexical translation probability $w(f \mid e)$ using the method described in (Wang et al., 2006), which is shown in (9). We named it *word* method in this paper.

$$w(f \mid e) = \sum_{p} w(f \mid p)w(p \mid e)sim(f, e; p) \quad (9)$$

Where $w(f \mid p)$ and $w(p \mid e)$ are two lexical probabilities, and $sim(f, e; p)$ is the cross-language word similarity.

5 Interpolated Model

If we have a small L_f-L_e bilingual corpus, we can employ this corpus to estimate a translation model as described in section 3. However, this model may perform poorly due to the sparseness of the data. In order to improve its performance, we can employ the additional L_f-L_p and L_p-L_e bilingual corpora. Moreover, we can use more than one pivot language to improve the translation performance if the corresponding bilingual corpora exist. Different pivot languages may catch different linguistic phe-

nomena, and improve translation quality for the desired language pair L_f-L_e in different ways.

If we include n pivot languages, n pivot models can be estimated using the method as described in section 4. In order to combine these n pivot models with the standard model trained with the L_f-L_e corpus, we use the linear interpolation method. The phrase translation probability and the lexical weight are estimated as shown in (10) and (11), respectively.

$$\phi(\bar{f} \mid \bar{e}) = \sum_{i=0}^{n} \alpha_i \phi_i(\bar{f} \mid \bar{e}) \quad (10)$$

$$p_w(\bar{f} \mid \bar{e}, a) = \sum_{i=0}^{n} \beta_i p_{w,i}(\bar{f} \mid \bar{e}, a) \quad (11)$$

Where $\phi_0(\bar{f} \mid \bar{e})$ and $p_{w,0}(\bar{f} \mid \bar{e}, a)$ denote the phrase translation probability and lexical weight trained with the L_f-L_e bilingual corpus, respectively. $\phi_i(\bar{f} \mid \bar{e})$ and $p_{w,i}(\bar{f} \mid \bar{e}, a)$ $(i = 1,...,n)$ are the phrase translation probability and lexical weight estimated by using the pivot languages. α_i and β_i are the interpolation coefficients.

6 Experiments on the Europarl Corpus

6.1 Data

A shared task to evaluate machine translation performance was organized as part of the NAACL/HLT 2006 Workshop on Statistical Machine Translation (Koehn and Monz, 2006). The shared task used the Europarl corpus (Koehn, 2005), in which four languages are involved: English, French, Spanish, and German. The shared task performed translation between English and the other three languages. In our work, we perform translation from French to the other three languages. We select French to Spanish and French to German translation that are not in the shared task because we want to use English as the pivot language. In general, for most of the languages, there exist bilingual corpora between these languages and English since English is an internationally used language.

Table 1 shows the information about the bilingual training data. In the table, "Fr", "En", "Es", and "De" denotes "French", "English", "Spanish", and "German", respectively. For the language pairs L_f-L_e not including English, the bilingual corpus is extracted from L_f-English and English-L_e since Europarl corpus is a multilingual corpus.

Language Pairs	Sentence Pairs	Source Words	Target Words
Fr-En	688,031	15,323,737	13,808,104
Fr-Es	640,661	14,148,926	13,134,411
Fr-De	639,693	14,215,058	12,155,876
Es-En	730,740	15,676,710	15,222,105
De-En	751,088	15,256,793	16,052,269
De-Es	672,813	13,246,255	14,362,615

Table 1. Training Corpus for European Languages

For the language models, we use the same data provided in the shared task. We also use the same development set and test set provided by the shared task. The in-domain test set includes 2,000 sentences and the out-of-domain test set includes 1,064 sentences for each language.

6.2 Translation System and Evaluation Method

To perform phrase-based SMT, we use Koehn's training scripts[1] and the Pharaoh decoder (Koehn, 2004). We run the decoder with its default settings and then use Koehn's implementation of minimum error rate training (Och, 2003) to tune the feature weights on the development set.

The translation quality was evaluated using a well-established automatic measure: BLEU score (Papineni et al., 2002). And we also use the tool provided in the NAACL/HLT 2006 shared task on SMT to calculate the BLEU scores.

6.3 Comparison of Different Lexical Weights

As described in section 4, we employ two methods to estimate the lexical weight in the translation model. In order to compare the two methods, we translate from French to Spanish, using English as the pivot language. We use the French-English and English-Spanish corpora described in Table 1 as training data. During training, before estimating the Spanish to French phrase translation probability, we filter those French-English and English-Spanish phrase pairs whose translation probabilities are below a fixed threshold 0.001.[2] The translation results are shown in Table 2.

[1] It is located at http://www.statmt.org/wmt06/shared-task/baseline.htm

[2] In the following experiments using pivot languages, we use the same filtering threshold for all of the language pairs.

The *phrase* method proposed in this paper performs better than the *word* method proposed in (Wang et al., 2006). This is because our method uses phrase translation probability as a confidence weight to estimate the lexical translation probability. It strengthens the frequently aligned pairs and weakens the infrequently aligned pairs. Thus, the following sections will use the *phrase* method to estimate the lexical weight.

Method	In-Domain	Out-of-Domain
Phrase	0.3212	0.2098
Word	0.2583	0.1672

Table 2. Results with Different Lexical Weights

6.4 Results of Using One Pivot Language

This section describes the translation results by using only one pivot language. For the language pair French and Spanish, we use English as the pivot language. The entire French-English and English-Spanish corpora as described in section 4 are used to train a pivot model for French-Spanish.

As described in section 5, if we have a small L_f-L_e bilingual corpus and large L_f-L_p and L_p-L_e bilingual corpora, we can obtain interpolated models.

In order to conduct the experiments, we randomly select 5K, 10K, 20K, 30K, 40K, 50K, and 100K sentence pairs from the French-Spanish corpus. Using each of these corpora, we train a standard translation model.

For each standard model, we interpolate it with the pivot model to get an interpolated model. The interpolation weights are tuned using the development set. For all the interpolated models, we set $\alpha_0 = 0.9$, $\alpha_1 = 0.1$, $\beta_0 = 0.9$, and $\beta_1 = 0.1$. We test the three kinds of models on both the in-domain and out-of-domain test sets. The results are shown in Figures 2 and 3.

The pivot model achieves BLEU scores of 0.3212 and 0.2098 on the in-domain and out-of-domain test set, respectively. It achieves an absolute improvement of 0.05 on both test sets (16.92% and 35.35% relative) over the standard model trained with 5,000 French-Spanish sentence pairs. And the performance of the pivot models are comparable with that of the standard models trained with 20,000 and 30,000 sentence pairs on the in-domain and out-of-domain test set, respectively. When the French-Spanish training corpus is increased, the standard models quickly outperform the pivot model.

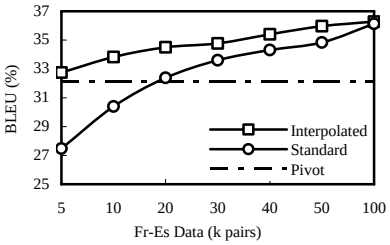

Figure 2. In-Domain French-Spanish Results

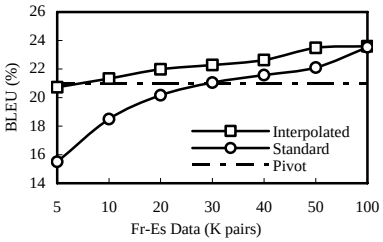

Figure 3. Out-of-Domain French-Spanish Results

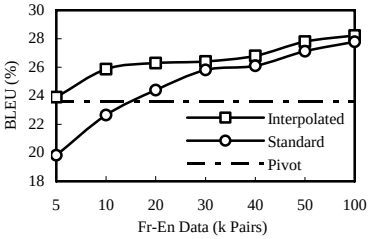

Figure 4. In-Domain French-English Results

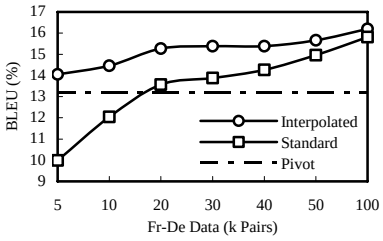

Figure 5. In-Domain French-German Results

When only a very small French-Spanish bilingual corpus is available, the interpolated method can greatly improve the translation quality. For example, when only 5,000 French-Spanish sentence pairs are available, the interpolated model outperforms the standard model by achieving a relative improvement of 17.55%, with the BLEU score improved from 0.2747 to 0.3229. With 50,000 French-Spanish sentence pairs available, the interpolated model significantly[3] improves the translation quality by achieving an absolute im-

[3] We conduct the significance test using the same method as described in (Koehn and Monz, 2006).

provement of 0.01 BLEU. When the French-Spanish training corpus increases to 100,000 sentence pairs, the interpolated model achieves almost the same result as the standard model. This indicates that our pivot language method is suitable for the language pairs with small quantities of training data available.

Besides experiments on French-Spanish translation, we also conduct translation from French to English and French to German, using German and English as the pivot language, respectively. The results on the in-domain test set[4] are shown in Figures 4 and 5. The tendency of the results is similar to that in Figure 2.

6.5 Results of Using More Than One Pivot Language

For French to Spanish translation, we also introduce German as a pivot language besides English. Using these two pivot languages, we build two different pivot models, and then perform linear interpolation on them. The interpolation weights for the English pivot model and the German pivot model are set to 0.6 and 0.4 respectively[5]. The translation results on the in-domain test set are 0.3212, 0.3077, and 0.3355 for the pivot models using English, German, and both German and English as pivot languages, respectively.

With the pivot model using both English and German as pivot languages, we interpolate it with the standard models trained with French-Spanish corpora of different sizes as described in the above section. The comparison of the translation results among the interpolated models, standard models, and the pivot model are shown in Figure 6.

It can be seen that the translation results can be further improved by using more than one pivot language. The pivot model "Pivot-En+De" using two pivot languages achieves an absolute improvement of 0.06 (22.13% relative) as compared with the standard model trained with 5,000 sentence pairs. And it achieves comparable translation result as compared with the standard model trained with 30,000 French-Spanish sentence pairs.

The results in Figure 6 also indicate the interpolated models using two pivot languages achieve the best results of all. Significance test shows that the interpolated models using two pivot languages significantly outperform those using one pivot language when less than 50,000 French-Spanish sentence pairs are available.

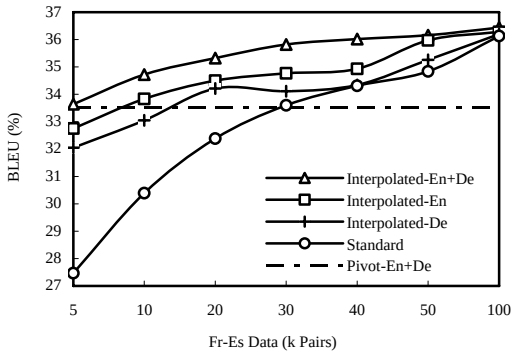

Figure 6. In-Domain French-Spanish Translation Results by Using Two Pivot Languages

6.6 Results by Using Pivot Language Related Corpora of Different Sizes

In all of the above results, the corpora used to train the pivot models are not changed. In order to examine the effect of the size of the pivot corpora, we decrease the French-English and English-French corpora. We randomly select 200,000 and 400,000 sentence pairs from both of them to train two pivot models, respectively. The translation results on the in-domain test set are 0.2376, 0.2954, and 0.3212 for the pivot models trained with 200,000, 400,000, and the entire French-English and English-Spanish corpora, respectively. The results of the interpolated models and the standard models are shown in Figure 7. The results indicate that the larger the training corpora used to train the pivot model are, the better the translation quality is.

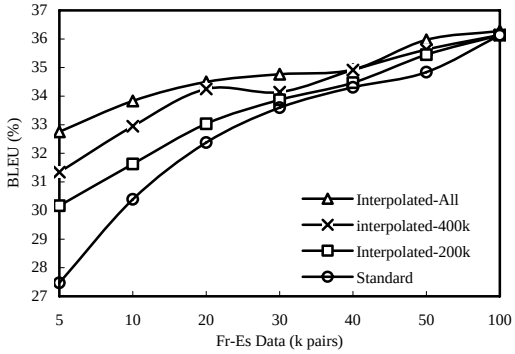

Figure 7. In-Domain French-Spanish Results by Using L_f-L_p and L_p-L_e Corpora of Different Sizes

[4] The results on the out-of-domain test set are similar to that in Figure 3. We only show the in-domain translation results in all of the following experiments because of space limit.

[5] The weights are tuned on the development set.

7 Experiments on Chinese to Japanese Translation

In section 6, translation results on the Europarl multilingual corpus indicate the effectiveness of our method. To investigate the effectiveness of our method by using independently sourced parallel corpora, we conduct Chinese-Japanese translation using English as a pivot language in this section, where the training data are not limited to a specific domain.

The data used for this experiment is the same as those used in (Wang et al., 2006). There are 21,977, 329,350, and 160,535 sentence pairs for the language pairs Chinese-Japanese, Chinese-English, and English-Japanese, respectively. The development data and testing data include 500 and 1,000 Chinese sentences respectively, with one reference for each sentence. For Japanese language model training, we use about 100M bytes Japanese corpus.

The translation result is shown in Figure 8. The pivot model only outperforms the standard model trained with 2,500 sentence pairs. This is because (1) the corpora used to train the pivot model are smaller as compared with the Europarl corpus; (2) the training data and the testing data are not limited to a specific domain; (3) The languages are not closely related.

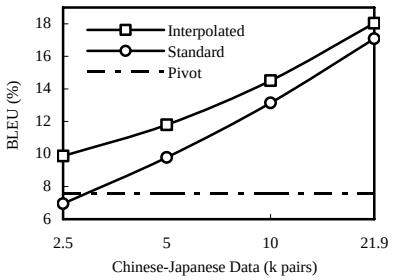

Figure 8. Chinese-Japanese Translation Results

The interpolated models significantly outperform the other models. When only 5,000 sentence pairs are available, the BLEU score increases relatively by 20.53%. With the entire (21,977 pairs) Chinese-Japanese available, the interpolated model relatively increases the BLEU score by 5.62%, from 0.1708 to 0.1804.

8 Conclusion

This paper proposed a novel method for phrase-based SMT on language pairs with a small bilingual corpus by bringing in pivot languages. To perform translation between L_f and L_e, we bring in a pivot language L_p, via which the large corpora of L_f-L_p and L_p-L_e can be used to induce a translation model for L_f-L_e. The advantage of this method is that it can perform translation between the language pair L_f-L_e even if no bilingual corpus for this pair is available. Using BLEU as a metric, our method achieves an absolute improvement of 0.06 (22.13% relative) as compared with the model directly trained with 5,000 sentence pairs for French-Spanish translation. And the translation quality is comparable with that of the model directly trained with 30,000 French-Spanish sentence pairs. The results also indicate that using more pivot languages leads to better translation quality.

With a small bilingual corpus available for L_f-L_e, we built a translation model, and interpolated it with the pivot model trained with the large L_f-L_p and L_p-L_e bilingual corpora. The results on both the Europarl corpus and Chinese-Japanese translation indicate that the interpolated models achieve the best results. Results also indicate that our pivot language approach is suitable for translation on language pairs with a small bilingual corpus. The less the L_f-L_e bilingual corpus is, the bigger the improvement is.

We also performed experiments using L_f-L_p and L_p-L_e corpora of different sizes. The results indicate that using larger training corpora to train the pivot model leads to better translation quality.

Bootstrapping a Stochastic Transducer for Arabic-English Transliteration Extraction

Abstract

We propose a bootstrapping approach to training a memoriless stochastic transducer for the task of extracting transliterations from an English-Arabic bitext. The transducer learns its similarity metric from the data in the bitext, and thus can function directly on strings written in different writing scripts without any additional language knowledge. We show that this bootstrapped transducer performs as well or better than a model designed specifically to detect Arabic-English transliterations.

1 Introduction

Transliterations are words that are converted from one writing script to another on the basis of their pronunciation, rather than being translated on the basis of their meaning. Transliterations include named entities (e.g. جين اوستن/*Jane Austen*) and lexical loans (e.g. تلفيزيون/*television*).

An algorithm to detect transliterations automatically in a bitext can be an effective tool for many tasks. Models of machine transliteration such as those presented in (Al-Onaizan and Knight, 2002) or (AbdulJaleel and Larkey, 2003) require a large set of sample transliterations to use for training. If such a training set is unavailable for a particular language pair, a detection algorithm would lead to a significant gain in time over attempting to build the set manually. Algorithms for cross-language information retrieval often encounter the problem of out-of-vocabulary words, or words not present in the algorithm's lexicon. Often, a significant proportion of these words are named entities and thus are candidates for transliteration. A transliteration detection algorithm could be used to map named entities in a query to potential transliterations in the target language text.

The main challenge in transliteration detection lies in the fact that transliteration is a *lossy* process. In other words, information can be lost about the original word when it is transliterated. This can occur because of phonetic gaps in one language or the other. For example, the English [p] sound does not exist in Arabic, and the Arabic [ʕ] sound (made by the letter ع) does not exist in English. Thus, *Paul* is transliterated as بول [bul], and علي [ʕali] is transliterated as *Ali*. Another form of löss occurs when the relationship between the orthographic and phonetic representations of a word are unclear. For example, the [k] sound will always be written with the letter ك in Arabic, but in English it can be written as *c*, *k ch*, *ck*, *cc* or *kk* (not to mention being one of the sounds produced by *x*). Finally, letters may be deleted in one language or the other. In Arabic, short vowels will often be omitted (e.g. يوسف/*Yousef*), while in English the Arabic ء and ع are often deleted (e.g. اسماعيل/*Ismael*).

We explore the use of word similarity metrics on the task of Arabic-English transliteration detection and extraction. One of our primary goals in exploring these metrics is to assess whether it is possible maintain high performance without making the algorithms language-specific. Many word-similarity metrics require that the strings being compared be

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 864–871,
Prague, Czech Republic, June 2007.

written in the same script. Levenshtein edit distance, for example, does not produce a meaningful score in the absence of character identities. Thus, if these metrics are to be used for transliteration extraction, modifications must be made to allow them to compare different scripts.

Freeman et al. (2006) take the approach of manually encoding a great deal of language knowledge directly into their Arabic-English fuzzy matching algorithm. They define equivalence classes between letters in the two scripts and perform several rule-based transformations to make word pairs more comparable. This approach is unattractive for two reasons. Firstly, predicting all possible relationships between letters in English and Arabic is difficult. For example, allowances have to be made for unusual pronunciations in foreign words such as the *ch* in *cliché* or the *c* in *Milosevic*. Secondly, the algorithm becomes completely language-specific, which means that it cannot be used for any other language pair.

We propose a method to learn letter relationships directly from the bitext containing the transliterations. Our model is based on the memoriless stochastic transducer proposed by Ristad and Yianilos (1998), which derives a probabilistic word-similarity function from a set of examples. The transducer is able to learn edit distance costs between disjoint sets of characters representing different writing scripts without any language-specific knowledge. The transducer approach, however, requires a large set of training examples, which is a limitation not present in the fuzzy matching algorithm. Thus, we propose a bootstrapping approach (Yarowsky, 1995) to train the stochastic transducer iteratively as it extracts transliterations from a bitext. The bootstrapped stochastic transducer is completely language-independent, and we show that it is able to perform at least as well as the Arabic-English specific fuzzy matching algorithm.

The remainder of this paper is organized as follows. Section 2 presents our bootstrapping method to train a stochastic transducer. Section 3 outlines the Arabic-English fuzzy matching algorithm. Section 4 discusses other word-similarity models used for comparison. Section 5 describes the results of two experiments performed to test the models. Section 6 briefly discusses previous approaches to detecting transliterations. Section 7 presents our conclusions and possibilities for future work.

2 Bootstrapping with a Stochastic Transducer

Ristad and Yianilos (1998) propose a probabilistic framework for word similarity, in which the similarity of a pair of words is defined as the sum of the probabilities of all paths through a memoriless stochastic transducer that generate the pair of words. This is referred to as the forward score of the pair of words. They outline a forward-backward algorithm to train the model and show that it outperforms Levenshtein edit distance on the task of pronunciation classification.

The training algorithm begins by calling the forward (Equation 1) and backward (Equation 2) functions to fill in the F and B tables for training pair s and t with respective lengths I and J.

$$\begin{aligned} F(0,0) &= 1 \\ F(i,j) &= P(s_i,\epsilon)F(i-1,j) \\ &\quad +P(\epsilon,t_j)F(i,j-1) \\ &\quad +P(s_i,t_j)F(i-1,j-1) \end{aligned} \tag{1}$$

$$\begin{aligned} B(I,J) &= 1 \\ B(i,j) &= P(s_{i+1},\epsilon)B(i+1,j) \\ &\quad +P(\epsilon,t_{j+1})B(i,j+1) \\ &\quad +P(s_{i+1},t_{j+1})B(i+1,j+1) \end{aligned} \tag{2}$$

The forward value at each position (i,j) in the F matrix signifies the sum of the probabilities of all paths through the transducer that produce the prefix pair (s_1^i, t_1^j), while $B(i,j)$ contains the sum of the probabilities of all paths through the transducer that generate the suffix pair (s_{i+1}^I, t_{j+1}^J). These tables can then be used to collect partial counts to update the probabilities. For example, the mapping (s_i, t_j) would contribute a count according to Equation 3. These counts are then normalized to produce the updated probability distribution.

$$C(s_i,t_j) += \frac{F(i-1,j-1)P(s_i,t_j)B(i,j)}{F(I,J)} \tag{3}$$

The major issue in porting the memoriless transducer over to our task of transliteration extraction

is that its training is supervised. In other words, it would require a relatively large set of known transliterations for training, and this is exactly what we would like the model to acquire. In order to overcome this problem, we look to the bootstrapping method outlined in (Yarowsky, 1995). Yarowsky trains a rule-based classifier for word sense disambiguation by starting with a small set of seed examples for which the sense is known. The trained classifier is then used to label examples for which the sense is unknown, and these newly labeled examples are then used to retrain the classifier. The process is repeated until convergence.

Our method uses a similar approach to train the stochastic transducer. The algorithm proceeds as follows:

1. Initialize the training set with the seed pairs.
2. Train the transducer using the forward-backward algorithm on the current training set.
3. Calculate the forward score for all word pairs under consideration.
4. If the forward score for a pair of words is above a predetermined acceptance threshold, add the pair to the training set.
5. Repeat steps 2-4 until the training set ceases to grow.

Once training stops, the transducer can be used to score pairs of words not in the training set. For our experiments, the acceptance threshold was optimized on a separate development set. Forward scores were normalized by the average of the lengths of the two words.

3 Arabic-English Fuzzy String Matching

In this section, we outline the fuzzy string matching algorithm proposed by Freeman et al. (2006). The algorithm is based on the standard Levenshtein distance approach, but encodes a great deal of knowledge about the relationships between English and Arabic letters.

Initially, the candidate word pair is modified in two ways. The first transformation is a rule-based letter normalization of both words. Some examples of normalization include:

- English double letter collapse: e.g. *Miller→Miler*.

ا,أ,آ,ى ↔ *a,e,i,o,u*	ب ↔ *b,p,v*
ت,ط,ث ↔ *t*	ج ↔ *j,g*
ظ ↔ *d,z*	ع,ء ↔ *',c,a,e,i,o,u*
ق ↔ *q,g,k*	ك ↔ *k,c,s*
ي ↔ *y,i,e,j*	ة ↔ *a,e*

Table 1: A sample of the letter equivalence classes for fuzzy string matching.

Algorithm VowelNorm $(Estring, Astring)$

for each $i := 0$ **to** $min(|Estring|, |Astring|)$
  for each $j := 0$ **to** $min(|Estring|, |Astring|)$
    if $Astring_i = Estring_j$
      $Outstring. = Estring_j; i++; j++;$
    if $vowel(Astring_i) \wedge vowel(Estring_j)$
      $Outstring. = Estring_j; i++; j++;$
    if $\neg vowel(Astring_i) \wedge vowel(Estring_j)$
      $j++;$
      if $j < |Estring_j|$
        $Outstring. = Estring_j; i++; j++;$
    else
      $Outstring. = Estring_j; i++; j++;$
while $j < |Estring|$
  if $\neg vowel(Estring_j)$
    $Outstring. = Estring_j;$
  $j++;$
return $Outstring;$

Figure 1: Pseudocode for the vowel transformation procedure.

- Arabic hamza collapse: e.g. أشرف→اشرف.
- Individual letter normalizations: e.g. *Hendrix→Hendriks* or شريف→سهريف.

The second transformation is an iteration through both words to remove any vowels in the English word for which there is no similarly positioned vowel in the Arabic word. The pseudocode for our implementation of this vowel transformation is presented in Figure 1.

After letter and vowel transformations, the Levenshtein distance is computed using the letter equivalences as matches instead of identities. Some equivalence classes between English and Arabic letters are shown in Table 1. The Arabic and English letters within a class are treated as identities. For example, the Arabic ف can match both *f* and *v* in English with no cost. The resulting Levenshtein distance is normalized by the sum of the lengths of both words.

	Levenshtein	ALINE	Fuzzy Match	Bootstrap
Lang.-specific	No	No	Yes	No
Preprocessing	Romanization	Phon. Conversion	None	None
Data-driven	No	No	No	Yes

Table 2: Comparison of the word-similarity models.

Several other modifications, such as light stemming and multiple passes to discover more difficult mappings, were also proposed, but they were found to influence performance minimally. Thus, the equivalence classes and transformations are the only modifications we reproduce for our experiments here.

4 Other Models of Word Similarity

In this section, we present two models of word similarity used for purposes of comparison. Levenshtein distance and ALINE are not language-specific per se, but require that the words being compared be written in a common script. Thus, they require some language knowledge in order to convert one or both of the words into the common script. A comparison of all the models presented is given in Table 2.

4.1 Levenshtein Edit Distance

As a baseline for our experiments, we used Levenshtein edit distance. The algorithm simply counts the minimum number of insertions, deletions and substitutions required to convert one string into another. Levenshtein distance depends on finding identical letters, so both words must use the same alphabet. Prior to comparison, we convert the Arabic words into the Latin alphabet using the intuitive mappings for each letter shown in Table 3. The distances are also normalized by the length of the longer of the two words to avoid excessively penalizing longer words.

4.2 ALINE

Unlike other algorithms presented here, the ALINE algorithm (Kondrak, 2000) operates in the phonetic, rather than the orthographic, domain. It was originally designed to identify cognates in related languages, but it can be used to compute similarity between any pair of words, provided that they are expressed in a standard phonetic notation. Individual

ا,أ,آ,ء → *a*	ب → *b*	ت,ط → *t*
ة → *a*	ث → *th*	ج → *j*
ه,ح → *h*	خ → *kh*	د,ض → *d*
ذ,ظ → *th*	ر → *r*	ز → *z*
س,ص → *s*	ش → *sh*	ع → ’
غ → *g*	ف → *f*	ق → *q*
ك → *k*	ل → *l*	م → *m*
ن → *n*	و → *w*	ي → *y*

Table 3: Arabic Romanization for Levenshtein distance.

phonemes input to the algorithm are decomposed into a dozen phonetic features, such as Place, Manner and Voice. A substitution score between a pair of phonemes is based on the similarity as assessed by a comparison of the individual features. After an optimal alignment of the two words is computed with a dynamic programming algorithm, the overall similarity score is set to the sum of the scores of all links in the alignment normalized by the length of the longer of the two words.

In our experiments, the Arabic and English words were converted into phonetic transcriptions using a deterministic rule-based transformation. The transcriptions were only approximate, especially for English vowels. Arabic emphatic consonants were depharyngealized.

5 Evaluation

The word-similarity metrics were evaluated on two separate tasks. In experiment 1 (Section 5.1) the task was to extract transliterations from a sentence aligned bitext. Experiment 2 (Section 5.2) provides the algorithms with named entities from an English document and requires them to extract the transliterations from the document’s Arabic translation.

The two bitexts used in the experiments were the

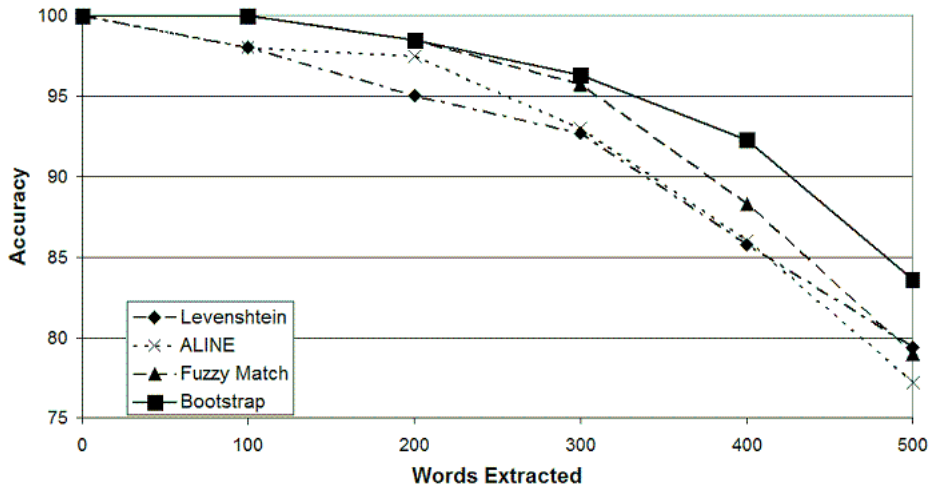

Figure 2: Precision per number of words extracted for the various algorithms from a sentence-aligned bitext.

Arabic Treebank Part 1-10k word English Translation corpus and the Arabic English Parallel News Part 1 corpus (approx. 2.5M words). Both bitexts contain Arabic news articles and their English translations aligned at the sentence level, and both are available from the Linguistic Date Consortium. The Treebank data was used as a development set to optimize the acceptance threshold used by the bootstrapped transducer. Testing for the sentence-aligned extraction task was done on the first 20k sentences (approx. 50k words) of the parallel news data, while the named entity extraction task was performed on the first 1000 documents of the parallel news data. The seed set for bootstrapping the stochastic transducer was manually constructed and consisted of 14 names and their transliterations.

5.1 Experiment 1: Sentence-Aligned Data

The first task used to test the models was to compare and score the words remaining in each bitext sentence pair after preprocessing the bitext in the following way:

- The English corpus is tokenized using a modified[1] version of Word Splitter[2].
- All uncapitalized English words are removed.
- Stop words (mainly prepositions and auxiliary verbs) are removed from both sides of the bitext.
- Any English words of length less than 4 and Arabic words of length less than 3 are removed.

Each algorithm finds the top match for each English word and the top match for each Arabic word. If two words mark each other as their top scorers, then the pair is marked as a transliteration pair. This one-to-one constraint is meant to boost precision, though it will also lower recall. This is because for many of the tasks in which transliteration extraction would be useful (such as building a lexicon), precision is deemed more important. Transliteration pairs are sorted according to their scores, and the top 500 hundred scoring pairs are returned.

The results for the sentence-aligned extraction task are presented in Figure 2. Since the number of actual transliterations in the data was unknown, there was no way to compute recall. The measure used here is the precision for each 100 words extracted up to 500. The bootstrapping method is equal to or outperforms the other methods at all levels, including the Arabic-English specific fuzzy match algorithm. Fuzzy matching does well for the first few hundred words extracted, but eventually falls below the level of the baseline Levenshtein.

Interestingly, the bootstrapped transducer does not seem to have trouble with digraphs, despite the one-to-one nature of the character operations. Word pairs with two-to-one mappings such as *sh*/ش or

[1]The way the program handles apostrophes(') had to be modified since they are sometimes used to represent glottal stops in transliterations of Arabic words, e.g. qala'a.

Table 4: A sample of the errors made by the word-similarity metrics.

x/كس tend to score lower than their counterparts composed of only one-to-one mappings, but nevertheless score highly.

A sample of the errors made by each word-similarity metric is presented in Table 4. Errors 1-6 are indicative of the weaknesses of each individual algorithm. The bootstrapping method encounters problems when erroneous pairs become part of the training data, thereby reinforcing the errors. The only problematic mapping in Error 1 is the خ/*g* mapping, and thus the pair has little trouble getting into the training data. Once the pair is part of training data, the algorithm learns that the mapping is acceptable and uses it to acquire other training pairs that contain the same erroneous mapping. The problem with the fuzzy matching algorithm seems to be that it creates too large a class of equivalent words. The pairs in errors 3 and 4 are given a total edit cost of 0. This is possible because of the overly general letter and vowel transformations, as well as unusual choices made for letter equivalences (e.g. ع/*c* in error 4). ALINE's errors tend to occur when it links two letters, based on phonetic similarity, that are never mapped to each other in transliteration because they each have a more direct equivalent in the other language (error 5). Although the Arabic ك [k] is phonetically similar to the English *g*, they would never be mapped to each other since English has several ways of representing an actual [k] sound. Errors made by Levenshtein distance (error 6) are simply due to the fact that it considers all non-identity mappings to be equivalent.

Errors 7-10 are examples of general errors made by all the algorithms. The most common error was related to inflection (error 7). The words are essentially transliterations of each other, but one or the other of the two words takes a plural or some other inflectional ending that corrupts the phonetic match. Error 8 represents the common problem of incidental letter similarity. The English *-ian* ending used for nationalities is very similar to the Arabic يون [ijun] and يين [ijin] endings which are used for the same purpose. They are similar phonetically and, since they are functionally similar, will tend to co-occur. Since neither can be said to be derived from the other, however, they cannot be considered transliterations. Error 9 is a case of two words of common origin taking on language-specific derivational endings that corrupt the phonetic match. Finally, error 10 shows a mapping (ك/*c*) that is often correct in transliteration, but is inappropriate in this particular case.

5.2 Experiment 2: Document-Aligned Named Entity Recognition

The second experiment provides a more challenging task for the evaluation of the models. It is structured as a cross-language named entity recognition task similar to those outlined in (Lee and Chang, 2003) and (Klementiev and Roth, 2006). Essentially, the goal is to use a language for which named entity recognition software is readily available as a reference for tagging named entities in a language for which such software is not available. For this task, the sentence alignment of the bitext is ignored. For each named entity in an English document, the models must select a transliteration from within the document's entire Arabic translation. This is meant to be a loose approximation of the "comparable" corpora used in (Klementiev and Roth, 2006). The comparable corpora are related documents in different languages that are not translations (e.g. news articles describing the same event), and thus sentence alignment is not possible.

The first 1000 documents in the parallel news data were used for testing. The English side of the bitext was tagged with Named Entity Tagger[3], which labels named entities as *person*, *location*, *organiza-*

3	Fuzzy Match	ثمن	thmn	Othman

Table 6: A sample of errors made on the NER detection task.

tion or *miscellaneous*. The words labeled as *person* were extracted. Person names are almost always transliterated, while for the other categories this is far less certain. The list was then hand-checked to ensure that all names were candidates for transliteration, leaving 822 names. The restrictions on word length and stop words were the same as before, but in this task each of the English person names from a given document were compared to all valid words in the corresponding Arabic document, and the top scorer for each English name was returned.

The results for the NER detection task are presented in Table 5. It seems the bootstrapped transducer's advantage is relative to the proportion of correct transliteration pairs to the total number of candidates. As this proportion becomes smaller the transducer is given more opportunities to corrupt its training data and performance is affected accordingly. Nevertheless, the transducer is able to perform as well as the language-specific fuzzy matching algorithm on this task, despite the greater challenge posed by selecting candidates from entire documents.

A sample of errors made by the bootstrapped transducer and fuzzy matching algorithms is shown in Table 6. Error 1 was due to the fact that names are sometimes split differently in Arabic and English. The Arabic عبد الله (2 words) is generally written as *Abdallah* in English, leading to partial matches with part of the Arabic name. Error 2 shows an issue with the one-to-one nature of the transducer. The deleted *h* can be learned in mappings such as *sh*/ش or *ph*/ف, but it is generally inappropriate to delete an *h* on its own. Error 3 again shows that the fuzzy matching algorithm's letter transformations are too general. The vowel removals lead to a 0 cost match in this case.

6 Related Work

Several other methods for detecting transliterations between various language pairs have been proposed. These methods differ in their complexity as well as in their applicability to language pairs other than the pair for which they were originally designed.

Collier et al. (1997) present a method for identifying transliterations in an English-Japanese bitext. Their model first transcribes the Japanese word expressed in the *katakana* syllabic script as the concatenation of all possible transliterations of the individual symbols. A depth-first search is then applied to compute the number of matches between this transcription and a candidate English transliteration. The method requires a manual enumeration of the possible transliterations for each katakana symbol, which is unfeasible for many language pairs.

In the method developed by Tsuji (2002), katakana strings are first split into their mora units, and then the transliterations of the units are assessed manually from a set of training pairs. For each katakana string in a bitext, all possible transliterations are produced based on the transliteration units determined from the training set. The transliteration candidates are then compared to the English words according to the Dice score. The manual enumeration of possible mappings makes this approach unattractive for many language pairs, and the generation of all possible transliteration candidates is problematic in terms of computational complexity.

Lee and Chang (2003) detect transliterations with a generative noisy channel transliteration model similar to the transducer presented in (Knight and Graehl, 1998). The English side of the corpus is tagged with a named entity tagger, and the model is used to isolate the transliterations in the Chinese translation. This model, like the transducer proposed by Ristad and Yianilos (1998), must be trained on a large number of sample transliterations, meaning it cannot be used if such a resource is not avail-

able.

Klementiev and Roth (2006) bootstrap with a perceptron and use temporal analysis to detect transliterations in comparable Russian-English news corpora. The English side is first tagged by a named entity tagger, and the perceptron proposes transliterations for the named entities. The candidate transliteration pairs are then reranked according the similarity of their distributions across dates, as calculated by a discrete Fourier transform.

7 Conclusion and Future Work

We presented a bootstrapping approach to training a stochastic transducer, which learns scoring parameters automatically from a bitext. The approach is completely language-independent, and was shown to perform as well or better than an Arabic-English specific similarity metric on the task of Arabic-English transliteration extraction.

Although the bootstrapped transducer is language-independent, it learns only one-to-one letter relationships, which is a potential drawback in terms of porting it to other languages. Our model is able to capture English digraphs and trigraphs, but, as of yet, we cannot guarantee the model's success on languages with more complex letter relationships (e.g. a logographic writing system such as Chinese). More research is necessary to evaluate the model's performance on other languages.

Another area open to future research is the use of more complex transducers for word comparison. For example, Linden (2006) presents a model which learns probabilities for edit operations by taking into account the context in which the characters appear. It remains to be seen how such a model could be adapted to a bootstrapping setting.

Abstract

In this paper, we describe our experiences in extending a standard cross-language information retrieval (CLIR) approach which uses parallel aligned corpora and Latent Semantic Indexing. Most, if not all, previous work which follows this approach has focused on bilingual retrieval; two examples involve the use of French-English or English-Greek parallel corpora. Our extension to the approach is 'massively parallel' in two senses, one linguistic and the other computational. First, we make use of a parallel aligned corpus consisting of almost 50 parallel translations in over 30 distinct languages, each in over 30,000 documents. Given the size of this dataset, a 'massively parallel' approach was also necessitated in the more usual computational sense. Our results indicate that, far from adding more noise, more linguistic parallelism is better when it comes to cross-language retrieval precision, in addition to the self-evident benefit that CLIR can be performed on more languages.

1 Introduction

Approaches to cross-language information retrieval (CLIR) fall generally into one of two types, or some combination thereof: the 'query translation' approach or the 'parallel corpus' approach. The first of these, which is perhaps more common, involves translation of the query into the target language, for example using machine translation or on-line dictionaries. The second makes use of parallel aligned corpora as training sets. One approach which uses parallel corpora does this in conjunction with Latent Semantic Indexing (LSI) (Landauer and Littman 1990, Young 1994). According to Berry et al. (1994:21), the use of LSI with parallel corpora can be just as effective as the query translation approach, and avoids some of the drawbacks of the latter, discussed in Nie et al. (1999).

Generally, research in CLIR has not attempted to use very many languages at a time (see for example Nie and Jin 2002). With query translation (although that is not the approach that Nie and Jin take), this is perhaps understandable, as for each new language, a new translation algorithm must be included. The effort involved in extending query translation to multiple languages, therefore, is likely to be in proportion to the number of languages.

With parallel corpora, the reason that research has been limited to only a few languages at a time – and usually just two at a time, as in the LSI work cited above – is more likely to be rooted in the widespread perception that good parallel corpora are difficult to obtain (see for example Asker 2004). However, recent work (Resnik et al. 1999, Chew et al. 2006) has challenged this idea.

One advantage of a 'massively parallel' multilingual corpus is perhaps self-evident: within the LSI framework, the more languages are mapped into the single conceptual space, the fewer restrictions there are on which languages documents can be selected from for cross-language retrieval. However, several questions were raised for us as

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 872–879,
Prague, Czech Republic, June 2007.

we contemplated the use of a massively parallel corpus. Would the addition of languages not used in testing create 'noise' for a given language pair, reducing the precision of CLIR? Could *partially* parallel corpora be used? Our work appears to show both that more languages are generally beneficial, and even incomplete parallel corpora can be used. In the remainder of this paper, we provide evidence for this claim. The paper is organized as follows: section 2 describes the work we undertook to build the parallel corpus and its characteristics. In section 3, we outline the mechanics behind the 'Rosetta-Stone' type method we use for cross-language comparison. In section 4, we present and discuss the results of the various tests we performed. Finally, we conclude on our findings in section 5.

2 The massively parallel corpus

Following Chew et al. (2006), our parallel corpus was built up from translations of the Bible which are freely available on the World Wide Web. Although reliable comparable statistics are hard to find, it appears to be generally agreed that the Bible is the world's most widely translated book, with complete translations in 426 languages and partial translations in 2,403 as of December 31, 2005 (Bible Society, 2006). Great care is taken over the translations, and they are alignable by chapter and verse. According to Resnik et al. (1999), the Bible's coverage of modern vocabulary may be as high as 85%. The vast majority of the translations we used came from the 'Unbound Bible' website (Biola University, 2005-2006); from this website, the text of a large number of different translations of the Bible can – most importantly for our purposes – be downloaded in a tab-delimited format convenient for loading into a database and then indexing by chapter and verse in order to ensure 'parallelism' in the corpus. The number of translations available at the website is apparently being added to, based on our observations accessing the website on a number of different occasions.

The languages we have included in our multilingual parallel corpus include those both ancient and modern, and are as follows:

Language	No. of translations	Used in tests
Afrikaans	1	12+
Albanian	1	27+
Arabic	1	All
Chinese (Simplified)	1	44+
Chinese (Traditional)	1	44+
Croatian	1	27+
Czech	2	12+
Danish	1	12+
Dutch	1	12+
English	7	All
Finnish	3	27+
French	2	All
German	4	8,27+
Greek (New Testament)	2	46+
Hebrew (Old Testament)	1	46+
Hebrew (Modern)	1	6,12+
Hungarian	1	6+
Italian	2	8,27+
Japanese*	1	9+
Korean	1	27+
Latin	1	8,9,28+
Maori	1	7,8,9,27+
Norwegian	1	27+
Polish*	1	27+
Portuguese	1	27+
Russian	1	All
Spanish	2	All
Swedish	1	27+
Tagalog	1	27+
Thai	1	27+
Vietnamese	1	27,44+

Table 1. Languages[1]

The languages above represent many of the major language groups: Austronesian (Maori and Tagalog); Altaic (Japanese and Korean); Sino-Tibetan (Chinese); Semitic (Arabic and Hebrew); Finno-Ugric (Finnish and Hungarian); Austro-Asiatic (Vietnamese); Tai-Kadai (Thai); and Indo-European (the remaining languages). The two New Testament Greek versions are the Byzantine/Majority Text (2000), and the parsed version of the same text, in which we treated distinct morphological elements (such as roots or inflectional endings) as distinct terms. Overall, the list includes

[1] Translations in languages marked with an asterisk above were obtained from websites other than the 'Unbound Bible' website. 'Used in tests' indicates in which tests in Table 2 below the language was used as training data, and hence the order of addition of languages to the training data.

47 versions in 31 distinct languages (assuming without further discussion here that each entry in the list represents a distinct language).

We aligned the translations by verse, and, since there are some differences in versification between translations (for example, the Hebrew Old Testament includes the headings for the Psalms as separate verses, unlike most translations), we spent some time cleaning the data to ensure the alignment was as good as possible, given available resources and our knowledge of the languages. (Even after this process, the alignment was not perfect, and differences in how well the various translations were aligned may account for some of the variability in the outcome of our experiments, depending on which translations were used.) The end result was that our parallel corpus consisted of 31,226 'mini-documents' – the total number of text chunks[2] after the cleaning process, aligned across all 47 versions. The two New Testament Greek versions, and the one Old Testament Hebrew version, were exceptions because these are only partially complete; the former have text in only 7,953 of the verses, and the latter has text in 23,266 of the verses. For some versions, a few of the verse translations are incomplete where a particular verse has been skipped in translation; this also explains the fact that the number of Hebrew and Greek text chunks together do not add up to 31,226. However, the number of such verses is negligible in comparison to the total.

3 Framework

The framework we used was the standard LSI framework described in Berry et al. (1994). Each aligned mini-document from the parallel corpus consists of the *combination* of text from all the 31 languages. A document-by-term matrix is formed in which each cell represents a weighted frequency of a particular term *t* in a particular document *k*. We used a standard log-entropy weighting scheme, where the weighted frequency W is given by:

$$W = \log_2 (F) \times (1 + H_t / \log_2 (N))$$

where F is the raw frequency of *t* in *k*, H_t is the standard '*p* log *p*' measure of the entropy of the term across all documents, and N is the number of documents in the corpus. The last term in the expression above, $\log_2 (N)$, is the maximum entropy that any term can have in the corpus, and therefore $(1 + H_t / \log_2 (N))$ is 1 for the most distinctive terms in the corpus, 0 for those which are least distinctive.

The sparse document-by-term matrix is subjected to singular value decomposition (SVD), and a reduced non-sparse matrix is output. Generally, we used the output corresponding to the top 300 singular values in our experiments. When we had a smaller number of languages in the mix, it was possible to use SVDPACK (Berry et al. 1996), which is an open-source non-parallel algorithm for computing the SVD, but for larger problems (involving more than a couple of dozen parallel versions), use of a parallel algorithm (in a library called Trilinos) was necessitated. (This was run on a Linux cluster consisting of 4,096 dual CPU compute nodes, running on Dell PowerEdge 1850 1U Servers with 6GB of RAM.)

In order to test the precision versus recall of our framework, we used translations of the 114 suras of the Qu'ran into five languages, Arabic, English, French, Russian and Spanish. The number of documents used for testing is fairly small, but large enough to give comparative results for our purposes which are still highly statistically significant. The test set was split into each of the 10 possible language-pair combinations: Arabic-English, Arabic-French, English-French, and so on.

For each language pair and test, 228 distinct 'queries' were submitted – each query consisting of one of the 228 sura 'documents'. If the highest-ranking document in the other language of the pair was in fact the query's translation, then the result was deemed 'correct'. To assess the aggregate performance of the framework, we used two measures: average precision at 0 (the maximum precision at any level of recall), and average precision at 1 document (1 if the 'correct' document ranked highest, zero otherwise). The second measure is a stricter one, but we generally found that there is a high rate of correlation between the two measures anyway.

4 Results and Discussion

The following tables show the results of our tests. First, we present in Table 2 the overall summary,

[2] The text chunks generally had the same boundaries as the verses in the original text.

with averages across all language pairs used in testing.

No. of parallel versions	Average precision	
	At 0	at 1 doc.
2	0.706064	0.571491
3	0.747620	0.649269
4	0.617615	0.531873
5	0.744951	0.656140
6	0.811666	0.732602
7	0.827246	0.753070
8	0.824501	0.750000
9	0.823430	0.746053
12	0.827761	0.752632
27	0.825577	0.751316
28	0.823137	0.747807
44	0.839346	0.765789
46	0.839319	0.766667
47	0.842936	0.774561

Table 2. Summary results for all language pairs

From the above, the following should be clear: as more parallel translations are added to the index, the average precision rises considerably at first, and then begins to level off after about the seventh parallel translation. The results will of course vary according to which combination of translations is selected for the index. The number of such combinations is generally very large: for example, with 47 translations available, there are 47! / (40! 7!), or 62,891,499, possible ways of selecting 7 translations. Thus, for any particular number of parallel versions, we had to use some judgement in which parallel versions to select, since there was no way to achieve anything like exhaustive coverage of the possibilities.

Further, with more than 7 parallel translations, there is certainly no justification for saying that adding more translations or languages increases the 'noise' for languages in the test set, since beyond 7 the average precision remains fairly level. If anything, in fact, the precision still appears to rise slightly. For example, the average precision at 1 document rises by more than 0.75 percentage points between 46 and 47 versions. Given that in each of these experiments, we are measuring precision 228 times per language pair, and therefore 2,280 times in total, this small rise in precision is significant ($p \approx 0.034$). Interestingly, the 47th version to be added was parsed New Testament Greek. It appears, therefore, that the parsing helped in particular; we also have evidence from other experiments (not presented here) that overall precision is generally improved for *all* languages when Arabic wordforms are replaced by their respective citation forms (the bare root, or stem) – also a form of morphological parsing. Ancient Greek, like Arabic, is morphologically highly complex, so it would be understandable that parsing (or stemming) would help when parsing of either language is used in training.

One other point needs to be made here: the three versions added after the 44th version were the three incomplete versions (the two Greek versions cover just the New Testament, while Ancient Hebrew covers just the Old Testament). The above-mentioned increase in precision which resulted from the addition of these three versions is clear evidence that even in the case where a parallel corpus is defective for some language(s), including those languages can still result in the twofold benefit that (1) those languages are now available for analysis, and (2) precision is maintained or increased for the remaining languages.

Finally, precision at 1 document, the stricter of the two measures, is by definition less than or equal to precision at 0. This taken into account, it is also interesting that the gap between the two measures seems to narrow as more parallel translations and parsing are added, as Figure 1 shows.

For certain applications where it is important that the translation is ranked first, not just highly, among all retrieved documents, there is thus a particular benefit in using a 'massively parallel' aligned corpus.

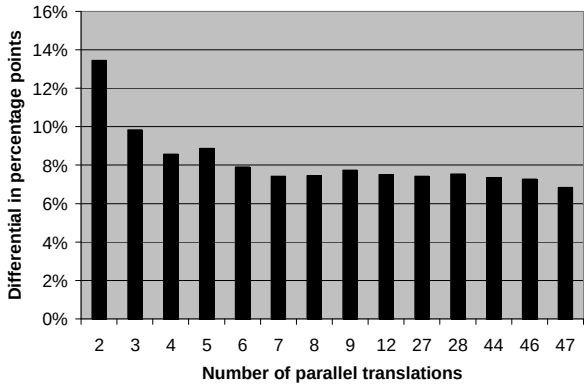

Figure 1. Differential between precision at 0 and precision at 1 document, by number of languages

Now we move on to look at more detailed results by language pair. Figure 2 below breaks down the results for precision at 1 document by language pair. In all tests, the two languages in each pair were (naturally) always included in the languages used for training. There is more volatility in the results by language pair than there is in the overall results, shown again at the right of the graph, which should come as no surprise since the averages are based on samples a tenth of the size. Generally, however, the pattern is the same for particular language pairs as it is overall; the more parallel versions are used in training, the better the average precision.

There are some more detailed observations which should also be made from Figure 2. First, the average precision clearly varies quite widely between language pairs. The language pairs with the best average precision are those in which two of English, French and Spanish are present. Of the five languages used for testing, these three cluster together genetically, since all three are Western (Germanic or Romance) Indo-European languages. Moreover, these are the three languages of the five which are written in the Roman alphabet.

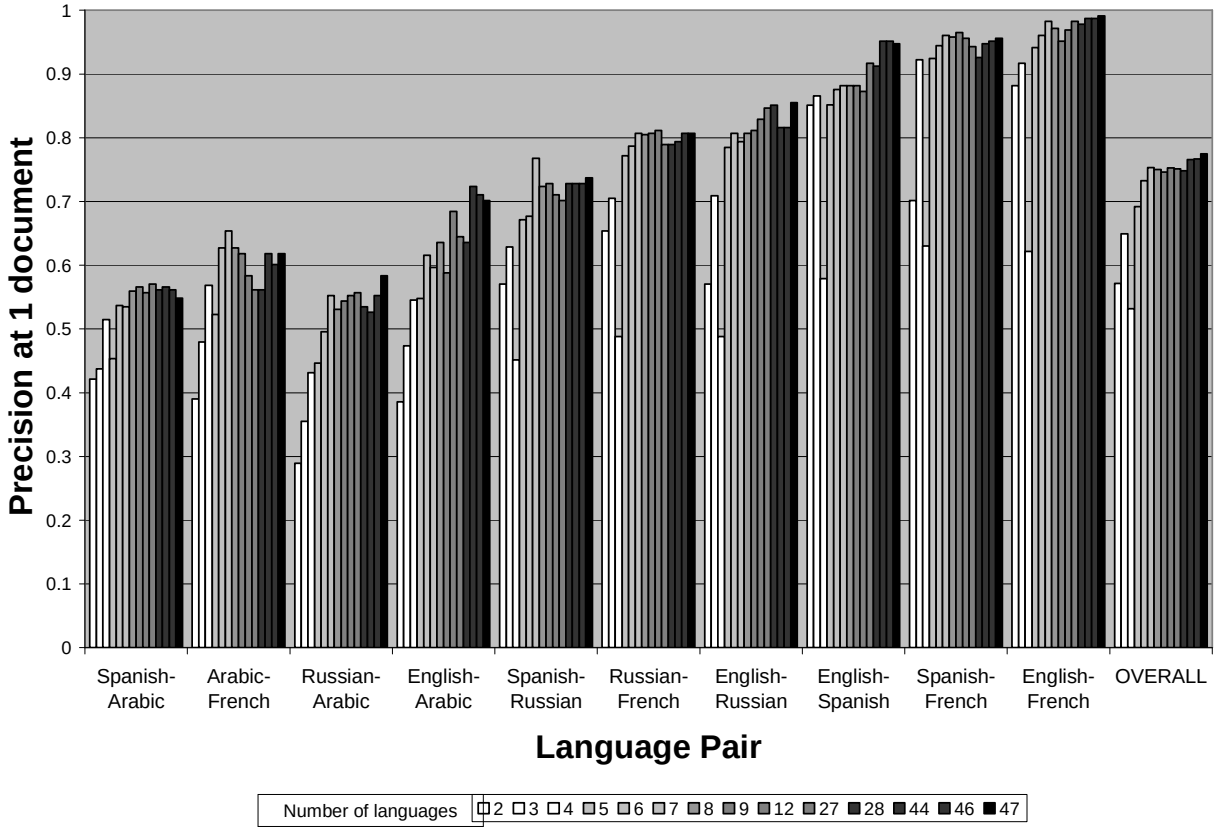

Figure 2. Chart of precision at 1 doc. by language pair and number of parallel training versions

However, we believe the explanation for the poorer results for language pairs involving either Arabic, Russian, or both, can be pinned down to something more specific. We have already partially alluded to the obvious difference between Arabic and Russian on the one hand, and English, French and Spanish on the other: that Arabic and Russian are highly morphologically rich, while English, French and Spanish are generally analytic languages. This has a clear effect on the statistics for the languages in question, as can be seen in Table 3, which is based on selected translations of the Bible for each of the languages in question.

Translation	Types	Tokens
English (King James)	12,335	789,744
Spanish (Reina Valera 1909)	28,456	704,004
Russian (Synodal 1876)	47,226	560,524
Arabic (Smith Van Dyke)	55,300	440,435
French (Darby)	20,428	812,947

Table 3. Statistics for Bible translations in 5 languages used in test data

Assuming that the respective translations are faithful (and we have no reason to believe otherwise), and based on the statistics in Table 3, it should be the case that Arabic contains the most 'information' per term (in the information theoretic sense), followed by Russian, Spanish, English and French.[3] Again, this corresponds to our intuition that much information is contained in Arabic patterns and Russian inflectional morphemes, which in English, French and Spanish would be contained in separate terms (for example, prepositions).

Without additional pre-processing, however, LSI cannot deal adequately with root-pattern or inflectional morphology. Moreover, it is clearly a weakness of LSI, or at least the standard log-entropy weighting scheme as applied within this framework, that it makes no adjustment for differences in information content per word between languages. Even though we can assume near-equivalency of information content between the different translations above, according to the standard log-entropy weighting scheme there are large differences between the total entropy of particular parallel documents; in general, languages such as English are overweighted while those such as Arabic are underweighted.

Now that this issue is in perspective, we should draw attention to another detail in Figure 2. Note that the language pairs which benefited most from the addition of Ancient Greek and Hebrew into the training data were those which included Russian, and Russian-Arabic saw the greatest increase in precision. Recall also that the 47th version to be added was the parsed Greek, so that essentially each Greek morpheme is represented by a distinct term. From Figure 2, it seems clear that the inclusion of parsed Greek in particular boosted the precision for Russian (this is most visible at the right-hand side of the set of columns for Russian-Arabic and English-Russian). There are, after all, notable similarities between modern Russian and Ancient Greek morphology (for example, the nominal case system). Essentially, the parsed Greek acts as a 'clue' to LSI in associating inflected forms in Russian with preposition/non-inflected combinations in other languages. These results seem to be further confirmation of the notion that parsing just one of the languages in the mix helps overall; the greatest boost is for those languages with morphology related to that of the parsed language, but there is at least a maintenance, and perhaps a small boost, in the precision for unrelated languages too.

Finally, we turn to look at some effects of the particular languages selected for training. Included in the results above, there were three separate tests run in which there were 6 training versions. In all three, Arabic, English, French, Russian and Spanish were included. The only factor we varied in the three tests was the sixth version. In the three tests, we used Modern Hebrew (a Semitic language, along with Arabic), Hungarian (a Uralic language, not closely related to any of the other five languages), and a second English version respectively. The results of these tests are shown in Figure 3, with figures for the test in which only 5 versions were included for comparative purposes.

From these results, it is apparent first of all that it was generally beneficial to add a sixth version, regardless of whether the version added was English, Hebrew or Hungarian. This is consistent with the results reported elsewhere in this paper. Second, it is also apparent that the greatest benefit overall was had by using an additional English version, rather than using Hebrew or Hungarian. Moreover, perhaps surprisingly, the use of Hebrew in training – even though Hebrew is related to Arabic – was of less benefit to Arabic than either Hungarian or an additional English version. It appears that the use of multiple versions in the same language is beneficial because it enables LSI to make use of the many different instantiations in the expression of a concept in a single language, and that this effect can be greater than the effect which obtains from using heterogeneous languages, even if there is a genetic relationship to existing languages.

[3] To clarify the meaning of 'term' here: for all languages except Chinese, text is tokenized in our framework into terms using regular expressions; each non-word character (such as punctuation or white space) is assumed to mark the boundary of a word. For Chinese, we made the simplifying assumption that each character represented a separate term.

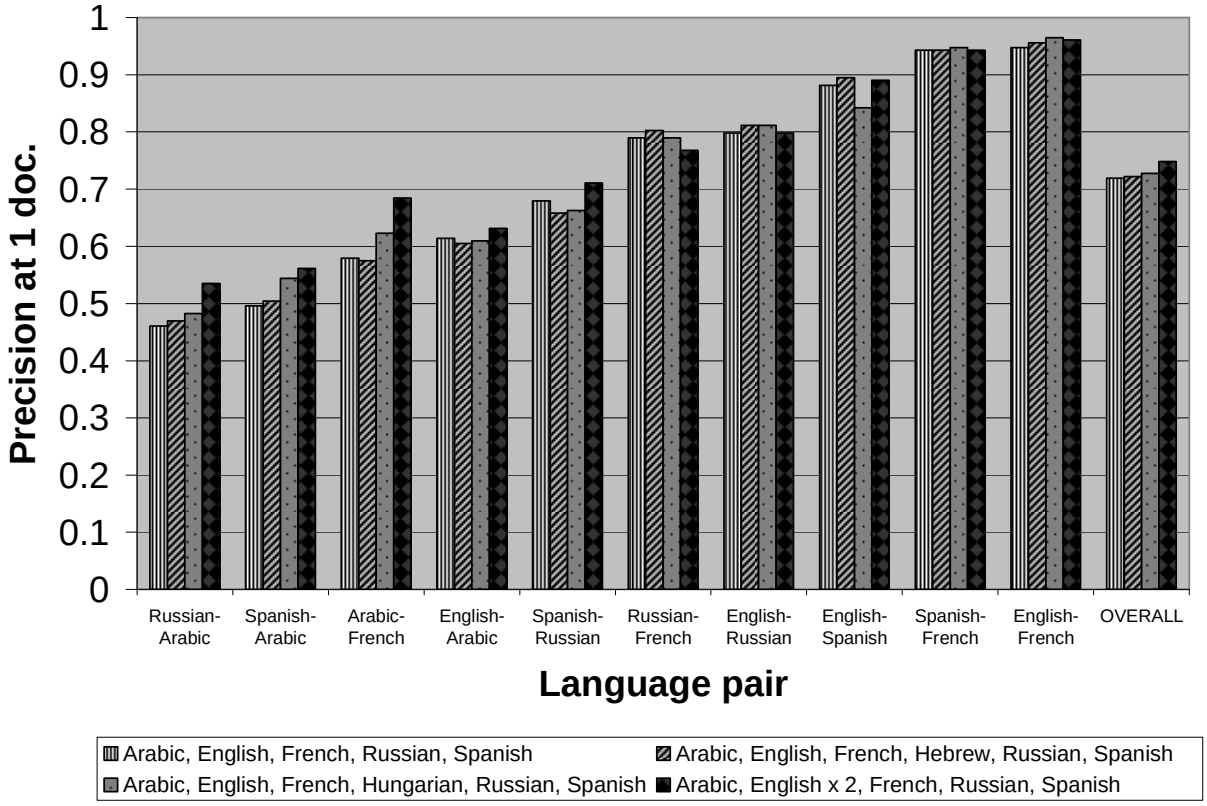

Figure 3. Precision at 1 document for 6 training versions, with results of using different mixes of languages for training

Figure 3 may also shed some additional light on one other detail from Figure 2: a perceptible jump in precision between 28 and 44 training versions for Arabic-English and Arabic-French. It should be mentioned that among the 16 additional versions were five English versions (American Standard Version, Basic English Bible, Darby, Webster's Bible, and Young's Literal Translation), and one French version (Louis Segond 1910). It seems that Figure 2 and Figure 3 both point to the same thing: that the use of parallel versions or translations in a *single* language can be particularly beneficial to overall precision within the LSI framework – even to a greater extent than the use of parallel translations in different languages.

5 Conclusion

In this paper, we have shown how 'massive parallelism' in an aligned corpus can be used to improve the results of cross-language information retrieval. Apart from the obvious advantage (the ability to automate the processing of a greater variety of linguistic data within a single framework), we have shown that including more parallel translations in training improves the precision of CLIR across the board. This is true whether the additional translations are in the language of another translation already within the training set, whether they are in a related language, or whether they are in an unrelated language; although this is not to say that these choices do not lead to (generally minor) variations in the results. The improvement in precision also appears to hold whether the additional translations are complete or incomplete, and it appears that morphological pre-processing helps, not just for the languages pre-processed, but again across the board.

Our work also offers further evidence that the supply of useful pre-existing parallel corpora is not perhaps as scarce as it is sometimes claimed to be. Compilation of the 47-version parallel corpus we used was not very time-consuming, especially if the time taken to clean the data is not taken into

account, and all the textual material we used is publicly available on the World Wide Web.

While the experiments we performed were on non-standard test collections (primarily because the Qu'ran was easy to obtain in multiple languages), it seems that there is no reason to believe our general observation – that more parallelism in the training data is beneficial for cross-language retrieval – would not hold for text from other domains. Whether the genre of text used as training data affects the *absolute* rate of retrieval precision for text of a different genre (e.g. news articles, shopping websites) is a separate question, and one we intend to address more fully in future work.

In summary, it appears that we are able to achieve the results we do partly because of the inherent properties of LSI. In essence, when the data from more and more parallel translations are subjected to SVD, the LSI 'concepts' become more and more reinforced. The resulting trend for precision to increase, despite 'blips' for individual languages, can be seen for all languages. To put it in more prosaic terms, the more different ways the same things are said in, the more understandable they become – including in cross-language information retrieval.

A Re-examination of Machine Learning Approaches for Sentence-Level MT Evaluation

Joshua S. Albrecht and Rebecca Hwa
Department of Computer Science
University of Pittsburgh
{jsa8,hwa}@cs.pitt.edu

Abstract

Recent studies suggest that machine learning can be applied to develop good automatic evaluation metrics for machine translated sentences. This paper further analyzes aspects of learning that impact performance. We argue that previously proposed approaches of training a *Human-Likeness classifier* is not as well correlated with human judgments of translation quality, but that *regression-based learning* produces more reliable metrics. We demonstrate the feasibility of regression-based metrics through empirical analysis of learning curves and generalization studies and show that they can achieve higher correlations with human judgments than standard automatic metrics.

1 Introduction

As machine translation (MT) research advances, the importance of its evaluation also grows. Efficient evaluation methodologies are needed both for facilitating the system development cycle and for providing an unbiased comparison between systems. To this end, a number of automatic evaluation metrics have been proposed to approximate human judgments of MT output quality. Although studies have shown them to correlate with human judgments at the document level, they are not sensitive enough to provide reliable evaluations at the sentence level (Blatz et al., 2003). This suggests that current metrics do not fully reflect the set of criteria that people use in judging sentential translation quality.

A recent direction in the development of metrics for sentence-level evaluation is to apply machine learning to create an improved composite metric out of less indicative ones (Corston-Oliver et al., 2001; Kulesza and Shieber, 2004). Under the assumption that good machine translation will produce "human-like" sentences, classifiers are trained to predict whether a sentence is authored by a human or by a machine based on features of that sentence, which may be the sentence's scores from individual automatic evaluation metrics. The confidence of the classifier's prediction can then be interpreted as a judgment on the translation quality of the sentence. Thus, the composite metric is encoded in the confidence scores of the classification labels.

While the learning approach to metric design offers the promise of ease of combining multiple metrics and the potential for improved performance, several salient questions should be addressed more fully. First, is learning a "Human Likeness" classifier the most suitable approach for framing the MT-evaluation question? An alternative is regression, in which the composite metric is explicitly learned as a function that approximates humans' quantitative judgments, based on a set of human evaluated training sentences. Although regression has been considered on a small scale for a single system as confidence estimation (Quirk, 2004), this approach has not been studied as extensively due to scalability and generalization concerns. Second, how does the diversity of the model features impact the learned metric? Third, how well do learning-based metrics generalize beyond their training examples? In particular, how well can a metric that was developed based

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 880–887,
Prague, Czech Republic, June 2007.

on one group of MT systems evaluate the translation qualities of new systems?

In this paper, we argue for the viability of a regression-based framework for sentence-level MT-evaluation. Through empirical studies, we first show that having an accurate Human-Likeness classifier does not necessarily imply having a good MT-evaluation metric. Second, we analyze the resource requirement for regression models for different sizes of feature sets through learning curves. Finally, we show that SVM-regression metrics generalize better than SVM-classification metrics in their evaluation of systems that are different from those in the training set (by languages and by years), and their correlations with human assessment are higher than standard automatic evaluation metrics.

2 MT Evaluation

Recent automatic evaluation metrics typically frame the evaluation problem as a comparison task: how *similar* is the machine-produced output to a set of human-produced reference translations for the same source text? However, as the notion of similarity is itself underspecified, several different families of metrics have been developed. First, similarity can be expressed in terms of string edit distances. In addition to the well-known word error rate (WER), more sophisticated modifications have been proposed (Tillmann et al., 1997; Snover et al., 2006; Leusch et al., 2006). Second, similarity can be expressed in terms of common word sequences. Since the introduction of BLEU (Papineni et al., 2002) the basic n-gram precision idea has been augmented in a number of ways. Metrics in the Rouge family allow for skip n-grams (Lin and Och, 2004a); Kauchak and Barzilay (2006) take paraphrasing into account; metrics such as METEOR (Banerjee and Lavie, 2005) and GTM (Melamed et al., 2003) calculate both recall and precision; METEOR is also similar to SIA (Liu and Gildea, 2006) in that word class information is used. Finally, researchers have begun to look for similarities at a deeper structural level. For example, Liu and Gildea (2005) developed the Sub-Tree Metric (STM) over constituent parse trees and the Head-Word Chain Metric (HWCM) over dependency parse trees.

With this wide array of metrics to choose from, MT developers need a way to evaluate them. One possibility is to examine whether the automatic metric ranks the human reference translations highly with respect to machine translations (Lin and Och, 2004b; Amigó et al., 2006). The reliability of a metric can also be more directly assessed by determining how well it correlates with human judgments of the same data. For instance, as a part of the recent NIST sponsored MT Evaluation, each translated sentence by participating systems is evaluated by two (non-reference) human judges on a five point scale for its *adequacy* (does the translation retain the meaning of the original source text?) and *fluency* (does the translation sound natural in the target language?). These human assessment data are an invaluable resource for measuring the reliability of automatic evaluation metrics. In this paper, we show that they are also informative in developing better metrics.

3 MT Evaluation with Machine Learning

A good automatic evaluation metric can be seen as a computational model that captures a human's decision process in making judgments about the adequacy and fluency of translation outputs. Inferring a cognitive model of human judgments is a challenging problem because the ultimate judgment encompasses a multitude of fine-grained decisions, and the decision process may differ slightly from person to person. The metrics cited in the previous section aim to capture certain aspects of human judgments. One way to combine these metrics in a uniform and principled manner is through a learning framework. The individual metrics participate as input features, from which the learning algorithm infers a composite metric that is optimized on training examples.

Reframing sentence-level translation evaluation as a classification task was first proposed by Corston-Oliver et al. (2001). Interestingly, instead of recasting the classification problem as a "Human Acceptability" test (distinguishing good translations outputs from bad one), they chose to develop a Human-Likeness classifier (distinguishing outputs seem human-produced from machine-produced ones) to avoid the necessity of obtaining manually labeled training examples. Later, Kulesza and Shieber (2004) noted that if a classifier provides a

confidence score for its output, that value can be interpreted as a quantitative estimate of the input instance's translation quality. In particular, they trained an SVM classifier that makes its decisions based on a set of input features computed from the sentence to be evaluated; the distance between input feature vector and the separating hyperplane then serves as the evaluation score. The underlying assumption for both is that improving the accuracy of the classifier on the Human-Likeness test will also improve the implicit MT evaluation metric.

A more direct alternative to the classification approach is to learn via regression and explicitly optimize for a function (i.e. MT evaluation metric) that approximates human judgments in training examples. Kulesza and Shieber (2004) raised two main objections against regression for MT evaluations. One is that regression requires a large set of labeled training examples. Another is that regression may not generalize well over time, and re-training may become necessary, which would require collecting additional human assessment data. While these are legitimate concerns, we show through empirical studies (in Section 4.2) that the additional resource requirement is not impractically high, and that a regression-based metric has higher correlations with human judgments and generalizes better than a metric derived from a Human-Likeness classifier.

3.1 Relationship between Classification and Regression

Classification and regression are both processes of function approximation; they use training examples as sample instances to learn the mapping from inputs to the desired outputs. The major difference between classification and regression is that the function learned by a classifier is a set of decision boundaries by which to classify its inputs; thus its outputs are discrete. In contrast, a regression model learns a continuous function that directly maps an input to a continuous value. An MT evaluation metric is inherently a continuous function. Casting the task as a 2-way classification may be too coarse-grained. The Human-Likeness formulation of the problem introduces another layer of approximation by assuming equivalence between "Like Human-Produced" and "Well-formed" sentences. In Section 4.1, we show empirically that high accuracy in the Human-Likeness test does not necessarily entail good MT evaluation judgments.

3.2 Feature Representation

To ascertain the resource requirements for different model sizes, we considered two feature models. The smaller one uses the same nine features as Kulesza and Shieber, which were derived from BLEU and WER. The full model consists of 53 features: some are adapted from recently developed metrics; others are new features of our own. They fall into the following major categories[1]:

String-based metrics over references These include the nine Kulesza and Shieber features as well as precision, recall, and fragmentation, as calculated in METEOR; ROUGE-inspired features that are non-consecutive bigrams with a gap size of m, where $1 \leq m \leq 5$ (skip-m-bigram), and ROUGE-L (longest common subsequence).

Syntax-based metrics over references We unrolled HWCM into their individual chains of length c (where $2 \leq c \leq 4$); we modified STM so that it is computed over unlexicalized constituent parse trees as well as over dependency parse trees.

String-based metrics over corpus Features in this category are similar to those in *String-based metric over reference* except that a large English corpus is used as "reference" instead.

Syntax-based metrics over corpus A large dependency treebank is used as the "reference" instead of parsed human translations. In addition to adaptations of the *Syntax-based metrics over references*, we have also created features to verify the argument structures for certain syntactic categories.

4 Empirical Studies

In these studies, the learning models used for both classification and regression are support vector machines (SVM) with Gaussian kernels. All models are trained with SVM-Light (Joachims, 1999). Our primary experimental dataset is from NIST's 2003

[1] As feature engineering is not the primary focus of this paper, the features are briefly described here, but implementational details will be made available in a technical report.

Chinese MT Evaluations, in which the fluency and adequacy of 919 sentences produced by six MT systems are scored by two human judges on a 5-point scale[2]. Because the judges evaluate sentences according to their individual standards, the resulting scores may exhibit a biased distribution. We normalize human judges' scores following the process described by Blatz et al. (2003). The overall human assessment score for a translation output is the average of the sum of two judges' normalized fluency and adequacy scores. The full dataset ($6 \times 919 = 5514$ instances) is split into sets of training, heldout and test data. Heldout data is used for parameter tuning (i.e., the slack variable and the width of the Gaussian). When training classifiers, assessment scores are not used, and the training set is augmented with all available human reference translation sentences ($4 \times 919 = 3676$ instances) to serve as positive examples.

To judge the quality of a metric, we compute Spearman rank-correlation coefficient, which is a real number ranging from -1 (indicating perfect negative correlations) to +1 (indicating perfect positive correlations), between the metric's scores and the averaged human assessments on test sentences. We use Spearman instead of Pearson because it is a distribution-free test. To evaluate the relative reliability of different metrics, we use bootstrapping re-sampling and paired t-test to determine whether the difference between the metrics' correlation scores has statistical significance (at 99.8% confidence level)(Koehn, 2004). Each reported correlation rate is the average of 1000 trials; each trial consists of n sampled points, where n is the size of the test set. Unless explicitly noted, the qualitative differences between metrics we report are statistically significant. As a baseline comparison, we report the correlation rates of three standard automatic metrics: BLEU, METEOR, which incorporates recall and stemming, and HWCM, which uses syntax. BLEU is smoothed to be more appropriate for sentence-level evaluation (Lin and Och, 2004b), and the bigram versions of BLEU and HWCM are reported because they have higher correlations than when longer n-grams are included. This phenomenon has been previously observed by Liu and Gildea (2005).

[2]This corpus is available from the Linguistic Data Consortium as Multiple Translation Chinese Part 4.

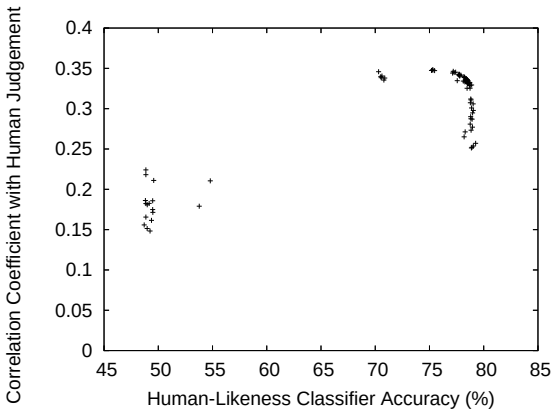

Figure 1: This scatter plot compares classifiers' accuracy with their corresponding metrics' correlations with human assessments

4.1 Relationship between Classification Accuracy and Quality of Evaluation Metric

A concern in using a metric derived from a Human-Likeness classifier is whether it would be predictive for MT evaluation. Kulesza and Shieber (2004) tried to demonstrate a positive correlation between the Human-Likeness classification task and the MT evaluation task empirically. They plotted the classification accuracy and evaluation reliability for a number of classifiers, which were generated as a part of a greedy search for kernel parameters and found some linear correlation between the two. This proof of concept is a little misleading, however, because the population of the sampled classifiers was biased toward those from the same neighborhood as the local optimal classifier (so accuracy and correlation may only exhibit linear relationship locally). Here, we perform a similar study except that we sampled the kernel parameter more uniformly (on a log scale). As Figure 1 confirms, having an accurate Human-Likeness classifier does not necessarily entail having a good MT evaluation metric. Although the two tasks do seem to be positively related, and in the limit there may be a system that is good at both tasks, one may improve classification without improving MT evaluation. For this set of heldout data, at the near 80% accuracy range, a derived metric might have an MT evaluation correlation coefficient anywhere between 0.25 (on par with

unsmoothed BLEU, which is known to be unsuitable for sentence-level evaluation) and 0.35 (competitive with standard metrics).

4.2 Learning Curves

To investigate the feasibility of training regression models from assessment data that are currently available, we consider both a small and a large regression model. The smaller model consists of nine features (same as the set used by Kulesza and Shieber); the other uses the full set of 53 features as described in Section 3.2. The reliability of the trained metrics are compared with those developed from Human-Likeness classifiers. We follow a similar training and testing methodology as previous studies: we held out 1/6 of the assessment dataset for SVM parameter tuning; five-fold cross validation is performed with the remaining sentences. Although the metrics are evaluated on unseen test sentences, the sentences are produced by the same MT systems that produced the training sentences. In later experiments, we investigate generalizing to more distant MT systems.

Figure 2(a) shows the learning curves for the two regression models. As the graph indicates, even with a limited amount of human assessment data, regression models can be trained to be comparable to standard metrics (represented by METEOR in the graph). The small feature model is close to convergence after 1000 training examples[3]. The model with a more complex feature set does require more training data, but its correlation began to overtake METEOR after 2000 training examples. This study suggests that the start-up cost of building even a moderately complex regression model is not impossibly high.

Although we cannot directly compare the learning curves of the Human-Likeness classifiers to those of the regression models (since the classifier's training examples are automatically labeled), training examples for classifiers are not entirely free: human reference translations still must be developed for the source sentences. Figure 2(c) shows the learning curves for training Human-Likeness classifiers (in terms of improving a classifier's accuracy) using the same two feature sets, and Figure 2(b) shows the correlations of the metrics derived from the corresponding classifiers. The pair of graphs show, especially in the case of the larger feature set, that a large improvement in classification accuracy does not bring proportional improvement in its corresponding metrics's correlation; with an accuracy of near 90%, its correlation coefficient is 0.362, well below METEOR.

This experiment further confirms that judging Human-Likeness and judging Human-Acceptability are not tightly coupled. Earlier, we have shown in Figure 1 that different SVM parameterizations may result in classifiers with the same accuracy rate but different correlations rates. As a way to incorporate some assessment information into classification training, we modify the parameter tuning process so that SVM parameters are chosen to optimize for assessment correlations in the heldout data. By incurring this small amount of human assessed data, this parameter search improves the classifier's correlations: the metric using the smaller feature set increased from 0.423 to 0.431, and that of the larger set increased from 0.361 to 0.422.

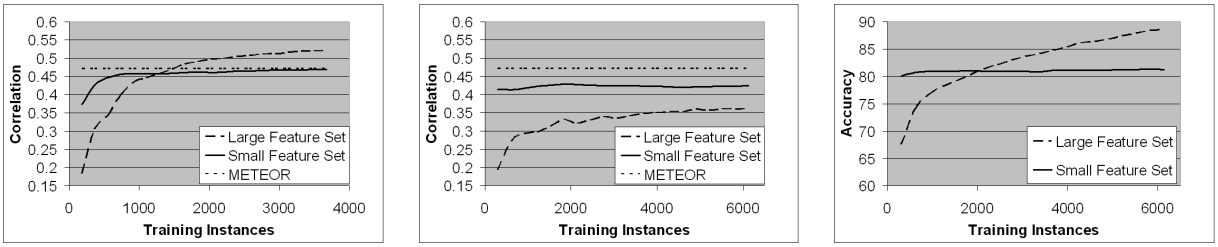
4.3 Generalization

We conducted two generalization studies. The first investigates how well the trained metrics evaluate systems from other years and systems developed for a different source language. The second study delves more deeply into how variations in the training examples affect a learned metric's ability to generalize to distant systems. The learning models for both experiments use the full feature set.

Cross-Year Generalization To test how well the learning-based metrics generalize to systems from different years, we trained both a regression-based metric (R03) and a classifier-based metric (C03) with the entire NIST 2003 Chinese dataset (using 20% of the data as heldout[4]). All metrics are then applied to three new datasets: NIST 2002 Chinese MT Evaluation (3 systems, 2634 sentences total), NIST 2003 Arabic MT Evaluation (2 systems, 1326 sentences total), and NIST 2004 Chinese MT Evaluation (10 systems, 4470 sentences total). The results

[3]The total number of labeled examples required is closer to 2000, since the heldout set uses 919 labeled examples.

[4]Here, too, we allowed the classifier's parameters to be tuned for correlation with human assessment on the heldout data rather than accuracy.



(a) (b) (c)

Dataset	R03	C03	BLEU	MET.	HWCM
2002 Ara	**0.466**	0.384	0.423	0.431	0.424
2002 Chn	**0.309**	0.250	0.269	0.290	0.260
2004 Chn	**0.602**	0.566	0.588	0.563	0.546

Table 1: Correlations for cross-year generalization. Learning-based metrics are developed from NIST 2003 Chinese data. All metrics are tested on datasets from 2003 Arabic, 2002 Chinese and 2004 Chinese.

are summarized in Table 1. We see that R03 consistently has a better correlation rate than the other metrics.

At first, it may seem as if the difference between R03 and BLEU is not as pronounced for the 2004 dataset, calling to question whether a learned metric might become quickly out-dated, we argue that this is not the case. The 2004 dataset has many more participating systems, and they span a wider range of qualities. Thus, it is easier to achieve a high rank correlation on this dataset than previous years because most metrics can qualitatively discern that sentences from one MT system are better than those from another. In the next experiment, we examine the performance of R03 with respect to each MT system in the 2004 dataset and show that its correlation rate is higher for better MT systems.

Relationship between Training Examples and Generalization Table 2 shows the result of a generalization study similar to before, except that correlations are performed on each system. The rows order the test systems by their translation qualities from the best performing system (2004-Chn1, whose average human assessment score is 0.655 out of 1.0) to the worst (2004-Chn10, whose score is 0.255). In addition to the regression metric from the previous experiment (R03-all), we consider two more regression metrics trained from subsets of the 2003 dataset: R03-Bottom5 is trained from the subset that excludes the best 2003 MT system, and R03-Top5 is trained from the subset that excludes the worst 2003 MT system.

We first observe that on a per test-system basis, the regression-based metrics generally have better correlation rates than BLEU, and that the gap is as wide as what we have observed in the earlier cross-years studies. The one exception is when evaluating 2004-Chn8. None of the metrics seems to correlate very well with human judges on this system. Because the regression-based metric uses these individual metrics as features, its correlation also suffers.

During regression training, the metric is optimized to minimize the difference between its prediction and the human assessments of the training data. If the input feature vector of a test instance is in a very distant space from training examples, the chance for error is higher. As seen from the results, the learned metrics typically perform better when the training examples include sentences from higher-quality systems. Consider, for example, the differences between R03-all and R03-Top5 versus the differences between R03-all and R03-Bottom5. Both R03-Top5 and R03-Bottom5 differ from R03-all by one subset of training examples. Since R03-all's correlation rates are generally closer to R03-Top5 than to R03-Bottom5, we see that having seen extra training examples from a bad system is not as harmful as having not seen training examples from a good system. This is expected, since there are many ways to create bad translations, so seeing a partic-

	R03-all	R03-Bottom5	R03-Top5	BLEU	METEOR	HWCM

Table 2: Metric correlations within each system. The columns specify which metric is used. The rows specify which MT system is under evaluation; they are ordered by human-judged system quality, from best to worst. For each evaluated MT system (row), the highest coefficient in bold font, and those that are statistically comparable to the highest are shown in italics.

ular type of bad translations from one system may not be very informative. In contrast, the neighborhood of good translations is much smaller, and is where all the systems are aiming for; thus, assessments of sentences from a good system can be much more informative.

4.4 Discussion

Experimental results confirm that learning from training examples that have been doubly approximated (class labels instead of ordinals, human-likeness instead of human-acceptability) does negatively impact the performance of the derived metrics. In particular, we showed that they do not generalize as well to new data as metrics trained from direct regression.

We see two lingering potential objections toward developing metrics with regression-learning. One is the concern that a system under evaluation might try to explicitly "game the metric[5]." This is a concern shared by all automatic evaluation metrics, and potential problems in stand-alone metrics have been analyzed (Callison-Burch et al., 2006). In a learning framework, potential pitfalls for individual metrics are ameliorated through a combination of evidences. That said, it is still prudent to defend against the potential of a system gaming a subset of the features. For example, our fluency-predictor features are not strong indicators of translation qualities by themselves. We want to avoid training a metric that assigns a higher than deserving score to a sentence that just happens to have many n-gram matches against the target-language reference corpus. This can be achieved by supplementing the current set of human assessed training examples with automatically assessed training examples, similar to the labeling process used in the Human-Likeness classification framework. For instance, as negative training examples, we can incorporate fluent sentences that are not adequate translations and assign them low overall assessment scores.

A second, related concern is that because the metric is trained on examples from current systems using currently relevant features, even though it generalizes well in the near term, it may not continue to be a good predictor in the distant future. While periodic retraining may be necessary, we see value in the flexibility of the learning framework, which allows for new features to be added. Moreover, adaptive learning methods may be applicable if a small sample of outputs of some representative translation systems is manually assessed periodically.

5 Conclusion

Human judgment of sentence-level translation quality depends on many criteria. Machine learning affords a unified framework to compose these criteria into a single metric. In this paper, we have demonstrated the viability of a regression approach to learning the composite metric. Our experimental results show that by training from some human as-

[5]Or, in a less adversarial setting, a system may be performing minimum error-rate training (Och, 2003)

sessments, regression methods result in metrics that have better correlations with human judgments even as the distribution of the tested population changes.

Abstract

This paper presents an approach for the automatic acquisition of qualia structures for nouns from the Web and thus opens the possibility to explore the impact of qualia structures for natural language processing at a larger scale. The approach builds on earlier work based on the idea of matching specific lexico-syntactic patterns conveying a certain semantic relation on the World Wide Web using standard search engines. In our approach, the qualia elements are actually ranked for each qualia role with respect to some measure. The specific contribution of the paper lies in the extensive analysis and quantitative comparison of different measures for ranking the qualia elements. Further, for the first time, we present a quantitative evaluation of such an approach for learning qualia structures with respect to a handcrafted gold standard.

1 Introduction

Qualia structures have been originally introduced by (Pustejovsky, 1991) and are used for a variety of purposes in natural language processing (NLP), such as for the analysis of compounds (Johnston and Busa, 1996) as well as co-composition and coercion (Pustejovsky, 1991), but also for bridging reference resolution (Bos et al., 1995). Further, it has also been argued that qualia structures and lexical semantic relations in general have applications in information retrieval (Voorhees, 1994; Pustejovsky et al., 1993). One major bottleneck however is that currently qualia structures need to be created by hand, which is probably also the reason why there are almost no practical NLP systems using qualia structures, but a lot of systems relying on publicly available resources such as WordNet (Fellbaum, 1998) or FrameNet (Baker et al., 1998) as source of lexical/world knowledge. The work described in this paper addresses this issue and presents an approach to automatically learning qualia structures for nouns from the Web. The approach is inspired in recent work on using the Web to identify instances of a relation of interest such as in (Markert et al., 2003) and (Etzioni et al., 2005). These approaches rely on a combination of the usage of lexico-syntactic pattens conveying a certain relation of interest as described in (Hearst, 1992) with the idea of using the web as a big corpus (cf. (Kilgariff and Grefenstette, 2003)).
Our approach directly builds on our previous work (Cimiano and Wenderoth, 2005) an adheres to the principled idea of learning ranked qualia structures. In fact, a ranking of qualia elements is useful as it helps to determine a cut-off point and as a reliability indicator for lexicographers inspecting the qualia structures. In contrast to our previous work, the focus of this paper lies in analyzing different measures for ranking the qualia elements in the automatically acquired qualia structures. We also introduce additional patterns for the agentive role which make use of wildcard operators. Further, we present a gold standard for qualia structures created for the 30 words used in the evaluation of Yamada and Baldwin (Yamada and Baldwin, 2004). The evaluation

[1]The work reported in this paper has been supported by the X-Media project, funded by the European Commission under EC grant number IST-FP6-026978 as well by the SmartWeb project, funded by the German Ministry of Research. Thanks to all our colleagues for helping to evaluate the approach.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 888–895,
Prague, Czech Republic, June 2007.

presented here is thus much more extensive than our previous one (Cimiano and Wenderoth, 2005), in which only 7 words were used. We present a quantitative evaluation of our approach and a comparison of the different ranking measures with respect to this gold standard. Finally, we also provide an evaluation in which test persons were asked to inspect and rate the learned qualia structures a posteriori. The paper is structured as follows: Section 2 introduces qualia structures for the sake of completeness and describes the specific structures we aim to acquire. Section 3 describes our approach in detail, while Section 4 discusses the ranking measures used. Section 5 then presents the gold standard as well as the qualitative evaluation of our approach. Before concluding, we discuss related work in Section 6.

2 Qualia Structures

In the Generative Lexicon (GL) framework (Pustejovsky, 1991), Pustejovsky reused Aristotle's basic factors (i.e. the material, agentive, formal and final causes) for the description of the meaning of lexical elements. In fact, he introduced so called *qualia structures* by which the meaning of a lexical element is described in terms of four roles: *Constitutive* (describing physical properties of an object, i.e. its weight, material as well as parts and components), *Agentive* (describing factors involved in the bringing about of an object, i.e. its creator or the causal chain leading to its creation), *Formal* (describing properties which distinguish an object within a larger domain, i.e. orientation, magnitude, shape and dimensionality), and *Telic* (describing the purpose or function of an object).

Most of the qualia structures used in (Pustejovsky, 1991) however seem to have a more restricted interpretation. In fact, in most examples the *Constitutive* role seems to describe the parts or components of an object, while the *Agentive* role is typically described by a verb denoting an action which typically brings the object in question into existence. The *Formal* role normally consists in typing information about the object, i.e. its hypernym. In our approach, we aim to acquire qualia structures according to this restricted interpretation.

3 Automatically Acquiring Qualia Structures

Our approach to learning qualia structures from the Web is on the one hand based on the assumption that instances of a certain semantic relation can be acquired by matching certain lexico-syntactic patterns more or less reliably conveying the relation of interest in line with the seminal work of Hearst (Hearst, 1992), who defined patterns conveying hyponym/hypernym relations. However, it is well known that Hearst-style patterns occur rarely, such that matching these patterns on the Web in order to alleviate the problem of data sparseness seems a promising solution. In fact, in our case we are not only looking for the hypernym relation (comparable to the *Formal*-role) but for similar patterns conveying a *Constitutive*, *Telic* or *Agentive* relation. Our approach consists of 5 phases; for each *qualia term* (the word we want to find the qualia structure for) we:

1. generate for each qualia role a set of so called *clues*, i.e. search engine queries indicating the relation of interest,
2. download the snippets (abstracts) of the 50 first web search engine results matching the generated clues,
3. part-of-speech-tag the downloaded snippets,
4. match patterns in the form of regular expressions conveying the qualia role of interest, and
5. weight and rank the returned qualia elements according to some measure.

The patterns in our pattern library are actually tuples (p, c) where p is a regular expression defined over part-of-speech tags and c a function $c : string \rightarrow string$ called the *clue*. Given a nominal n and a clue c, the query $c(n)$ is sent to the web search engine and the abstracts of the first m documents matching this query are downloaded. Then the snippets are processed to find matches of the pattern p. For example, given the clue $f(x) =$ "$such\ as\ p(x)''$ and the qualia term *computer* we would download m abstracts matching the query f(computer), i.e. "such as computers". Hereby $p(x)$ is a function returning the plural form of x. We implemented this function as a lookup in a lexicon in which plural nouns are mapped to their base form. With the use of such clues, we thus download a num-

ber of snippets returned by the web search engine in which a corresponding regular expression will probably be matched, thus restricting the linguistic analysis to a few promising pages. The downloaded abstracts are then part-of-speech tagged using QTag (Tufis and Mason, 1998). Then we match the corresponding pattern p in the downloaded snippets thus yielding candidate qualia elements as output. The qualia elements are then ranked according to some measure (compare Section 4), resulting in what we call *Ranked Qualia Structures* (RQSs). The clues and patterns used for the different roles can be found in Tables 1 - 4. In the specification of the clues, the function a(x) returns the appropriate indefinite article – *'a'* or *'an'* – or no article at all for the noun x. The use of an indefinite article or no article at all accounts for the distinction between countable nouns (e.g. such as knife) and mass nouns (e.g. water). The choice between using the articles *'a'*, *'an'* or no article at all is determined by issuing appropriate queries to the web search engine and choosing the article leading to the highest number of results. The corresponding patterns are then matched in the 50 snippets returned by the search engine for each clue, thus leading to up to 50 potential qualia elements per clue and pattern[2]. The patterns are actually defined over part-of-speech tags. We indicate POS-tags in square brackets. However, for the sake of simplicity, we largely omit the POS-tags for the lexical elements in the patterns described in Tables 1 - 4. Note that we use traditional regular expression operators such as $*$ (sequence), $+$ (sequence with at least one element) | (alternative) and ? (option). In general, we define a noun phrase (NP) by the following regular expression: NP:=[DT]? ([JJ])+? [NN(S?)])+[3], where the head is the underlined expression, which is lemmatized and considered as a candidate qualia element. For all the patterns described in this section, the underlined part corresponds to the extracted qualia element. In the patterns for the formal role (compare Table 1), NP_{QT} is a noun phrase with the qualia term as head, whereas NP_F is a noun phrase with the potential qualia element as head. For the constitutive role patterns, we use a noun phrase variant NP' defined by the regular expression NP':= (NP of[IN])? NP (, NP)* ((,)? (and|or) NP)?, which allows to extract enumerations of constituents (compare Table 2). It is important to mention that in the case of expressions such as *"a car comprises a fixed number of basic components"*, *"data mining comprises a range of data analysis techniques"*, *"books consist of a series of dots"*, or *"a conversation is made up of a series of observable interpersonal exchanges"*, only the NP after the preposition 'of' is taken into account as qualia element. The *Telic* Role is in principle acquired in the same way as the *Formal* and *Constitutive* roles with the exception that the qualia element is not only the head of a noun phrase, but also a verb or a verb followed by a noun phrase. Table 3 gives the corresponding clues and patterns. In particular, the returned candidate qualia elements are the lemmatized underlined expressions in PURP:=[VB] NP | NP | be[VBD]. Finally, concerning the clues and patterns for the agentive role shown in Table 4, it is interesting to emphasize the usage of the adjectives 'new' and 'complete'. These adjectives are used in the patterns to increase the expectation for the occurrence of a creation verb. According to our experiments, these patterns are indeed more reliable in finding appropriate qualia elements than the alternative version without the adjectives 'new' and 'complete'. Note that in all patterns, the participle (VBD) is always reduced to base form (VB) via a lexicon lookup. In general, the patterns have been crafted by hand, testing and refining them in an iterative process, paying attention to maximize their coverage but also accuracy. In the future, we plan to exploit an approach to automatically learn the patterns.

Clue	Pattern
Singular	
"a(x) x is a kind of "	NP_{QT} is a kind of NP_F
"a(x) x is"	NP_{QT} is a kind of NP_F
"a(x) x and other"	NP_{QT} (,)? and other NP_F
"a(x) x or other"	NP_{QT} (,)? or other NP_F
Plural	
"such as p(x)"	NP_F such as NP_{QT}
"p(x) and other"	NP_{QT} (,)? and other NP_F
"p(x) or other"	NP_{QT} (,)? or other NP_F
"especially p(x)"	NP_F (,)? especially NP_{QT}
"including p(x)"	NP_F (,)? including NP_{QT}

Table 1: Clues and Patterns for the *Formal* role

[2]For the constitutive role these can be even more due to the fact that we consider enumerations.

[3]Though Qtag uses another part-of-speech tagset, we rely on the well-known Penn Treebank tagset for presentation purposes.

Clue	Pattern
Singular	
"a(x) x is made up of "	NP_{QT} is made up of NP'$_C$
"a(x) x is made of"	NP_{QT} is made of NP'$_C$
"a(x) x comprises"	NP_{QT} comprises (of)? NP'$_C$
"a(x) x consists of"	NP_{QT} consists of NP'$_C$
Plural	
"p(x) are made up of "	NP_{QT} is made up of NP'$_C$
"p(x) are made of"	NP_{QT} are made of NP'$_C$
"p(x) comprise"	NP_{QT} comprise (of)? NP'$_C$
"p(x) consist of"	NP_{QT} consist of NP'$_C$

4 Ranking Measures

In order to rank the different qualia elements of a given qualia structure, we rely on a certain ranking measure. In our experiments, we analyze four different ranking measures. On the one hand, we explore measures which use the Web to calculate the correlation strength between a qualia term and its qualia elements. These measures are Web-based versions of the Jaccard coefficient (Web-Jac), the Pointwise Mutual Information (Web-PMI) and the conditional probability (Web-P). We also present a version of the conditional probability which does not use the Web but merely relies on the counts of each qualia element as produced by the lexico-syntactic patterns (P-measure). We describe these measures in the following.

4.1 Web-based Jaccard Measure (Web-Jac)

Our web-based Jaccard (Web-Jac) measure relies on the web search engine to calculate the number of documents in which x and y co-occur close to each other, divided by the number of documents each one occurs, i.e.

$$\textit{Web-Jac}(x,y) := \frac{Hits(x * y)}{Hits(x) + Hits(y) - Hits(x\ AND\ y)}$$

So here we are relying on the wildcard operator '*' provided by the Google search engine API[4]. Though the specific function of the '*' operator as implemented by Google is actually unknown, the behavior is similar to the formerly available Altavista NEAR operator[5].

[4]In fact, for the experiments described in this paper we rely on the Google API.

Clue	Pattern
Singular	
"to * a(x) new x"	to [RB]? [VB] a? new x
"to * a(x) complete x"	to [RB]? [VB] a? complete x
"a(x) new has been *"	a? new x has been [VBD]
"a(x) complete x has been *"	a? complete has been [VBD]
Plural	
"to * new p(x)"	to [RB]? [VB] new p(x)
"to * complete p(x)"	to [RB]? [VB] complete p(x)

Table 4: Clues and Patterns for the *Agentive* Role

4.2 Web-based Pointwise Mutual Information (Web-PMI)

In line with Magnini et al. (Magnini et al., 2001), we define a PMI-based measure as follows:

$$Web - PMI(x,y) := log_2 \frac{Hits(x\ AND\ y)\ \textit{MaxPages}}{Hits(y)\ Hits(y)}$$

where maxPages is an approximation for the maximum number of English web pages[6].

4.3 Web-based Conditional Probability (Web-P)

The conditional probability $P(x|y)$ is essentially the probability that x is true given that y is true, i.e.

$$\textit{Web-P}(x,y) := P(x|y) = \frac{P(x,y)}{P(y)} = \frac{Hits(x\ NEAR\ y)}{Hits(y)}$$

whereby $Hits(x\ NEAR\ y)$ is calculated as mentioned above using the '*' operator. In contrast to the measures described above, this one is asymmetric so that order indeed matters. Given a qualia term qt as well as a qualia element qe we actually calculate Web-P(qe,qt) for a specific qualia role.

4.4 Conditional Probability (P)

The non web-based conditional probability essentially differs from the Web-based conditional probability in that we only rely on the qualia elements

[5]Initial experiments indeed showed that counting pages in which the two terms occur near each other in contrast to counting pages in which they merely co-occur improved the results of the Jaccard measure by about 15%.

[6]We determine this number experimentally as the number of web pages containing the words 'the' and 'and'.

matched. On the basis of these, we then calculate the probability of a certain qualia element given a certain role on the basis of its frequency of appearance with respect to the total number of qualia elements derived for this role, i.e. we simply calculate $P(qe|qr, qt)$ on the basis of the derived occurrences, where qt is a given qualia term, qr is the specific qualia role and qe is a qualia element.

5 Evaluation

In this section, we first of all describe our evaluation measures. Then we describe the creation of the gold standard. Further, we present the results of the comparison of the different ranking measures with respect to the gold standard. Finally, we present an *'a posteriori'* evaluation showing that the qualia structures learned are indeed reasonable.

5.1 Evaluation Measures

As our focus is to compare the different measures described above, we need to evaluate their corresponding rankings of the qualia elements for each qualia structure. This is a similar case to evaluating the ranking of documents within information retrieval systems. In fact, as done in standard information retrieval research, our aim is to determine for each ranking the precision/recall trade-off when considering more or less of the items starting from the top of the ranked list. Thus, we evaluate our approach calculating precision at standard recall levels as typically done in information retrieval research (compare (Baeza-Yates and Ribeiro-Neto, 1999)). Hereby the 11 standard recall levels are 0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90% and 100%. Further, precision at these standard recall levels is calculated by interpolating recall as follows: $P(r_j) = max_{r_j \leq r \leq r_{j+1}} P(r)$, where, $j \in \{0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1\}$. This way we can compare the precision over standard recall figures for the different rankings, thus observing which measure leads to the better precision/recall trade-off.

In addition, in order to provide one single value to compare, we also calculate the F-Measure corresponding to the best precision/recall trade-off for each ranking measure. This F-Measure thus corresponds to the best cut-off point we can find for the items in the ranked list. In fact, we use the well-known F_1 measure corresponding to the harmonic mean between recall and precision:

$$F_1 := max_j \frac{2\ P(r_j)\ r_j}{P(r_j) + r_j}$$

As a baseline, we compare our results to a naive strategy without any ranking, i.e. we calculate the F-Measure for all the items in the (unranked) list of qualia elements. Consequently, for the rankings to be useful, they need to yield higher F-Measures than this naive baseline.

5.2 Gold Standard

The gold standard was created for the 30 words used already in the experiments described in (Yamada and Baldwin, 2004): *accounting, beef, book, car, cash, clinic, complexity, counter, county, delegation, door, estimate, executive, food, gaze, imagination, investigation, juice, knife, letter, maturity, novel, phone, prisoner, profession, review, register, speech, sunshine, table.* These words were distributed more or less uniformly between 30 participants of our experiment, making sure that three qualia structures for each word were created by three different subjects. The participants, who were all non-linguistics, received a short instruction in the form of a short presentation explaining what qualia structures are, the aims of the experiment as well as their specific task. They were also shown some examples for qualia structures for words not considered in our experiments. Further, they were asked to provide between 5 and 10 qualia elements for each qualia role. The participants completed the test via e-mail. As a first interesting observation, it is worth mentioning that the participants only delivered 3-5 qualia elements on average depending on the role in question. This shows already that participants had trouble in finding different qualia elements for a given qualia role. We calculate the agreement for the task of specifying qualia structures for a particular term and role as the averaged pairwise agreement between the qualia elements delivered by the three subjects, henceforth S_1, S_2 and S_3 as:

$$Agr := \frac{\frac{|S_1 \cap S_2|}{|S_1 \cup S_2|} + \frac{|S_1 \cap S_3|}{|S_1 \cup S_3|} + \frac{|S_2 \cup S_3|}{|S_2 \cap S_3|}}{3}$$

Averaging over all the roles and words, we get an average agreement of 11.8%, i.e. our human test

subjects coincide in slightly more than every 10th qualia element. This is certainly a very low agreement and certainly hints at the fact that the task considered is certainly difficult. The agreement was lowest (7.29%) for the telic role.

A further interesting observation is that the lowest agreement is yielded for more abstract words, while the agreement for very concrete words is reasonable. For example, the five words with the highest agreement are indeed concrete things: *knife* (31%), *cash* (29%), *juice* (21%), *car* (20%) and *door* (19%). The words with an agreement below 5% are *gaze*, *prisoner*, *accounting*, *maturity*, *complexity* and *delegation*. In particular, our test subjects had substantial difficulties in finding the purpose of such abstract words. In fact, the agreement on the telic role is below 5% for more than half of the words.

In general, this shows that any automatic approach towards learning qualia structures faces severe limits. For sure, we can not expect the results of an automatic evaluation to be very high. For example, for the telic role of *'clinic'*, one test subject specified the qualia element *'cure'*, while another one specified *'cure disease'*, thus leading to a disagreement in spite of the obvious agreement at the semantic level. In this line, the average agreement reported above has in fact to be regarded as a lower bound for the actual agreement. Of course, our approach to calculating agreement is too strict, but in absence of a clear and computable definition of semantic agreement, it will suffice for the purposes of this paper.

5.3 Gold Standard Evaluation

We ran experiments calculating the qualia structure for each of the 30 words, ranking the resulting qualia elements for each qualia structure using the different measures described in Section 4.

Figure 1 shows the best F-Measure corresponding to a cut-off leading to an optimal precision/recall trade-off. We see that the P-measure performs best, while the Web-P measure and the Web-Jac measure follow at about 0.05 and 0.2 points distance. The PMI-based measure indeed leads to the worst F-Measure values.

Indeed, the P-measure delivered the best results for the formal and agentive roles, while for the constitutive and telic roles the Web-Jac measure performed best. The reason why PMI performs so badly is the fact that it favors too specific results which are unlikely to occur as such in the gold standard. For example, while the conditional probability ranks highest: *explore, help illustrate, illustrate* and *enrich* for the telic role of *novel*, the PMI-based measure ranks highest: *explore great themes*, *illustrate theological points*, *convey truth*, *teach reading skills* and *illustrate concepts*. A series of significance tests (paired Student's t-test at an α-level of 0.05) showed that the three best performing measures (P, Web-P and Web-Jaccard) show no real difference among them, while all three show significant difference to the Web-PMI measure. A second series of significance tests (again paired Student's t-test at an α-level of 0.05) showed that all ranking measures indeed significantly outperform the baseline, which shows that our rankings are indeed reasonable. Interestingly, there seems to be an interesting positive correlation between the F-Measure and the human agreement. For example, for the best performing ranking measure, i.e. the P-measure, we get an average F-Measure of 21% for words with an agreement over 5%, while we get an F-Measure of 9% for words with an agreement below 5%. The reason here probably is that those words and qualia elements for which people are more confident also have a higher frequency of appearance on the Web.

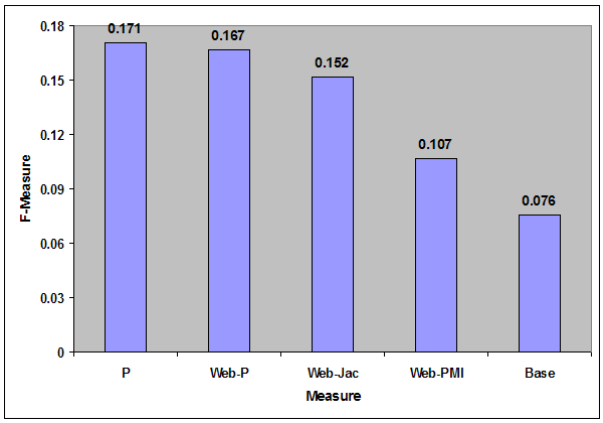

Figure 1: Average F_1 measure for the different ranking measures

5.4 A posteriori Evaluation

In order to check whether the automatically learned qualia structures are reasonable from an intuitive point of view, we also performed an a posteriori

evaluation in the lines of (Cimiano and Wenderoth, 2005). In this experiment, we presented the top 10 ranked qualia elements for each qualia role for 10 randomly selected words to the different test persons. Here we only used the P-measure for ranking as it performed best in our previous evaluation with regard to the gold standard. In order to verify that our sample is not biased, we checked that the F-Measure yielded by our 10 randomly selected words (17.7%) does not differ substantially from the overall average F-Measure (17.1%) to be sure that we have chosen words from all F-Measure ranges. In particular, we asked different test subjects which also participated in the creation of the gold standard to rate the qualia elements with respect to their appropriateness for the qualia term using a scale from 0 to 3, whereby 0 means 'wrong', 1 'not totally wrong', 2 'acceptable' and 3 'totally correct'. The participants confirmed that it was easier to validate existing qualia structures than to create them from scratch, which already corroborates the usefulness of our automatic approach. The qualia structure for each of the 10 randomly selected words was validated independently by three test persons. In fact, in what follows we always report results averaged for three test subjects. Figure 2 shows the average values for different roles. We observe that the constitutive role yields the best results, followed by the formal, telic and agentive roles (in this order). In general, all results are above 2, which shows that the qualia structures produced are indeed acceptable. Though we do not present these results in more detail due to space limitations, it is also interesting to mention that the F-Measure calculated with respect to the gold standard was in general highly correlated with the values assigned by the human test subjects in this *a posteriori* validation.

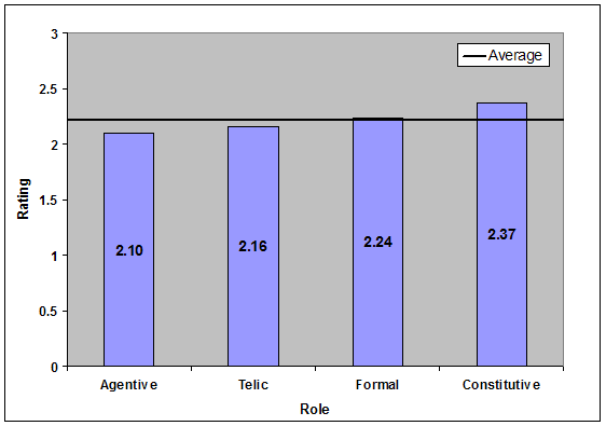

Figure 2: Average ratings for each qualia role

6 Related Work

Instead of matching Hearst-style patterns (Hearst, 1992) in a large text collection, some researchers have recently turned to the Web to match these patterns such as in (Markert et al., 2003) or (Etzioni et al., 2005). Our approach goes further in that it not only learns typing, superconcept or instance-of relations, but also *Constitutive*, *Telic* and *Agentive* relations.

There also exist approaches specifically aiming at learning qualia elements from corpora based on machine learning techniques. Claveau et al. (Claveau et al., 2003) for example use Inductive Logic Programming to learn if a given verb is a qualia element or not. However, their approach does no go as far as learning the complete qualia structure for a lexical element as in our approach. Further, in their approach they do not distinguish between different qualia roles and restrict themselves to verbs as potential fillers of qualia roles.

Yamada and Baldwin (Yamada and Baldwin, 2004) present an approach to learning *Telic* and *Agentive* relations from corpora analyzing two different approaches: one relying on matching certain lexico-syntactic patterns as in the work presented here, but also a second approach consisting in training a maximum entropy model classifier. The patterns used by (Yamada and Baldwin, 2004) differ substantially from the ones used in this paper, which is mainly due to the fact that search engines do not provide support for regular expressions and thus instantiating a pattern as 'V[+ing] Noun' is impossible in our approach as the verbs are unknown a priori.

Poesio and Almuhareb (Poesio and Almuhareb, 2005) present a machine learning based approach to classifying attributes into the six categories: *quality*, *part*, *related-object*, *activity*, *related-agent* and *non-attribute*.

7 Conclusion

We have presented an approach to automatically learning qualia structures from the Web. Such an approach is especially interesting either for lexicog-

raphers aiming at constructing lexicons, but even more for natural language processing systems relying on deep lexical knowledge as represented by qualia structures. In particular, we have focused on learning ranked qualia structures which allow to find an ideal cut-off point to increase the precision/recall trade-off of the learned structures. We have abstracted from the issue of finding the appropriate cut-off, leaving this for future work. In particular, we have evaluated different ranking measures for this purpose, showing that all of the analyzed measures (Web-P, Web-Jaccard, Web-PMI and the conditional probability) significantly outperformed a baseline using no ranking measure. Overall, the plain conditional probability P (not calculated over the Web) as well as the conditional probability calculated over the Web (Web-P) delivered the best results, while the PMI-based ranking measure yielded the worst results. In general, our main aim has been to show that, though the task of automatically learning qualia structures is indeed very difficult as shown by our low human agreement, reasonable structures can indeed be learned with a pattern-based approach as presented in this paper. Further work will aim at inducing the patterns automatically given some seed examples, but also at using the automatically learned structures within NLP applications. The created qualia structure gold standard is available for the community[7].

A Sequencing Model for Situation Entity Classification

Alexis Palmer, Elias Ponvert, Jason Baldridge, and Carlota Smith
Department of Linguistics
University of Texas at Austin
{alexispalmer,ponvert,jbaldrid,carlotasmith}@mail.utexas.edu

Abstract

Situation entities (SEs) are the events, states, generic statements, and embedded facts and propositions introduced to a discourse by clauses of text. We report on the first data-driven models for labeling clauses according to the type of SE they introduce. SE classification is important for discourse mode identification and for tracking the temporal progression of a discourse. We show that (a) linguistically-motivated cooccurrence features and grammatical relation information from deep syntactic analysis improve classification accuracy and (b) using a sequencing model provides improvements over assigning labels based on the utterance alone. We report on genre effects which support the analysis of discourse modes having characteristic distributions and sequences of SEs.

1 Introduction

Understanding discourse requires identifying the participants in the discourse, the situations they participate in, and the various relationships between and among both participants and situations. Coreference resolution, for example, is concerned with understanding the relationships between references to discourse participants. This paper addresses the problem of identifying and classifying references to situations expressed in written English texts.

Situation entities (SEs) are the events, states, generic statements, and embedded facts and propositions which clauses introduce (Vendler, 1967; Verkuyl, 1972; Dowty, 1979; Smith, 1991; Asher, 1993; Carlson and Pelletier, 1995). Consider the text passage below, which introduces an *event*-type entity in (1), a *report*-type entity in (2), and a *state*-type entity in (3).

(1) Sony Corp. has heavily promoted the Video Walkman since the product's introduction last summer ,

(2) but Bob Gerson , video editor of This Week in Consumer Electronics , says

(3) Sony conceives of 8mm as a "family of products , camcorders and VCR decks , "

SE classification is a fundamental component in determining the discourse mode of texts (Smith, 2003) and, along with aspectual classification, for temporal interpretation (Moens and Steedman, 1988). It may be useful for discourse relation projection and discourse parsing.

Though situation entities are well-studied in linguistics, they have received very little computational treatment. This paper presents the first data-driven models for SE classification. Our two main strategies are (a) the use of linguistically-motivated features and (b) the implementation of SE classification as a sequencing task. Our results also provide empirical support for the very notion of discourse modes, as we see clear genre effects in SE classification.

We begin by discussing SEs in more detail. Section 3 describes our two annotated data sets and provides examples of each SE type. Section 4 discusses feature sets, and sections 5 and 6 present models, experiments, and results.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 896–903,
Prague, Czech Republic, June 2007.

2 Discourse modes and situation entities

In this section, we discuss some of the linguistic motivation for SE classification and the relation of SE classification to discourse mode identification.

2.1 Situation entities

The categorization of SEs into aspectual classes is motivated by patterns in their linguistic behavior. We adopt an expanded version of a paradigm relating SEs to discourse mode (Smith, 2003) and characterize SEs with four broad categories:

1. **Eventualities**. *Events* (E), particular *states* (S), and *reports* (R). R is a sub-type of E for SEs introduced by verbs of speech (e.g., *say*).

2. **General statives**. *Generics* (G) and *generalizing sentences* (GS). The former are utterances predicated of a general class or kind rather than of any specific individual. The latter are habitual utterances that refer to ongoing actions or properties predicated of specific individuals.

3. **Abstract entities**. *Facts* (F) and *propositions* (P).[1]

4. **Speech-act types**. *Questions* (Q) and *imperatives* (IMP).

Examples of each SE type are given in section 3.2.

There are a number of linguistic tests for identifying situation entities (Smith, 2003). The term *linguistic test* refers to a rule which correlates an SE type to particular linguistic forms. For example, event-type verbs in simple present tense are a linguistic correlate of GS-type SEs.

These linguistic tests vary in their precision and different tests may predict different SE types for the same clause. A rule-based implementation using them to classify SEs would require careful rule ordering or mediation of rule conflicts. However, since these rules are exactly the sort of information extracted as features in data-driven classifiers, they can be cleanly integrated by assigning them empirically determined weights. We use maximum entropy models (Berger et al., 1996), which are particularly well-suited for tasks (like ours) with many overlapping features, to harness these linguistic insights by using features in our models which encode, directly or indirectly, the linguistic correlates to SE types. The features are described in detail in section 4.

[1] In our system these two SE types are identified largely as complements of factive and propositional verbs as discussed in Peterson (1997). Fact and propositional complements have some linguistic as well as some notional differences. Facts may have causal effects, and facts are in the world. Neither of these is true for propositions. In addition, the two have somewhat different semantic consequences of a presuppositional nature.

2.2 Basic and derived situation types

Situation entities each have a *basic situation type*, determined by the verb plus its arguments, the verb constellation. The verb itself plays a key role in determining basic situation type but it is not the only factor. Changes in the arguments or tense of the verb sometimes change the basic situation types:

(4) Mickey painted the house. (E)

(5) Mickey paints houses. (GS)

If SE type could be determined solely by the verb constellation, automatic classification of SEs would be a relatively straightforward task. However, other parts of the clause often override the basic situation type, resulting in aspectual coercion and a *derived situation type*. For example, a modal adverb can trigger aspectual coercion:

(6) Mickey probably paints houses. (P)

Serious challenges for SE classification arise from the aspectual ambiguity and flexibility of many predicates as well as from aspectual coercion.

2.3 Discourse modes

Much of the motivation of SE classification is toward the broader goal of identifying discourse modes, which provide a linguistic characterization of textual passages according to the situation entities introduced. They correspond to intuitions as to the rhetorical or semantic character of a text. Passages of written text can be classified into modes of discourse – Narrative, Description, Argument, Information, and Report – by examining concrete linguistic cues in the text (Smith, 2003). These cues are of two forms: the distribution of situation entity types and the mode of progression (either temporal or metaphorical) through the text.

For example, the Narration and Report modes both contain mainly events and temporally bounded states; they differ in their principles of temporal progression. Report passages progress with respect to (deictic) speech time, whereas Narrative passages progress with respect to (anaphoric) reference time. Passages in the Description mode are predominantly stative, and Argument mode passages tend to be characterized by propositions and Information mode passages by facts and states.

3 Data

This section describes the data sets used in the experiments, the process for creating annotated training data, and preprocessing steps. Also, we give examples of the ten SE types.

There are no established data sets for SE classification, so we created annotated training data to test our models. We have annotated two data sets, one from the Brown corpus and one based on data from the Message Understanding Conference 6 (MUC6).

3.1 Segmentation

The Brown texts were segmented according to SE-containing clausal boundaries, and each clause was labeled with an SE label. Segmentation is itself a difficult task, and we made some simplifications. In general, clausal complements of verbs like *say* which have clausal direct objects were treated as separate clauses and given an SE label. Clausal complements of verbs which have an entity as a direct object and second clausal complement (such as *notify*) were not treated as separate clauses. In addition, some modifying and adjunct clauses were not assigned separate SE labels.

The MUC texts came to us segmented into elementary discourse units (EDUs), and each EDU was labeled by the annotators. The two data sets were segmented according to slightly different conventions, and we did not normalize the segmentation. The inconsistencies in segmentation introduce some error to the otherwise gold-standard segmentations.

3.2 Annotation

Each text was independently annotated by two experts and reviewed by a third. Each clause was assigned precisely one SE label from the set of ten possible labels. For clauses which introduce more than one SE, the annotators selected the most salient one. This situation arose primarily when complement clauses were not treated as distinct clauses, in which case the SE selected was the one introduced by the main verb. The label N was used for clauses which do not introduce any situation entity.

SE	Text
S	That compares with roughly paperback-book dimensions for VHS.
G	Accordingly, most VHS camcorders are usually bulky and weigh around eight pounds or more.
S	"Carl is a tenacious fellow,"
R	said a source close to USAir.

Table 1: Example clauses and their SE annotation. Horizontal lines separate extracts from different texts.

The Brown data set consists of 20 "popular lore" texts from section **cf** of the Brown corpus. Segmentation of these texts resulted in a total of 4390 clauses. Of these, 3604 were used for training and development, and 786 were held out as final testing data. The MUC data set consists of 50 Wall Street Journal newspaper articles segmented to a total of 1675 clauses. 137 MUC clauses were held out for testing. The Brown texts are longer than the MUC texts, with an average of 219.5 clauses per document as compared to MUC's average of 33.5 clauses. The average clause in the Brown data contains 12.6 words, slightly longer than the MUC texts' average of 10.9 words.

Table 1 provides examples of the ten SE types as well as showing how clauses were segmented. Each SE-containing example is a sequence of EDUs from the data sets used in this study.

W	
WORDS	words & punctuation
WT	
W	(see above)
POSONLY	POS tag for each word
WORD/POS	word/POS pair for each word
WTL	
WT	(see above)
FORCEPRED	T if clause (or preceding clause) contains *force* predicate
PROPPRED	T if clause (or preceding clause) contains propositional verb
FACTPRED	T if clause (or preceding clause) contains factive verb
GENPRED	T if clause contains generic predicate
HASFIN	T if clause contains finite verb
HASMODAL	T if clause contains modal verb
FREQADV	T if clause contains frequency adverb
MODALADV	T if clause contains modal adverb
VOLADV	T if clause contains volitional adverb
FIRSTVB	lexical item and POS tag for first verb
WTLG	
WTL	(see above)
VERBS	all verbs in clause
VERBTAGS	POS tags for all verbs
MAINVB	main verb of clause
SUBJ	subject of clause (lexical item)
SUPER	CCG supertag

Table 2: Feature sets for SE classification

3.3 Preprocessing

The linguistic tests for SE classification appeal to multiple levels of linguistic information; there are lexical, morphological, syntactic, categorial, and structural tests. In order to access categorial and structural information, we used the C&C[2] toolkit (Clark and Curran, 2004). It provides part-of-speech tags and Combinatory Categorial Grammar (CCG) (Steedman, 2000) categories for words and syntactic dependencies across words.

4 Features

One of our goals in undertaking this study was to explore the use of linguistically-motivated features and deep syntactic features in probabilistic models for SE classification. The nature of the task requires features characterizing the entire clause. Here, we describe our four feature sets, summarized in table 2. The feature sets are additive, extending very basic feature sets first with linguistically-motivated features and then with deep syntactic features.

[2] svn.ask.it.usyd.edu.ap/trac/candc/wiki

4.1 Basic feature sets: W and WT

The WORDS (W) feature set looks only at the words and punctuation in the clause. These features are obtained with no linguistic processing.

WORDS/TAGS (WT) incorporates part-of-speech (POS) tags for each word, number, and punctuation mark in the clause and the word/tag pairs for each element of the clause. POS tags provide valuable information about syntactic category as well as certain kinds of shallow semantic information (such as verb tense). The tags are useful for identifying verbs, nouns, and adverbs, and the words themselves represent lexico-semantic information in the feature sets.

4.2 Linguistically-motivated feature set: WTL

The WORDS/TAGS/LINGUISTIC CORRELATES (WTL) feature set introduces linguistically-motivated features gleaned from the literature on SEs; each feature encodes a linguistic cue that may correlate to one or more SE types. These features are not directly annotated; instead they are extracted by comparing words and their tags for the current and immediately preceding clauses to lists containing appropriate triggers. The lists are compiled from the literature on SEs.

For example, clauses embedded under predicates like *force* generally introduce E-type SEs:

(7) I forced [John to run the race with me].

(8) * I forced [John to know French].

The feature `force-PREV` is extracted if a member of the *force*-type predicate word list occurs in the previous clause.

Some of the correlations discussed in the literature rely on a level of syntactic analysis not available in the WTL feature set. For example, stativity of the main verb is one feature used to distinguish between event and state SEs, and particular verbs and verb tenses have tendencies with respect to stativity. To approximate the main verb without syntactic analysis, WTL uses the lexical item of the first verb in the clause and the POS tags of all verbs in the clause.

These linguistic tests are non-absolute, making them inappropriate for a rule-based model. Our models handle the defeasibility of these correlations probabilistically, as is standard for machine learning for natural language processing.

4.3 Addition of deep features: WTLG

The WORDS/TAGS/LINGUISTIC CORRELATES/GRAMMATICAL RELATIONS (WTLG) feature set uses a deeper level of syntactic analysis via features extracted from CCG parse representations for each clause. This feature set requires an additional step of linguistic processing but provides a basis for more accurate classification.

WTL approximated the main verb by sloppily taking the first verb in the clause; in contrast, WTLG uses the main verb identified by the parser. The parser also reliably identifies the subject, which is used as a feature.

Supertags –CCG categories assigned to words– provide an interesting class of features in WTLG. They succinctly encode richer grammatical information than simple POS tags, especially subcategorization and argument types. For example, the tag S\NP denotes an intransitive verb, whereas (S\NP)/NP denotes a transitive verb. As such, they can be seen as a way of encoding the verbal constellation and its effect on aspectual classification.

5 Models

We consider two types of models for the automatic classification of situation entities. The first, a labeling model, utilizes a maximum entropy model to predict SE labels based on clause-level linguistic features as discussed above. This model ignores the discourse patterns that link multiple utterances. Because these patterns recur, a sequencing model may be better suited to the SE classification task. Our second model thus extends the first by incorporating the previous n ($0 \leq n \leq 6$) labels as features.

Sequencing is standardly used for tasks like part-of-speech tagging, which generally assume smaller units to be both tagged and considered as context for tagging. We are tagging at the clause level rather than at the word level, but the structure of the problem is essentially the same. We thus adapted the OpenNLP maximum entropy part-of-speech tagger[3] (Hockenmaier et al., 2004) to extract features from utterances and to tag sequences of utterances instead of words. This allows the use of features of adjacent clauses as well as previously-predicted labels when making classification decisions.

6 Experiments

In this section we give results for testing on Brown data. All results are reported in terms of accuracy, defined as the percentage of correctly-labeled clauses. Standard 10-fold cross-validation on the training data was used to develop models and feature sets. The optimized models were then tested on the held-out Brown and MUC data.

The baseline was determined by assigning *S* (state), the most frequent label in both training sets, to each clause. Baseline accuracy was 38.5% and 36.2% for Brown and MUC, respectively.

In general, accuracy figures for MUC are much higher than for Brown. This is likely due to the fact that the MUC texts are more consistent: they are all newswire texts of a fairly consistent tone and genre. The Brown texts, in contrast, are from the 'popular lore' section of the corpus and span a wide range of topics and text types. Nonetheless, the patterns between the feature sets and use of sequence prediction hold across both data sets; here, we focus our discussion on the results for the Brown data.

6.1 Labeling results

The results for the labeling model appear in the two columns labeled 'n=0' in table 3. On Brown, the simple W feature set beats the baseline by 6.9% with an accuracy of 45.4%. Adding POS information (WT) boosts accuracy 4.5% to 49.9%. We did not see the expected increase in performance from the linguistically motivated WTL features, but rather a slight decrease in accuracy to 48.9%. These features may require a greater amount of training material to be effective. Addition of deep linguistic information with WTLG improved performance to 50.6%, a gain of 5.2% over words alone.

6.2 Oracle results

To determine the potential effectiveness of sequence prediction, we performed oracle experiments on Brown by including previous gold-standard labels as features. Figure 1 illustrates the results from oracle experiments incorporating from zero to six previous gold-standard SE labels (the *lookback*). The increase in performance illustrates the importance of context in the identification of SEs and motivates the use of sequence prediction.

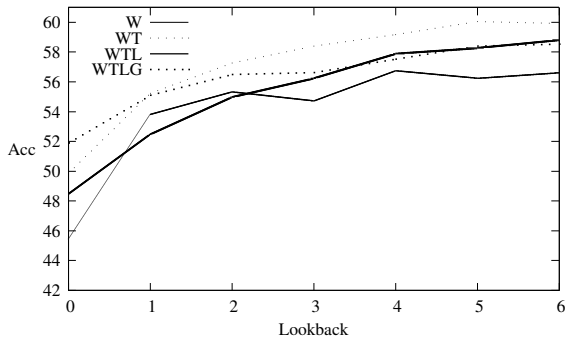

Figure 1: **Oracle results** on Brown data.

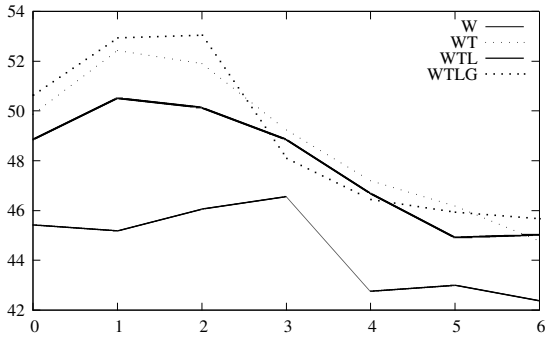

Figure 2: Sequencing results on Brown data.

6.3 Sequencing results

Table 3 gives the results of classification with the sequencing model on the Brown data. As with the labeling model, accuracy is boosted by WT and WTLG feature sets. We see an unexpected degradation in performance in the transition from WT to WTL.

The most interesting results here, though, are the gains in accuracy from use of previously-predicted labels as features for classification. When labeling performance is relatively poor, as with feature set W, previous labels help very little, but as labeling accuracy increases, previous labels begin to effect noticeable increases in accuracy. For the best two feature sets, considering the previous two labels raises the accuracy 2.0% and 2.5%, respectively.

In most cases, though, performance starts to degrade as the model incorporates more than two previous labels. This degradation is illustrated in Figure 2. The explanation for this is that the model is still very weak, with an accuracy of less than 54% for the Brown data. The more previous predicted labels the model conditions on, the greater the likelihood that one or more of the labels is incorrect. With gold-standard labels, we see a steady increase in accuracy as we look further back, and we would need a better performing model to fully take advantage of knowledge of SE patterns in discourse.

The sequencing model plays a crucial role, particularly with such a small amount of training material, and our results indicate the importance of local context in discourse analysis.

BROWN	Lookback (n)						
	0	1	2	3	4	5	6
W	45.4	45.2	46.1	46.6	42.8	43.0	42.4
WT	49.9	52.4	51.9	49.2	47.2	46.2	44.8
WTL	48.9	50.5	50.1	48.9	46.7	44.9	45.0
WTLG	50.6	52.9	**53.1**	48.1	46.4	45.9	45.7
Baseline	38.5						

Table 3: SE classification results with sequencing on **Brown test set**. Bold cell indicates accuracy attained by model parameters that performed best on development data.

6.4 Error analysis

Given that a single one of the ten possible labels occurs for more than 35% of clauses in both data sets, it is useful to look at the distribution of errors over the labels. Table 4 is a confusion matrix for the held-out Brown data using the best feature set.[4] The first column gives the label and number of occurrences of that label, and the second column is the accuracy achieved for that label. The next two columns show the percentage of erroneous labels taken by the labels S and GS. These two labels are the most common labels in the development set (38.5% and 32.5%). The final column sums the percentages of errors assigned to the remaining seven labels. As one would expect, the model learns the predominance of these two labels. There are a few interesting points to make about this data.

First, 66% of G-type clauses are mistakenly assigned the label GS. This is interesting because these two SE-types constitute the broader SE cat-

[4]Thanks to the anonymous reviewer who suggested this useful way of looking at the data.

Label	% Correct Label	% Incorrect S	GS	Other
S(278)	72.7	n/a	14.0	13.3
E(203)	50.7	37.0	11.8	0.5
GS(203)	44.8	46.3	n/a	8.9
R(26)	38.5	30.8	11.5	19.2
N(47)	23.4	31.9	23.4	21.3
G(12)	0.0	25.0	66.7	8.3
IMP(8)	0.0	75.0	25.0	0.0
P(7)	0.0	71.4	28.6	0.0
F(2)	0.0	100.0	0.0	0.0

Table 4: Confusion matrix for Brown held-out test data, WTLG feature set, lookback n = 2. Numbers in parentheses indicate how many clauses have the associated gold standard label.

egory of generalizing statives. The distribution of errors for R-type clauses points out another interesting classification difficulty.[5] Unlike the other categories, the percentage of *false-other* labels for R-type clauses is higher than that of *false-GS* labels. 80% of these *false-other* labels are of type E. The explanation for this is that R-type clauses are a subtype of the event class.

6.5 Genre effects in classification

Different text domains frequently have different characteristic properties. Discourse modes are one way of analyzing these differences. It is thus interesting to compare SE classification when training and testing material come from different domains.

Table 5 shows the performance on Brown when training on Brown and/or MUC using the WTLG feature set with simple labeling and with sequence prediction with a lookback of two. A number of things are suggested by these figures. First, the labeling model (lookback of zero), beats the baseline even when training on out-of-domain texts (43.1% vs. 38.5%), but this is unsurprisingly far below training on in-domain texts (43.1% vs. 50.6%). Second, while sequence prediction helps with in-domain training (53.1% vs 50.6%), it makes no difference with out-of-domain training (42.9% vs 43.1%). This indicates that the patterns of SEs in a text do indeed correlate with domains and their discourse modes, in line with case-studies in the discourse modes theory (Smith, 2003). Finally, mixing out-of-domain training material with in-domain material does not hurt labelling accuracy (50.4% vs 50.6%), but it does take away the gains from sequencing (49.5% vs 53.1%).

[5]Thanks to an anonymous reviewer for bringing this to our attention.

WTLG	**lookback**	Brown test set
train:Brown	0	50.6
	2	53.1
train:MUC	0	43.1
	2	42.9
train:all	0	50.4
	2	49.5

Table 5: Cross-domain SE classification

These genre effects are suggestive, but inconclusive. A similar setup with much larger training and testing sets would be necessary to provide a clearer picture of the effect of mixed domain training.

7 Related work

Though we are aware of no previous work in SE classification, others have focused on automatic detection of aspectual and temporal data.

Klavans and Chodorow (1992) laid the foundation for probabilistic verb classification with their interpretation of aspectual properties as gradient and their use of statistics to model the gradience. They implement a single linguistic test for stativity, treating lexical properties of verbs as tendencies rather than absolute characteristics.

Linguistic indicators for aspectual classification are also used by Siegel (1999), who evaluates 14 indicators to test verbs for stativity and telicity. Many of his indicators overlap with our features.

Siegel and McKeown (2001) address classification of verbs for stativity (event vs. state) and for completedness (culminated vs. non-culminated events). They compare three supervised and one unsupervised machine learning systems. The systems obtain relatively high accuracy figures, but they are domain-specific, require extensive human supervision, and do not address aspectual coercion.

Merlo and Stevenson (2001) use corpus-based thematic role information to identify and classify unergative, unaccusative, and object-drop verbs. Stevenson and Merlo note that statistical analysis cannot and should not be separated from deeper linguistic analysis, and our results support that claim.

The advantages of our approach are the broadened conception of the classification task and the use of sequence prediction to capture a wider context.

8 Conclusions

Situation entity classification is a little-studied but important classification task for the analysis of discourse. We have presented the first data-driven models for SE classification, motivating the treatment of SE classification as a sequencing task.

We have shown that linguistic correlations to situation entity type are useful features for probabilistic models, as are grammatical relations and CCG supertags derived from syntactic analysis of clauses. Models for the task perform poorly given very basic feature sets, but minimal linguistic processing in the form of part-of-speech tagging improves performance even on small data sets used for this study. Performance improves even more when we move beyond simple feature sets and incorporate linguistically-motivated features and grammatical relations from deep syntactic analysis. Finally, using sequence prediction by adapting a POS-tagger further improves results.

The tagger we adapted uses beam search; this allows tractable use of maximum entropy for each labeling decision but forgoes the ability to find the *optimal* label sequence using dynamic programming techniques. In contrast, Conditional Random Fields (CRFs) (Lafferty et al., 2001) allow the use of maximum entropy to set feature weights with efficient recovery of the optimal sequence. Though CRFs are more computationally intensive, the small set of SE labels should make the task tractable for CRFs.

In future, we intend to test the utility of SEs in discourse parsing, discourse mode identification, and discourse relation projection.

Abstract

Frequency distribution models tuned to words and other linguistic events can predict the number of distinct types and their frequency distribution in samples of arbitrary sizes. We conduct, for the first time, a rigorous evaluation of these models based on cross-validation and separation of training and test data. Our experiments reveal that the prediction accuracy of the models is marred by serious overfitting problems, due to violations of the random sampling assumption in corpus data. We then propose a simple pre-processing method to alleviate such non-randomness problems. Further evaluation confirms the effectiveness of the method, which compares favourably to more complex correction techniques.

1 Introduction

Large-Number-of-Rare-Events (LNRE) models (Baayen, 2001) are a class of specialized statistical models that allow us to estimate the characteristics of the distribution of type probabilities in type-rich linguistic populations (such as words) from limited samples (our corpora). They also allow us to extrapolate quantities such as vocabulary size (the number of distinct types) and the number of hapaxes (types occurring just once) beyond a given corpus or make predictions for completely unseen data from the same underlying population.

LNRE models have applications in theoretical linguistics, e.g. for comparing the type richness of morphological or syntactic processes that are attested to different degrees in the data (Baayen, 1992). Consider for example a very common prefix such as *re-* and a rather rare prefix such as *meta-*. With LNRE models we can answer questions such as: If we could obtain as many tokens of *meta-* as we have of *re-*, would we also see as many distinct types? In other words, is the prefix *meta-* as productive as the prefix *re-*? Practical NLP applications, on the other hand, include estimating how many out-of-vocabulary words we will encounter given a lexicon of a certain size, or making informed guesses about type counts in very large data sets (e.g., *how many typos are there on the Internet?*)

In this paper, after introducing LNRE models (Section 2), we present an evaluation of their performance based on separate training and test data as well as cross-validation (Section 3). As far as we know, this is the first time that such a rigorous evaluation has been conducted. The results show how evaluating on the training set, a common strategy in LNRE research, favours models that overfit the training data and perform poorly on unseen data. They also confirm the observation by Evert and Baroni (2006) that current LNRE models achieve only unsatisfactory prediction accuracy, and this is the issue we turn to in the second part of the paper (Section 4). Having identified the violation of the random sampling assumption by real-world data as one of the main factors affecting the quality of the models, we present a new approach to alleviating non-randomness problems. Further evaluation shows our solution to outperform Baayen's (2001) partition-adjustment method, the former state-of-the-art in non-randomness correction. Section 5 concludes by

pointing out directions for future work.

2 LNRE models

Baayen (2001) introduces a family of models for Zipf-like frequency distributions of linguistic populations, referred to as *LNRE models*. Such a linguistic population is formally described by a finite or countably infinite set of types ω_i and their occurrence probabilities π_i. Word frequency models are not concerned with the probabilities (i.e., relative frequencies) of specific individual types, but rather the overall distribution of these probabilities.

Numbering the types in order of decreasing probability ($\pi_1 \geq \pi_2 \geq \pi_3 \geq \ldots$, called a population *Zipf ranking*), we can specify a LNRE model for their distribution as a function that computes π_i from the Zipf rank i of ω_i. For instance, the Zipf-Mandelbrot law[1] is defined by the equation

$$\pi_i = \frac{C}{(i+b)^a} \tag{1}$$

with parameters $a > 1$ and $b > 0$. It is mathematically more convenient to formulate LNRE models in terms of a type density function $g(\pi)$ on the interval $\pi \in [0, 1]$, such that

$$\int_A^B g(\pi)\, d\pi \tag{2}$$

is the (approximate) number of types ω_i with $A \leq \pi_i \leq B$. Evert (2004) shows that Zipf-Mandelbrot corresponds to a type density of the form

$$g(\pi) := \begin{cases} C \cdot \pi^{-\alpha-1} & A \leq \pi \leq B \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

with parameters $0 < \alpha < 1$ and $0 \leq A < B$.[2] Models that are formulated in terms of such a type density g have many direct applications (e.g. using g as a Bayesian prior), and we refer to them as *proper* LNRE models.

Assuming that a corpus of N tokens is a random sample from such a population, we can make predictions about lexical statistics such as the number $V(N)$ of different types in the corpus (the *vocabulary size*), the number $V_1(N)$ of *hapax legomena* (types occurring just once), as well as the further distribution of type frequencies $V_m(N)$. Since the precise values would be different from sample to sample, the model predictions are given by expectations $E[V(N)]$ and $E[V_m(N)]$, which can be computed with relative ease from the type density function g.

By comparing expected and observed values of V and V_m (for the lowest frequency ranks, usually up to $m = 15$), the parameters of a LNRE model can be estimated (we refer to this as *training* the model), allowing inferences about the population (such as the total number of types in the population) as well as further applications of the estimated type density (e.g. for Good-Turing smoothing). Since we can calculate expected values for samples of arbitrary size N, we can use the trained model to predict how many new types would be seen in a larger corpus, how many hapaxes there would be, etc. This kind of vocabulary growth *extrapolation* has become one of the most important applications of LNRE models in linguistics and NLP.

A detailed account of the mathematics of LNRE models can be found in Baayen (2001, Ch. 2). Baayen describes two LNRE models, *lognormal* and *GIGP*, as well as several other approaches (including a version of *Zipf's law* and the *Yule-Simon* model) that are not based on a type density and hence do not qualify as proper LNRE models. Two LNRE models based on Zipf's law, *ZM* and *fZM*, are introduced by Evert (2004).

In the following, we will only consider proper LNRE models because of their considerably greater utility, and because their performance in extrapolation tasks appears to be better than, or at least comparable to, the other models (Evert and Baroni, 2006). In addition, we exclude the lognormal model because of its computational complexity and numerical instability.[3] In initial evaluation experiments, the performance of lognormal was also inferior to the remaining three models (ZM, fZM and GIGP). Note that ZM is the most simplistic model, with only 2 parameters and assuming an infinite population vocabulary, while fZM and GIGP have 3 parameters

[1] The Zipf-Mandelbrot law is an extension of Zipf's law (which has $a = 1$ and $b = 0$). While the latter originally refers to type frequencies in a given sample, the Zipf-Mandelbrot law is formulated for type probabilities in a population.

[2] In this equation, C is a normalizing constant required in order to ensure $\int_0^1 \pi g(\pi)\, d\pi = 1$, the equivalent of $\sum_i \pi_i = 1$.

[3] There are no closed form equations for the expectations of the lognormal model, which have to be calculated by numerical integration.

and can model populations of different sizes.

3 Evaluation of LNRE models

LNRE models are traditionally evaluated by looking at how well expected values generated by them fit empirical counts extracted from the same dataset used for parameter estimation, often by visual inspection of differences between observed and predicted data in plots. More rigorously, Baayen (2001) and Evert (2004) compare the frequency distribution observed in the training set to the one predicted by the model with a multivariate chi-squared test. As we will show below, evaluating standard LNRE models on the same data that were used to estimate their parameters favours overfitting, which results in poor performance on unseen data.

Evert and Baroni (2006) attempt, for the first time, to evaluate LNRE models on unseen data. However, rather than splitting the data into separate training and test sets, they evaluate the models in an extrapolation setting, where the parameters of the model are estimated on a *subset* of the data used for testing. Evert and Baroni do not attempt to cross-validate the results, and they do not provide a quantitative evaluation, relying instead on visual inspection of empirical and observed vocabulary growth curves.

3.1 Data and procedure

We ran our experiments with three corpora in different languages and representing different textual typologies: the British National Corpus (BNC), a "balanced" corpus of British English of about 100 million tokens illustrating different communicative settings, genres and topics; the deWaC corpus, a Web-crawled corpus of about 1.5 billion German words; and the la Repubblica corpus, an Italian newspaper corpus of about 380 million words.[4]

From each corpus, we extracted 20 non-overlapping samples of randomly selected documents, amounting to a total of 4 million tokens each (punctuation marks and entirely non-alphabetical tokens were removed before sampling, and all words were converted to lowercase). Each of these samples was then split into a training set of 1 million tokens (the *training size* N_0) and a test set of 3 million tokens. The documents in the la Repubblica samples were ordered chronologically before splitting, to simulate a typical scenario arising when working with newspaper data, where the data available for training precede, chronologically, the data one wants to generalize to.

We estimate parameters of the ZM, fZM and GIGP models on each training set, using the zipfR toolkit.[5] The models are then used to predict the expected number of distinct types, i.e., vocabulary size V, at sample sizes of 1, 2 and 3 million tokens, equivalent to 1, 2 and 3 times the size of the training set (we refer to these as the *prediction sizes* N_0, $2N_0$ and $3N_0$, respectively). Finally, the expected vocabulary size $E[V(N)]$ is compared to the observed value $V(N)$ in the test set for $N = N_0$, $N = 2N_0$ and $N = 3N_0$. We also look at $V_1(N)$, the number of hapax legomena, in the same way.

Our main focus is V prediction, since this is by far the most useful measure in practical applications, where we are typically interested in knowing how many types (or how many types belonging to a certain category) we will see as our sample size increases (How many typos are there on the Web? How many types with prefix *meta-* would we see if we had as many types of *meta-* as we have of *re-*?) Hapax legomena counts, on the other hand, play a central role in quantifying morphological productivity (Baayen, 1992) and they give us a first insight into how good the models are at predicting frequency distributions, besides vocabulary size (as we will see, a model's success in predicting V does not necessary imply that the model is also capturing the right frequency distribution).

For all models, corpora and prediction sizes, goodness-of-fit of the model on the training set is measured with a multivariate chi-squared test (Baayen, 2001, 118-122). Performance of the models in prediction of V is assessed via *relative error*, computed for each of the 20 samples from a corpus and the 3 prediction sizes as follows:

$$e = \frac{E[V(N)] - V(N)}{V(N)}$$

where $N = k \cdot N_0$ is the prediction size (for $k = 1, 2, 3$), $V(N)$ is the observed V in the relevant test

[4] See `www.natcorp.ox.ac.uk`, `http://wacky.sslmit.unibo.it` and `http://sslmit.unibo.it/repubblica`

[5] `http://purl.org/stefan.evert/zipfR`

set at size N, and $E[V(N)]$ is the corresponding expected V predicted by a model.[6]

For each corpus and prediction size we obtain 20 values e_i (viz., $e_1, \ldots, e_{20}$). As a summary measure, we report the square root of the mean square relative error (rMSE) calculated according to

$$\sqrt{\text{rMSE}} = \sqrt{\frac{1}{20} \cdot \sum_{i=1}^{20} (e_i)^2}$$

This gives us an overall assessment of prediction accuracy (we take the square root to obtain values on the same scale as relative errors, and thus easier to interpret). We complement rMSEs with reports on the average relative error (indicating whether there is a systematic under- or overestimation bias) and its asymptotic 95% confidence intervals, based on the empirical standard deviation of the e_i across the 20 trials (the confidence intervals are usually somewhat larger than the actual range of values found in the experiments, so they should be seen as "pessimistic estimates" of the actual variance).

3.2 Results

The panels of Figure 1 report rMSE values for the 3 corpora and for each prediction size. For now, we focus on the first 3 histograms of each panel, that present rMSEs for the 3 LNRE models introduced above: ZM, fZM and GIGP (the remaining histograms will be discussed later).[7]

For all corpora and all extrapolation sizes beyond N_0, the simple ZM model outperforms the more sophisticated fZM and GIGP models (which seem to be very similar to each other). Even at the largest prediction size of $3N_0$, ZM's rMSE is well below 10%, whereas the other models have, in the worst case (BNC $3N_0$), a rMSE above 15%. Figure 2 presents plots of average relative error and its empirical confidence intervals (again, focus for now on the ZM, fZM and GIGP results; the rest of the figure is discussed later). We see that the poor performance of fZM and GIGP is due to their tendency to underestimate the true vocabulary size V, while variance is comparable across models.

The rMSEs of V_1 prediction are reported in Figure 3. V_1 prediction performance is poorer across the board, and ZM is no longer outperforming the other models. For space reasons, we do not present relative error and variance plots for V_1, but the general trends are the same observed for V, except that the bias of ZM towards V_1 overestimation is much clearer than for V.

Interestingly, goodness-of-fit on the training data is not a good predictor of V and V_1 prediction performance on unseen data. This is shown in Figure 4, which plots rMSE for prediction of V against goodness-of-fit (quantified by multivariate X^2 on the training set, as discussed above) for all corpora and LNRE models at the $3N_0$ prediction size (but the same patterns emerge at other prediction sizes and with V_1). The larger X^2, the poorer the training set fit; the larger rMSE, the worse the prediction. Thus, ideally, we should see a positive correlation between X^2 and rMSE. Focusing for now on the circles (pinpointing the ZM, fZM and GIGP models), we see that there is instead a *negative* correlation between goodness of fit on the training set and quality of prediction on unseen data.[8]

First, these results indicate that, if we take goodness of fit on the training set as a criterion for choosing the best model (as done by Baayen and Evert), we end up selecting the *worst* model for actual prediction tasks. This is, we believe, a very strong case for applying the split train-test cross-validation method used in other areas of statistical NLP to frequency distribution modeling. Second, the data suggest that the more sophisticated models are *overfitting* the training set, leading to poorer performance than the simpler ZM on unseen data. We turn now to what we think is the main cause for this overfitting.

4 Non-randomness and echoes

The results in the previous section indicate that the Vs predicted by LNRE models are at best "ballpark estimates" (and V_1 predictions, with a relative error that is often above 20%, do not even qualify as plau-

[6] We normalize by $V(N)$ rather than (a function of) $E[V(N)]$ because in the latter case we would favour models that overestimate V, compared to ones that are equally "close" to the correct value but underestimate V.

[7] A table with the full numerical results is available upon request; we find, however, that graphical summaries such as those presented in this paper make the results easier to interpret.

[8] With correlation coefficients of $r < -.8$, significant at the 0.01 level despite the small sample size.

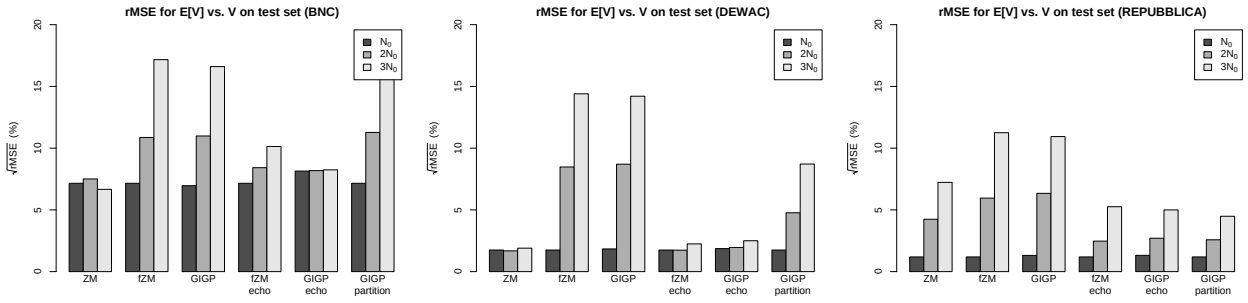

Figure 1: rMSEs of predicted V on the BNC, deWaC and la Repubblica data-sets

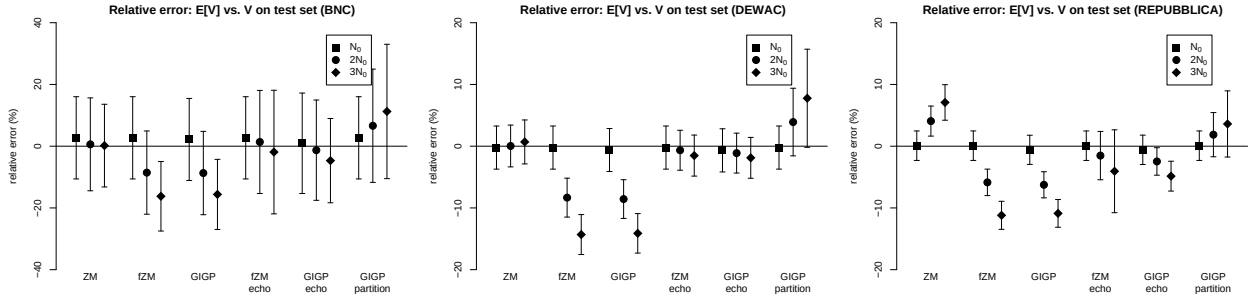

Figure 2: Average relative errors and asymptotic 95% confidence intervals of V prediction on BNC, deWaC and la Repubblica data-sets

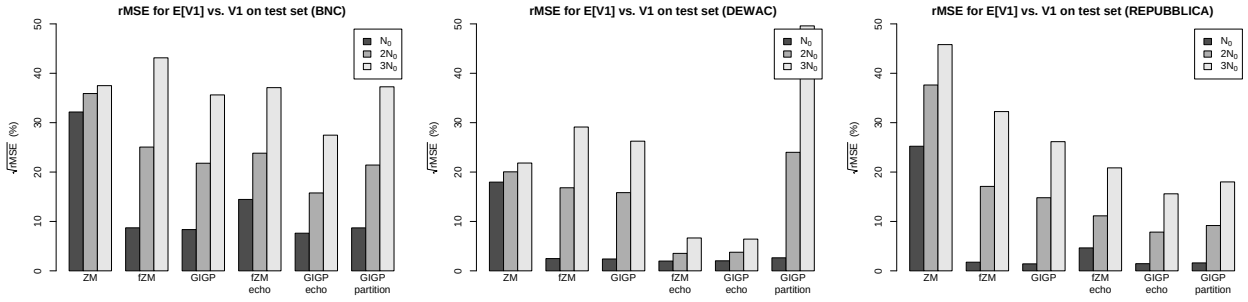

Figure 3: rMSEs of predicted V_1 on the BNC, deWaC and la Repubblica data-sets

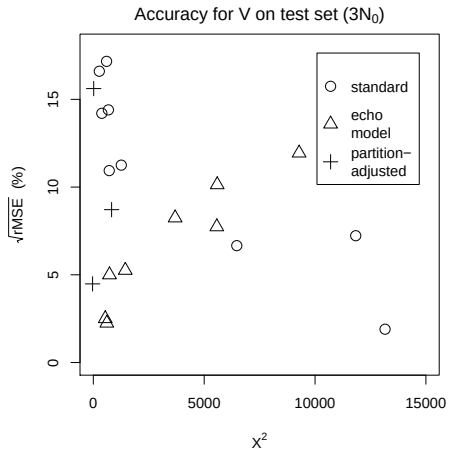

Figure 4: Correlation between X^2 and V prediction rMSE across corpora and models

sible ballpark estimates). Although such rough estimates might be more than adequate for many practical applications, is it possible to further improve the quality of LNRE predictions?

A major factor hampering prediction quality is that real texts massively violate the *randomness assumption* made in LNRE modeling: words, rather obviously, are not picked at random on the basis of their population probability (Evert and Baroni, 2006; Baayen, 2001). The topic-driven "clumpiness" of low frequency content words reduces the number of hapax legomena and other rare events used to estimate the parameters of LNRE models, leading the models to underestimate the type richness of the population. Interestingly (but unsurprisingly), ZM with its assumption of an infinite population, is less prone to this effect, and thus it has a better prediction performance than the more sophisticated fZM and GIGP models, despite its poor goodness-of-fit.

The effect of non-randomness is illustrated very clearly for the BNC (but the same could be shown for the other corpora) by Figure 5, a comparison of rMSE for prediction of V from our experiments above to results obtained on versions of the BNC samples with words scrambled in random order, thus forcibly removing non-randomness effects. We see from this figure that the performance of both fZM and GIGP improves dramatically when they are trained and tested on randomized sequences of words. Interestingly, randomization has instead a *negative* effect on ZM performance.

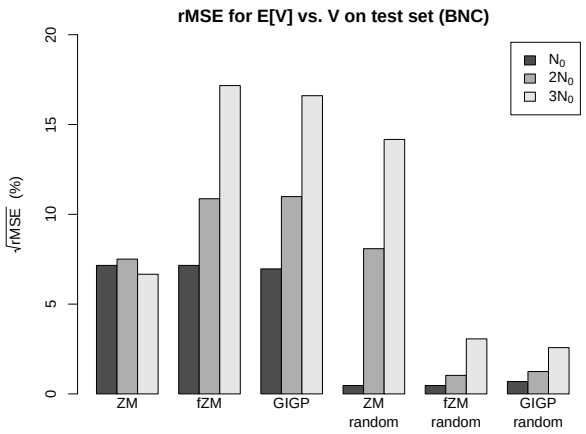

Figure 5: rMSEs of predicted V on unmodified vs. randomized versions of the BNC sets

4.1 Previous approaches to non-randomness

While non-randomness is widely acknowledged as a serious problem for the statistical analysis of corpus data, very few authors have suggested correction strategies. The key problem of non-random data seems to be that the occurrence frequencies of a type in different documents do not follow the binomial distribution assumed by random sampling models. One approach is therefore to model this distribution explicitly, replacing the binomial with its single parameter π by a more complex distribution that has additional parameters (Church and Gale, 1995; Katz, 1996). However, these distributions are currently not applicable to LNRE modeling, which is based on the overall frequencies of types in a corpus rather than their frequencies in individual documents. The overall frequencies can only be calculated by summation over all documents in the corpus, resulting in a mathematically and numerically intractable model. In addition, the type density $g(\pi)$ would have to be extended to a multi-dimensional function, requiring a large number of parameters to be estimated from the data.

Baayen (2001) suggests a different approach, which partitions the population into "normal" types that satisfy the random sampling assumption, and "totally underdispersed" types, which are assumed to concentrate all occurrences in the corpus into a

single "burst". Using a standard LNRE model for the normal part of the population and a simple linear growth model for the underdispersed part, adjusted values for $E[V]$ and $E[V_m]$ can easily be calculated. These so-called *partition-adjusted* models (which introduce one additional parameter) are thus the only viable models for non-randomness correction in LNRE modeling and have to be considered the state of the art.

4.2 *Echo* adjustment

Rather than making more complex assumptions about the population distribution or the sampling model, we propose that non-randomness should be tackled as a *pre-processing* problem. The issue, we argue, is really with the way we count occurrences of types. The fact that a rare topic-specific word occurs, say, four times in a single document does not make it any less a hapax legomenon for our purposes than if the word occurred once (this is the case, for example, of the word *chondritic* in the BNC, which occurs 4 times, all in the same scientific document).

We operationalize our intuition by proposing that, for our purposes, each content word (at least each rare, topic-specific content word) occurs maximally once in a document, and all other instances of that word in the document are really instances of a special "anaphoric" type, whose function is that of "echoing" the content words in the document. Thus, in the BNC document mentioned above, the word *chondritic* is counted only once, whereas the other three occurrences are considered as tokens of the *echo* type. Thus, we are counting what in the information retrieval literature is known as *document frequencies*. Intuitively, these are less susceptible to topical clumpiness effects than plain token frequencies. However, by replacing repeated words with echo tokens, we can stick to a sampling model based on random word token sampling (rather than document sampling), so that the LNRE models can be applied "as is" to echo-adjusted corpora.

Echo-adjustment does not affect the sample size N nor the vocabulary size V, making the interpretation of results obtained with echo-adjusted models entirely straightforward. N does not change because repeated types are replaced with echo tokens, not deleted. V does not change because only repeated types are replaced. Thus, no type present in the original corpus disappears (more precisely, V increases by 1 because of the addition of the echo type, but given the large size of V this can be ignored for all practical purposes). Thus, the expected V computed for a specified sample size N with a model trained on an echo-adjusted corpus can be directly compared to observed values at N, and to predictions made for the same N by models trained on an unprocessed corpus. The same is not true for the prediction of the frequency distribution, where, for the same N, echo-based models predict the distribution of *document* frequencies.

We are proposing echoes as a model for the usage of (rare) content words. It would be difficult to decide where the boundary is between topical words that are inserted once in a discourse and then anaphorically modulated and "general-purpose" words that constitute the frame of the discourse and can occur multiple times. Luckily, we do not have to make this decision when estimating a LNRE model, since model fitting is based on the distribution of the lowest frequencies. For example, with the default zipfR model fitting setting, only the lowest 15 spectrum elements are used to fit the models. For any reasonably sized corpus, it is unlikely that function words and common content words will occur in less than 16 documents, and thus their distribution will be irrelevant for model fitting. Thus, we can ignore the issue of what is the boundary between topical words to be echo-adjusted and general words, as long as we can be confident that the set of lowest frequency words used for model fitting belong to the topical set.[9] This makes practical echo-adjustment extremely simple, since all we have to do is to replace all repetitions of a word in the same document with echo tokens, and estimate the parameters of a plain LNRE model with the resulting version of the training corpus.

4.3 Experiments with echo adjustment

Using the same training and test sets as in Section 3.1, we train the partition-adjusted GIGP model

[9] The issue becomes more delicate if we want to predict the frequency spectrum rather than V, since a model trained on echo-adjusted data will predict echo-adjusted frequencies across the board. However, in many theoretical and practical settings only the lowest frequency spectrum elements are of interest, where, again, it is safe to assume that words are highly topic-dependent, and echo-adjustment is appropriate.

implemented in the LEXSTATS toolkit (Baayen, 2001). We estimate the parameters of echo-adjusted ZM, fZM and GIGP models on versions of the training corpora that have been pre-processed as described above. The performance of the models is evaluated with the same measures as in Section 3.1 (for prediction of V_1, echo-adjusted versions of the test data are used).

Figure 1 reports the performance of the echo-adjusted fZM and GIGP models and of partition-adjusted GIGP (echo-adjusted ZM performed systematically much worse than the other echo-adjusted models and typically worse than uncorrected ZM, and it is not reported in the figure). Both correction methods lead to a dramatic improvement, bringing the prediction performance of fZM and GIGP to levels comparable to ZM (with the latter outperforming the corrected models on the BNC, but being outperformed on la Repubblica). Moreover, echo-adjusted GIGP is as good as partitioned GIGP on la Repubblica, and better on both BNC and deWaC, suggesting that the much simpler echo-adjustment method is at least as good and probably better than Baayen's partitioning. The mean error and confidence interval plots in Figure 2 show that the echo-adjusted models have a much weaker underestimation bias than the corresponding unadjusted models, and are comparable to, if not better than, ZM (although they might have a tendency to display more variance, as clearly illustrated by the performance of echo-adjusted fZM on la Repubblica at $3N_0$ prediction size). Finally, the echo-adjusted models clearly stand out with respect to ZM when it comes to V_1 prediction (Figure 3), indicating that echo-adjusted versions of the more sophisticated fZM and GIGP models should be the focus of future work on improving prediction of the full frequency distribution, rather than plain ZM. Moreover, echo-adjusted GIGP is outperforming partitioned GIGP, and emerging as the best model overall.[10] Reassuringly, for the echoed models there is a very strong *positive* correlation between goodness-of-fit on the training set and quality of prediction, as illustrated for V prediction at $3N_0$ by the triangles in Figure 4 (again, the patterns in this figure represent the general trend for echo-adjusted models found in all settings).[11] This indicates that the over-fitting problem has been resolved, and for echo-adjusted models goodness-of-fit on the training set is a reliable indicator of prediction accuracy.

[10] In looking at the V_1 data, it must be kept in mind, however, that V_1 has a different interpretation when predicted by echo-adjusted models, i.e., it is the number of *document-based* hapaxes, the number of types that occur in one document only.

5 Conclusion

Despite the encouraging results we reported, much work, of course, remains to be done. Even with the echo-adjusted models, prediction of V_1 suffers from large errors and prediction of V quickly deteriorates with increasing prediction size N. If the models' estimates for 3 times the size of the training set have acceptable errors of around 5%, for many applications we might want to extrapolate to $100N_0$ or more (recall the example of estimating type counts for the entire Web). Moreover, echo-adjusted models make predictions pertaining to the distribution of document frequencies, rather than plain token frequencies. The full implications of this remain to be investigated. Finally, future work should systematically explore to what extent different textual typologies are affected by the non-randomness problem (notice, e.g., that non-randomness seems to be a greater problem for the BNC than for the more uniform la Repubblica corpus).

Abstract

This paper describes the first system for large-scale acquisition of subcategorization frames (SCFs) from English corpus data which can be used to acquire comprehensive lexicons for verbs, nouns and adjectives. The system incorporates an extensive rule-based classifier which identifies 168 verbal, 37 adjectival and 31 nominal frames from grammatical relations (GRs) output by a robust parser. The system achieves state-of-the-art performance on all three sets.

1 Introduction

Research into automatic acquisition of lexical information from large repositories of unannotated text (such as the web, corpora of published text, etc.) is starting to produce large scale lexical resources which include frequency and usage information tuned to genres and sublanguages. Such resources are critical for natural language processing (NLP), both for enhancing the performance of state-of-art statistical systems and for improving the portability of these systems between domains.

One type of lexical information with particular importance for NLP is subcategorization. Access to an accurate and comprehensive subcategorization lexicon is vital for the development of successful parsing technology (e.g. (Carroll et al., 1998), important for many NLP tasks (e.g. automatic verb classification (Schulte im Walde and Brew, 2002)) and useful for any application which can benefit from information about predicate-argument structure (e.g. Information Extraction (IE) ((Surdeanu et al., 2003)).

The first systems capable of automatically learning a small number of verbal subcategorization frames (SCFs) from unannotated English corpora emerged over a decade ago (Brent, 1991; Manning, 1993). Subsequent research has yielded systems for English (Carroll and Rooth, 1998; Briscoe and Carroll, 1997; Korhonen, 2002) capable of detecting comprehensive sets of SCFs with promising accuracy and demonstrated success in application tasks (e.g. (Carroll et al., 1998; Korhonen et al., 2003)). Recently, a large publicly available subcategorization lexicon was produced using such technology which contains frame and frequency information for over 6,300 English verbs – the VALEX lexicon (Korhonen et al., 2006).

While there has been considerable work in the area, most of it has focussed on verbs. Although verbs are the richest words in terms of subcategorization and although verb SCF distribution data is likely to offer the greatest boost in parser performance, accurate and comprehensive knowledge of the many noun and adjective SCFs in English could improve the accuracy of parsing at several levels (from tagging to syntactic and semantic analysis).

Furthermore the selection of the correct analysis from the set returned by a parser which does not initially utilize fine-grained lexico-syntactic information can depend on the *interaction* of conditional probabilities of lemmas of different classes occur-

Prague, Czech Republic, June 2007.

ring with specific SCFs. For example, a) and b) below indicate the most plausible analyses in which the sentential complement attaches to the noun and verb respectively

a) Kim (VP believes (NP the evidence (Scomp that Sandy was present)))

b) Kim (VP persuaded (NP the judge) (Scomp that Sandy was present))

However, both a) and b) consist of an identical sequence of coarse-grained lexical syntactic categories, so correctly ranking them requires learning that $P(NP \mid believe).P(Scomp \mid evidence) > P(NP\&Scomp \mid believe).P(None \mid evidence)$ and $P(NP \mid persuade).P(Scomp \mid judge) < P(NP\&Scomp \mid persuade).P(None \mid judge)$. If we acquired frames and frame frequencies for all open-class predicates taking SCFs using a single system applied to similar data, we would have a better chance of modeling such interactions accurately.

In this paper we present the first system for large-scale acquisition of SCFs from English corpus data which can be used to acquire comprehensive lexicons for verbs, nouns and adjectives. The classifier incorporates 168 verbal, 37 adjectival and 31 nominal SCF distinctions. An improved acquisition technique is used which expands on the ideas Yallop et al. (2005) recently explored for a small experiment on adjectival SCF acquisition. It involves identifying SCFs on the basis of grammatical relations (GRs) in the output of the RASP (Robust Accurate Statistical Parsing) system (Briscoe et al., 2006).

As detailed later, the system performs better with verbs than previous comparable state-of-art systems, achieving 68.9 F-measure in detecting SCF types. It achieves similarly good performance with nouns and adjectives (62.2 and 71.9 F-measure, respectively).

Additionally, we have developed a tool for linguistic annotation of SCFs in corpus data aimed at alleviating the process of obtaining training and test data for subcategorization acquisition. The tool incorporates an intuitive interface with the ability to significantly reduce the number of frames presented to the user for each sentence.

We introduce the new system for SCF acquisition in section 2. Details of the experimental evaluation are supplied in section 3. Section 4 provides discussion of our results and future work, and section 5 concludes.

2 Description of the System

A common strategy in existing large-scale SCF acquisition systems (e.g. (Briscoe and Carroll, 1997)) is to extract SCFs from parse trees, introducing an unnecessary dependence on the details of a particular parser. In our approach SCFs are extracted from GRs — representations of head-dependent relations which are more parser/grammar independent but at the appropriate level of abstraction for extraction of SCFs.

A similar approach was recently motivated and explored by Yallop et al. (2005). A decision-tree classifier was developed for 30 adjectival SCF types which tests for the presence of GRs in the GR output of the RASP (Robust Accurate Statistical Parsing) system (Briscoe and Carroll, 2002). The results reported with 9 test adjectives were promising (68.9 F-measure in detecting SCF types).

Our acquisition process consists of four main steps: 1) extracting GRs from corpus data, 2) feeding the GR sets as input to a rule-based classifier which incrementally matches them with the corresponding SCFs, 3) building lexical entries from the classified data, and 4) filtering those entries to obtain a more accurate lexicon. The details of these steps are provided in the subsequent sections.

2.1 Obtaining Grammatical Relations

We obtain the GRs using the recent, second release of the RASP toolkit (Briscoe et al., 2006). RASP is a modular statistical parsing system which includes a tokenizer, tagger, lemmatizer, and a wide-coverage unification-based tag-sequence parser. We use the standard scripts supplied with RASP to output the set of GRs for the most probable analysis returned by the parser or, in the case of parse failures, the GRs for the most likely sequence of subanalyses. The GRs are organized as a subsumption hierarchy as shown in Figure 1.

The dependency relationships which the GRs embody correspond closely to the head-complement structure which subcategorization acquisition attempts to recover, which makes GRs ideal input to the SCF classifier. Consider the arguments of *easy*

ncsubj	?W : pos=VV0	?V : pos=pron	

Figure 4: Pattern for frame `adj-obj-for-to-inf`

`NP` headed by *examples* is marked as the subject of the frame by `ncsubj(be[6] examples[2])`, and `ncsubj(comprehend[12] we+[10])` corresponds to the coindexation marked by 3: the subject of the `VP` is the `NP` of the `PP`. The only part of the feature structure which is not represented by the GRs is coindexation between the omitted direct object 1 of the `VP`-complement and the subject of the whole clause.

2.2 SCF Classifier

SCF Frames

The SCFs recognized by the classifier were obtained by manually merging the frames exemplified in the COMLEX Syntax (Grishman et al., 1994), ANLT (Boguraev et al., 1987) and/or NOMLEX (Macleod et al., 1997) dictionaries and including additional frames found by manual inspection of unclassifiable examples during development of the classifier. These consisted of e.g. some occurrences of phrasal verbs with complex complementation and with flexible ordering of the preposition/particle, some non-passivizable words with a surface direct object, and some rarer combinations of governed preposition and complementizer combinations.

The frames were created so that they abstract over specific lexically-governed particles and prepositions and specific predicate selectional preferences

but include some derived semi-predictable bounded dependency constructions.

Classifier

The classifier operates by attempting to match the set of GRs associated with each sentence against one or more rules which express the possible mappings from GRs to SCFs. The rules were manually developed by examining a set of development sentences to determine which relations were actually emitted by the parser for each SCF.

In our rule representation, a GR pattern is a set of partially instantiated GRs with variables in place of heads and dependents, augmented with constraints that restrict the possible instantiations of the variables. A match is successful if the set of GRs for a sentence can be unified with any rule. Unification of sentence GRs and a rule GR pattern occurs when there is a one-to-one correspondence between sentence elements and rule elements that includes a consistent mapping from variables to values.

A sample pattern for matching `adj-obj-for-to-inf` can be seen in Figure 4. Each element matches either an empty GR slot (_), a variable with possible constraints on part of speech (pos) and word value (val), or an already instantiated variable. Unlike in Yallop's work (Yallop et al., 2005), our rules are declarative rather than procedural and these rules, written independently of the acquisition system, are expanded by the system in a number of ways prior to execution. For example, the verb rules which contain an `ncsubj` relation will not contain one inside an embedded clause. For verbs, the basic rule set contains 248 rules but automatic expansion gives rise to 1088 classifier rules for verbs.

Numerous approaches were investigated to allow an efficient execution of the system: for example, for each target word in a sentence, we initially find the number of ARGument GRs (see Figure 1) containing it in head position, as the word must appear in exactly the same set in a matching rule. This allows us to discard all patterns which specify a different number of GRs: for example, for verbs each group only contains an average of 109 patterns.

For a further increase in speed, both the sentence GRs and the GRs within the patterns are ordered (according to frequency) and matching is performed using a backing off strategy allowing us to exploit the relatively low number of possible GRs (compared to the number of possible rules). The system executes on 3500 sentences in approx. 1.5 seconds of real time on a machine with a 3.2 GHz Intel Xenon processor and 4GB of RAM.

Lexicon Creation and Filtering

Lexical entries are constructed for each word and SCF combination found in the corpus data. Each lexical entry includes the raw and relative frequency of the SCF with the word in question, and includes various additional information e.g. about the syntax of detected arguments and the argument heads in different argument positions[1].

Finally the entries are filtered to obtain a more accurate lexicon. A way to maximise the accuracy of the lexicon would be to smooth (correct) the acquired SCF distributions with back-off estimates based on lexical-semantic classes of verbs (Korhonen, 2002) (see section 4) before filtering them. However, in this first experiment with the new system we filtered the entries directly so that we could evaluate the performance of the new classifier without any additional modules. For the same reason, the filtering was done by using a very simple method: by setting empirically determined thresholds on the relative frequencies of SCFs.

3 Experimental Evaluation

3.1 Data

In order to test the accuracy of our system, we selected a set of 183 verbs, 30 nouns and 30 adjectives for experimentation. The words were selected at random, subject to the constraint that they exhibited multiple complementation patterns and had a sufficient number of corpus occurrences (> 150) for experimentation. We took the 100M-word British National Corpus (BNC) (Burnard, 1995), and extracted all sentences containing an occurrence of one of the test words. The sentences were processed using the SCF acquisition system described in the previous section. The citations from which entries were derived totaled approximately 744K for verbs and 219K for nouns and adjectives, respectively.

[1]The lexical entries are similar to those in the VALEX lexicon. See (Korhonen et al., 2006) for a sample entry.

3.2 Gold Standard

Our gold standard was based on a manual analysis of some of the test corpus data, supplemented with additional frames from the ANLT, COMLEX, and/or NOMLEX dictionaries. The gold standard for verbs was available, but it was extended to include additional SCFs missing from the old system. For nouns and adjectives the gold standard was created. For each noun and adjective, 100-300 sentences from the BNC (an average of 267 per word) were randomly extracted. The resulting c. 16K sentences were then manually associated with appropriate SCFs, and the SCF frequency counts were recorded.

To alleviate the manual analysis we developed a tool which first uses the RASP parser with some heuristics to reduce the number of SCF presented, and then allows an annotator to select the preferred choice in a window. The heuristics reduced the average number of SCFs presented alongside each sentence from 52 to 7. The annotator was also presented with an example sentence of each SCF and an intuitive name for the frame, such as PRED (e.g. *Kim is silly*). The program includes an option to record that particular sentences could not (initially) be classified. A screenshot of the tool is shown in Figure 5.

The manual analysis was done by two linguists; one who did the first annotation for the whole data, and another who re-evaluated and corrected some of the initial frame assignments, and classified most of the data left unclassified by the first annotator[2]). A total of 27 SCF types were found for the nouns and 30 for the adjectives in the annotated data. The average number of SCFs taken by nouns was 9 (with the average of 2 added from dictionaries to supplement the manual annotation) and by adjectives 11 (3 of which were from dictionaries). The latter are rare and may not be exemplified in the data given the extraction system.

3.3 Evaluation Measures

We used the standard evaluation metrics to evaluate the accuracy of the SCF lexicons: type precision (the percentage of SCF types that the system proposes which are correct), type recall (the percentage of SCF types in the gold standard that the system proposes) and the F-measure which is the harmonic mean of type precision and recall.

[2]The process precluded measurements of inter-annotator agreement, but this was judged less important than the enhanced accuracy of the gold standard data.

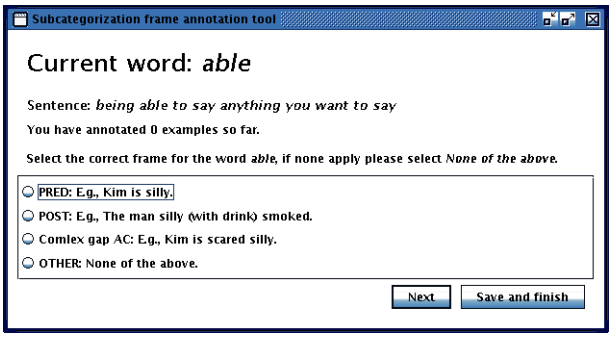

Figure 5: Sample screen of the annotation tool

We also compared the similarity between the acquired unfiltered[3] SCF distributions and gold standard SCF distributions using various measures of distributional similarity: the Spearman rank correlation (RC), Kullback-Leibler distance (KL), Jensen-Shannon divergence (JS), cross entropy (CE), skew divergence (SD) and intersection (IS). The details of these measures and their application to subcategorization acquisition can be found in (Korhonen and Krymolowski, 2002).

Finally, we recorded the total number of gold standard SCFs unseen in the system output, i.e. the type of false negatives which were never detected by the classifier.

3.4 Results

Table 1 includes the average results for the 183 verbs. The first column shows the results for Briscoe and Carroll's (1997) (B&C) system when this system is run with the original classifier but a more recent version of the parser (Briscoe and Carroll, 2002) and the same filtering technique as our new system (thresholding based on the relative frequencies of SCFs). The classifier of B&C system is comparable to our classifier in the sense that it targets almost the same set of verbal SCFs (165 out of the 168; the 3 additional ones are infrequent in language and thus unlikely to affect the comparison). The second column shows the results for our new system (New).

[3]No threshold was applied to remove the noisy SCFs from the distributions.

Measures	Verbs - Method	
	B&C	New
Precision (%)	47.3	81.8
Recall (%)	40.4	59.5
F-measure	43.6	68.9
KL	3.24	1.57
JS	0.20	0.11
CE	4.85	3.10
SD	1.39	0.74
RC	0.33	0.66
IS	0.49	0.76
Unseen SCFs	28	17

Table 1: Average results for verbs

Measures	Nouns	Adjectives
Precision (%)	91.2	95.5
Recall (%)	47.2	57.6
F-measure	62.2	71.9
KL	0.91	0.69
JS	0.09	0.05
CE	2.03	2.01
SD	0.48	0.36
RC	0.70	0.77
IS	0.62	0.72
Unseen SCFs	15	7

Table 2: Average results for nouns and adjectives

The figures show that the new system clearly performs better than the B&C system. It yields 68.9 F-measure which is a 25.3 absolute improvement over the B&C system. The better performance can be observed on all measures, but particularly on SCF type precision (81.8% with our system vs. 47.3% with the B&C system) and on measures of distributional similarity. The clearly higher IS (0.76 vs. 0.49) and the fewer gold standard SCFs unseen in the output of the classifier (17 vs. 28) indicate that the new system is capable of detecting a higher number of SCFs.

The main reason for better performance is the ability of the new system to detect a number of challenging or complex SCFs which the B&C system could not detect[4]. The improvement is partly attributable to more accurate parses produced by the second release of RASP and partly to the improved SCF classifier developed here. For example, the new system is now able to distinguish predicative PP arguments, such as *I sent him as a messenger* from the wider class of referential PP arguments, supporting discrimination of several syntactically similar SCFs with distinct semantics.

Running our system on the adjective and noun test data yielded the results summarized in Table 2. The F-measure is lower for nouns (62.2) than for verbs (68.9); for adjectives it is slightly better (71.9).[5]

The noun and adjective classifiers yield very high precision compared to recall. The lower recall figures are mostly due to the higher number of gold standard SCFs unseen in the classifier output (rather than, for example, the filtering step). This is particularly evident for nouns for which 15 of the 27 frames exemplified in the gold standard are missing in the classifier output. For adjectives only 7 of the 30 gold standard SCFs are unseen, resulting in better recall (57.6% vs. 47.2% for nouns).

For verbs, subcategorization acquisition performance often correlates with the size of the input data to acquisition (the more data, the better performance). When considering the F-measure results for the individual words shown in Table 3 there appears to be little such correlation for nouns and adjectives. For example, although there are individual high frequency nouns with high performance (e.g. *plan*, freq. 5046, F 90.9) and low frequency nouns with low performance (e.g. *characterisation*, freq. 91, F 40.0), there are also many nouns which contradict the trend (compare e.g. *answer*, freq. 2510, F 50.0 with *fondness*, freq. 71, F 85.7).[6]

Although the SCF distributions for nouns and adjectives appear Zipfian (i.e. the most frequent frames are highly probable, but most frames are infrequent), the total number of SCFs per word is typically smaller than for verbs, resulting in better resistance to sparse data problems.

There is, however, a clear correlation between the performance and the type of gold standard SCFs taken by individual words. Many of the gold stan-

[4]The results reported here for the B&C system are lower than those recently reported in (Korhonen et al., 2006) for the same set of 183 test verbs. This is because we use an improved gold standard. However, the results for the B&C system reported using the less ambitious gold standard are still less accurate (58.6 F-measure) than the ones reported here for the new system.

[5]The results for different word classes are not directly comparable because they are affected by the total number of SCFs evaluated for each word class, which is higher for verbs and lower for nouns and adjectives. This particularly applies to the sensitive measures of distributional similarity.

[6]The frequencies here refer to the number of citations successfully processed by the parser and the classifier.

Noun	F	Adjective	F
abundance	75.0	*able*	66.7

Table 3: System performance for each test noun and adjective

dard nominal and adjectival SCFs unseen by the classifier involve complex complementation patterns which are challenging to extract, e.g. those exemplified in *The* **argument** *of Jo with Kim about Fido surfaced, Jo's* **preference** *that Kim be sacked surfaced*, and *that Sandy came is* **certain**. In addition, many of these SCFs unseen in the data are also very low in frequency, and some may even be true negatives (recall that the gold standard was supplemented with additional SCFs from dictionaries, which may not necessarily appear in the test data).

The main problem is that the RASP parser systematically fails to select the correct analysis for some SCFs with nouns and adjectives regardless of their context of occurrence. In future work, we hope to alleviate this problem by using the weighted GR output from the top *n*-ranked parses returned by the parser as input to the SCF classifier.

4 Discussion

The current system needs refinement to alleviate the bias against some SCFs introduced by the parser's unlexicalized parse selection model. We plan to investigate using weighted GR output with the classifier rather than just the GR set from the highest ranked parse. Some SCF classes also need to be further resolved mainly to differentiate control options with predicative complementation. This requires a lexico-semantic classification of predicate classes.

Experiments with Briscoe and Carroll's system have shown that it is possible to incorporate some semantic information in the acquisition process using a technique that smooths the acquired SCF distributions using back-off (i.e. probability) estimates based on lexical-semantic classes of verbs (Korhonen, 2002). The estimates help to correct the acquired SCF distributions and predict SCFs which are rare or unseen e.g. due to sparse data. They could also form the basis for predicting control of predicative complements.

We plan to modify and extend this technique for the new system and use it to improve the performance further. The technique has so far been applied to verbs only, but it can also be applied to nouns and adjectives because they can also be classified on lexical-semantic grounds. For example, the adjective *simple* belongs to the class of EASY adjectives, and this knowledge can help to predict that it takes similar SCFs to the other class members and that control of 'understood' arguments will pattern with *easy* (e.g. *easy, difficult, convenient*): *The problem will be simple for John to solve*, *For John to solve the problem will be simple*, *The problem will be simple to solve*, etc.

Further research is needed before highly accurate lexicons encoding information also about semantic aspects of subcategorization (e.g. different predicate senses, the mapping from syntactic arguments to semantic representation of argument structure, selectional preferences on argument heads, diathesis alternations, etc.) can be obtained automatically. However, with the extensions suggested above, the system presented here is sufficiently accurate for building an extensive SCF lexicon capable of supporting various NLP application tasks. Such a lexicon will be built and distributed for research pur-

poses along with the gold standard described here.

5 Conclusion

We have described the first system for automatically acquiring verbal, nominal and adjectival subcategorization and associated frequency information from English corpora, which can be used to build large-scale lexicons for NLP purposes. We have also described a new annotation tool for producing training and test data for the task. The acquisition system, which is capable of distinguishing 168 verbal, 37 adjectival and 31 nominal frames, classifies corpus occurrences to SCFs on the basis of GRs produced by a robust statistical parser. The information provided by GRs closely matches the structure that subcategorization acquisition seeks to recover. Our experiment shows that the system achieves state-of-the-art performance with each word class. The discussion suggests ways in which we could improve the system further before using it to build a large subcategorization lexicon capable of supporting various NLP application tasks.

A Language-Independent Unsupervised Model for Morphological Segmentation

Vera Demberg

v.demberg@sms.ed.ac.uk

Abstract

Morphological segmentation has been shown to be beneficial to a range of NLP tasks such as machine translation, speech recognition, speech synthesis and information retrieval. Recently, a number of approaches to unsupervised morphological segmentation have been proposed. This paper describes an algorithm that draws from previous approaches and combines them into a simple model for morphological segmentation that outperforms other approaches on English and German, and also yields good results on agglutinative languages such as Finnish and Turkish. We also propose a method for detecting variation within stems in an unsupervised fashion. The segmentation quality reached with the new algorithm is good enough to improve grapheme-to-phoneme conversion.

1 Introduction

Morphological segmentation has been shown to be beneficial to a number of NLP tasks such as machine translation (Goldwater and McClosky, 2005), speech recognition (Kurimo et al., 2006), information retrieval (Monz and de Rijke, 2002) and question answering. Segmenting a word into meaning-bearing units is particularly interesting for morphologically complex languages where words can be composed of several morphemes through inflection, derivation and composition. Data sparseness for such languages can be significantly decreased when words are decomposed morphologically. There exist a number of rule-based morphological segmentation systems for a range of languages. However, expert knowledge and labour are expensive, and the analyzers must be updated on a regular basis in order to cope with language change (the emergence of new words and their inflections). One might argue that unsupervised algorithms are not an interesting option from the engineering point of view, because rule-based systems usually lead to better results. However, segmentations from an unsupervised algorithm that is language-independent are "cheap", because the only resource needed is unannotated text. If such an unsupervised system reaches a performance level that is good enough to help another task, it can constitute an attractive additional component.

Recently, a number of approaches to unsupervised morphological segmentation have been proposed. These algorithms autonomously discover morpheme segmentations in unannotated text corpora. Here we describe a modification of one such unsupervised algorithm, RePortS (Keshava and Pitler, 2006). The RePortS algorithm performed best on English in a recent competition on unsupervised morphological segmentation (Kurimo et al., 2006), but had very low recall on morphologically more complex languages like German, Finnish or Turkish. We add a new step designed to achieve higher recall on morphologically complex languages and propose a method for identifying related stems that underwent regular non-concatenative morphological processes such as umlauting or ablauting, as well as morphological alternations along morpheme boundaries.

The paper is structured as follows: Section

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 920–927,
Prague, Czech Republic, June 2007.

2 discusses the relationship between language-dependency and the level of supervision of a learning algorithm. We then give an outline of the main steps of the RePortS algorithm in section 3 and explain the modifications to the original algorithm in section 4. Section 5 compares results for different languages, quantifies the gains from the modifications on the algorithm and evaluates the algorithm on a grapheme-to-phoneme conversion task. We finally summarize our results in section 6.

2 Previous Work

The world's languages can be classified according to their morphology into isolating languages (little or no morphology, e.g. Chinese), agglutinative languages (where a word can be decomposed into a large number of morphemes, e.g. Turkish) and inflectional languages (morphemes are fused together, e.g. Latin).

Phenomena that are difficult to cope with for many of the unsupervised algorithms are non-concatenative processes such as vowel harmonization, ablauting and umlauting, or modifications at the boundaries of morphemes, as well as infixation (e.g. in Tagalog: sulat 'write', s-um-ulat 'wrote', s-in-ulat 'was written'), circumfixation (e.g. in German: mach-en 'do', ge-mach-t 'done'), the Arabic broken plural or reduplications (e.g. in Pingelapese: mejr 'to sleep', mejmejr 'sleeping', mejmejmejr 'still sleeping'). For words that are subject to one of the above processes it is not trivial to automatically group related words and detect regular transformational patterns.

A range of automated algorithms for morphological analysis cope with concatenative phenomena, and base their mechanics on statistics about hypothesized stems and affixes. These approaches can be further categorized into ones that use conditional entropy between letters to detect segment boundaries (Harris, 1955; Hafer and Weiss, 1974; Déjean, 1998; Monson et al., 2004; Bernhard, 2006; Keshava and Pitler, 2006; Bordag, 2006), approaches that use minimal description length and thereby minimize the size of the lexicon as measured in entries and links between the entries to constitute a word form (Goldsmith, 2001; Creutz and Lagus, 2006). These two types of approaches very closely tie the orthographic form of the word to the morphemes. They are thus not well-suited for coping with stem changes or modifications at the edges of morphemes. Only very few approaches have addressed word internal variations (Yarowski and Wicentowski, 2000; Neuvel and Fulop, 2002).

A popular and effective approach for detecting inflectional paradigms and filter affix lists is to cluster together affixes or regular transformational patterns that occur with the same stem (Monson et al., 2004; Goldsmith, 2001; Gaussier, 1999; Schone and Jurafsky, 2000; Yarowski and Wicentowski, 2000; Neuvel and Fulop, 2002; Jacquemin, 1997). We draw from this idea of clustering in order to detect orthographic variants of stems; see Section 4.3.

A few approaches also take into account syntactic and semantic information from the context the word occurs (Schone and Jurafsky, 2000; Bordag, 2006; Yarowski and Wicentowski, 2000; Jacquemin, 1997). Exploiting semantic and syntactic information is very attractive because it adds an additional dimension, but these approaches have to cope with more severe data sparseness issues than approaches that emphasize word-internal cues, and they can be computationally expensive, especially when they use LSA.

The original RePortS algorithm assumes morphology to be concatenative, and specializes on prefixation and suffixation, like most of the above approaches, which were developed and implemented for English (Goldsmith, 2001; Schone and Jurafsky, 2000; Neuvel and Fulop, 2002; Yarowski and Wicentowski, 2000; Gaussier, 1999). However, many languages are morphologically more complex. For example in German, an algorithm also needs to cope with compounding, and in Turkish words can be very long and complex. We therefore extended the original RePortS algorithm to be better adapted to complex morphology and suggest a method for coping with stem variation. These modifications render the algorithm more language-independent and thereby make it attractive for applying to other languages as well.

3 The RePortS Algorithm

On English, the RePortS algorithm clearly outperformed all other systems in Morpho Challenge

2005[1] (Kurimo et al., 2006), obtaining an F-measure of 76.8% (76.2% prec., 77.4% recall). The next best system obtained an F-score of 69%. However, the algorithm does not perform as well on other languages (Turkish, Finnish, German) due to low recall (see (Keshava and Pitler, 2006) and (Demberg, 2006), p. 47).

There are three main steps in the algorithm. First, the data is structured in two trees, which provide the basis for efficient calculation of transitional probabilities of a letter given its context. The second step is the affix acquisition step, during which a set of morphemes is identified from the corpus data. The third step uses these morphemes to segment words.

3.1 Data Structure

The data is stored in two trees, the forward tree and the backward tree. Branches correspond to letters, and nodes are annotated with the total corpus frequency of the letter sequence from the root of the tree up to the node. During the affix identification process, the forward tree is used for discovering suffixes by calculating the probability of seeing a certain letter given the previous letters of the word. The backward tree is used to determine the probability of a letter given the following letters of a word in order to find prefixes. If the transitional probability is high, the word should not be split, whereas low probability is a good indicator of a morpheme boundary. In such a tree, stems tend to stay together in long unary branches, while the branching factor is high in places where morpheme boundaries occur.

The underlying idea of exploiting "Letter Successor Variety" was first proposed in (Harris, 1955), and has since been used in a number of morphemic segmentation algorithms (Hafer and Weiss, 1974; Bernhard, 2006; Bordag, 2006).

3.2 Finding Affixes

The second step is concerned with finding good affixes. The procedure is quite simple and can be divided into two subtasks. (1) generating all possible affixes and (2) validating them. The validation step is necessary to exclude bad affix candidates (e.g. letter sequences that occur together frequently such as *sch*, *spr* or *ch* in German or *sh*, *th*, *qu* in English). An affix is validated if all three criteria are satisfied for at least 5% of its occurrences:

1. The substring that remains after peeling off an affix is also a word in the lexicon.
2. The transitional probability between the second-last and the last stem letter is ≈ 1.
3. The transitional probability of the affix letter next to the stem is <1 (tolerance 0.02).

Finally, all affixes that are concatenations of two or more other suffixes (e.g., *-ungen* can be split up in *-ung* and *-en* in German) are removed. This step returns two lists of morphological segments. The prefix list contains prefixes as well as stems that usually occur at the beginning of words, while the suffix list contains suffixes and stems that occur at the end of words. In the remainder of the paper, we will refer to the content of these lists as "prefixes" and "suffixes", although they also include stems. There are several assumptions encoded in this procedure that are specific to English, and cause recall to be low for other languages: 1) all stems are valid words in the lexicon; 2) affixes occur at the beginning or end of words only; and 3) affixation does not change stems. In section 4, we propose ways of relaxing these assumptions to make this step less language-specific.

3.3 Segmenting Words

The final step is the complete segmentation of words given the list of affixes acquired in the previous step. The original RePortS algorithm uses a very simple method that peels off the most probable suffix that has a transitional probability smaller than 1, until no more affixes match or until less than half of the word remains. This last condition is problematic since it does not scale up well to languages with complex morphology. The same peeling-off process is executed for prefixes.

Although this method is better than using a heuristic such as 'always peel off the longest possible affix', because it takes into account probable sites of fractures in words, it is not sensitive to the affix context or the morphotactics of the language. Typical mistakes that arise from this condition are that inflectional suffixes, which can only occur word-finally, might be split off in the middle of a word after previously having peeled off a number of other suffixes.

[1] www.cis.hut.fi/morphochallenge2005/

4 Modifications and Extensions

4.1 Morpheme Acquisition

When we ran the original algorithm on a German data set, no suffixes were validated but reasonable prefix lists were found. The algorithm works fine for English suffixes – why does it fail on German? The algorithm's failure to detect German suffixes is caused by the invalid assumption that a stem must be a word in the corpus. German verb stems do not occur on their own (except for certain imperative forms). After stripping off the suffix of the verb *abholst* 'fetch', the remaining string *abhol* cannot be found in the lexicon. However, words like *abholen*, *abholt*, *abhole* or *Abholung* are part of the corpus. The same problem also occurs for German nouns.

Therefore, this first condition of the affix acquisition step needs to be replaced. We therefore introduced an additional step for building an intermediate stem candidate list into the affix acquisition process. The first condition is replaced by a condition that checks whether a stem is in the stem candidate list. This new stem candidate acquisition procedure comprises three steps:

Step 1: Creation of stem candidate list

All substrings that satisfy conditions 2 and 3 but not condition 1, are stored together with the set of affixes they occur with. This process is similar to the idea of registering signatures (Goldsmith, 2001; Neuvel and Fulop, 2002). For example, let us assume our corpus contains the words *Aufführender*, *Aufführung*, *aufführt* and *Aufführlaune* but not the stem itself, since *aufführ* 'act' is not a valid German word. Conditions 2 and 3 are met, because the transitional probability between *aufführ* and the next letter is low (there are a lot of different possible continuations) and the transitional probability $P(r|auffüh) \approx 1$. The stem candidate *aufführ* is then stored together with the suffix candidates $\{$*ender*, *ung*, *en*, *t*, *laune*$\}$.

Step 2: Ranking candidate stems

There are two types of affix candidates: type-1 affix candidates are words that are contained in the data base as full words (those are due to compounding); type-2 affix candidates are inflectional and derivational suffixes. When ranking the stem candidates, we take into account the number of type-1 affix candidates and the average frequency of tpye-2 affix candidates.

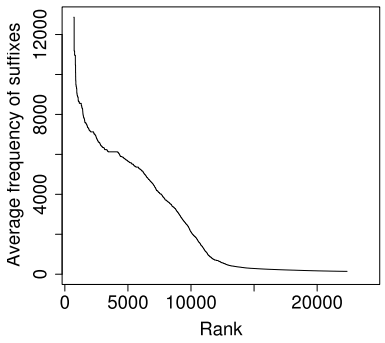

Figure 1: Determining the threshold for validating the best candidates from the stem candidate list.

The first condition has very good precision, similar to the original method. The morphemes found with this method are predominantly stem forms that occur in compounding or derivation (Kompositionsstämme and Derivationsstämme). The second condition enables us to differentiate between stems that occur with common suffixes (and therefore have high average frequencies), and pseudostems such as *runtersch* whose affix list contains many non-morphemes (e.g. *lucken*, *iebt*, *aute*). These non-morphemes are very rare since they are not generated by a regular process.

Step 3: Pruning

All stem candidates that occur less than three times are removed from the list. The remaining stem candidates are ordered according to the average frequency of their non-word suffixes. This criterion puts the high quality stem candidates (that occur with very common suffixes) to the top of the list. In order to obtain a high-precision stem list, it is necessary to cut the list of candidates at some point. The threshold for this is determined by the data: we choose the point at which the function of list-rank vs. score changes steepness (see Figure 1). This visual change of steepness corresponds to the point where potential stems found get more noisy because the strings with which they occur are not common affixes. We found the performance of the resulting morphological system to be quite stable ($\pm 1\%$ f-score) for any cutting point on the slope between 20% and 50% of the list (for the German data set ranks 4000 and 12000), but importantly before the function tails off. The threshold was also robust across the other languages and data sets.

4.2 Morphological Segmentation

As discussed in section 3.3, the original implementation of the algorithm iteratively chops off the most probable affixes at both edges of the word without taking into account the context of the affix. In morphologically complex languages, this context-blind approach often leads to suboptimal results, and also allows segmentations that are morphotactically impossible, such as inflectional suffixes in the middle of words. Another risk is that the letter sequence that is left after removing potential prefixes and suffixes from both ends is not a proper stem itself but just a single letter or vowel-less letter-sequence.

These problems can be solved by using a bi-gram language model to capture the morphotactic properties of a particular language. Instead of simply peeling off the most probable affixes from both ends of the word, all possible segmentations of the word are generated and ranked using the language model. The probabilities for the language model are learnt from a set of words that were segmented with the original simple approach. This bootstrapping allows us to ensure that the approach remains fully unsupervised. At the beginning and end of each word, an edge marker '#' is attached to the word. The model can then also acquire probabilities about which affixes occur most often at the edges of words.

Table 2 shows that filtering the segmentation results with the n-gram language model caused a significant improvement on the overall F-score for most languages, and led to significant changes in precision and recall. Whereas the original segmentation yielded balanced precision and recall (both 68%), the new filtering boosts precision to over 73%, with 64% recall. Which method is preferable (i.e. whether precision or recall is more important) is task-dependent.

In future work, we plan to draw on (Creutz and Lagus, 2006), who use a HMM with morphemic categories to impose morphotactic constraints. In such an approach, each element from the affix list is assigned with a certain probability to the underlying categories of "stem", "prefix" or "suffix", depending on the left and right perplexity of morphemes, as well as morpheme length and frequency. The transitional probabilities from one category to the next model the morphotactic rules of a language, which can thus be learnt automatically.

4.3 Learning Stem Variation

Stem variation through ablauting and umlauting (an English example is run–ran) is an interesting problem that cannot be captured by the algorithm outlined above, as variations take place within the morphemes. Stem variations can be context-dependent and do not constitute a morpheme in themselves. German umlauting and ablauting leads to data sparseness problems in morphological segmentation and affix acquisition. One problem is that affixes which usually cause ablauting or umlauting are very difficult to find. Typically, ablauted or umlauted stems are only seen with a very small number of different affixes, which means that the affix sets of such stems are divided into several unrelated subsets, causing the stem to be pruned from the stem candidate list. Secondly, ablauting and umlauting lead to low transitional probabilities at the positions in stems where these phenomena occur. Consider for example the affix set for the stem candidate *bockspr*, which contains the pseudoaffixes *ung*, *ünge* and *ingen*. The morphemes *sprung*, *sprüng* and *springen* are derived from the root *spring* 'to jump'. In the segmentation step this low transitional probability thus leads to oversegmentation.

We therefore investigated whether we can learn these regular stem variations automatically. A simple way to acquire the stem variations is to look at the suffix clusters which are calculated during the stem-acquisition step. When looking at the sets of substrings that are clustered together by having the same prefix, we found that they are often inflections of one another, because lexicalized compounds are used frequently in different inflectional variants. For example, we find *Trainingssprung* as well as *Trainingssprünge* in the corpus. The affix list of the stem candidate *trainings* thus contains the words *sprung* and *sprünge*. Edit distance can then be used to find differences between all words in a certain affix list. Pairs with small edit distances are stored and ranked by frequency. Regular transformation rules (e.g. ablauting and umlauting, $u \rightarrow \ddot{u}..e$) occur at the top of the list and are automatically accepted as rules (see Table 1). This method allows us to not only find the relation between two words in the lexicon (*Sprung* and *Sprünge*) but also to automatically learn rules that can be applied to unknown words to check whether their variant is a word in the lexicon.

freq.	diff.	examples
1682	a ä..e	sack-säcke, brach-bräche, stark-stärke

Table 1: Excerpts from the stem variation detection algorithm results. Morphologically unrelated word pairs are marked with an asterisk.

We integrated information about stem variation from the regular stem transformation rules (those with the highest frequencies) into the segmentation step by creating equivalence sets of letters. For example, the rule $u \rightarrow ü..e$ generates an equivalence set {ü, u}. These two letters then count as the same letter when calculating transitional probabilities. We evaluated the benefit of integrating stem variation information for German on the German CELEX data set, and achieved an improvement of 2% in recall, without any loss in precision (F-measure: 69.4%, Precision: 68.1%, Recall: 70.8%; values for RePortS-stems). For better comparability to other systems and languages, results reported in the next section refer to the system version that does not incorporate stem variation.

5 Evaluation

For evaluating the different versions of the algorithm on English, Turkish and Finnish, we used the training and test sets from MorphoChallenge to enable comparison with other systems. Performance of the algorithm on German was evaluated on 244k manually annotated words from CELEX because German was not included in the MorphoChallenge data.

Table 2 shows that the introduction of the stem candidate acquisition step led to much higher recall on German, Finnish and Turkish, but caused some losses in precision. For English, adding both components did not have a large effect on either precision or recall. This means that this component is well behaved, i.e. it improves performance on languages where the intermediate stem-acquisition step is needed, but does not impair results on other languages. Recall for Finnish is still very low. It can be improved (at the expense of precision) by selecting the analysis with the largest number of segments in the segmentation step. The results for this heuristic was only evaluated on a smaller test set (ca. 700 wds), hence marked with an asterisk in Table 2.

Lang.	alg.version	F-Meas.	Prec.	Recall
Eng[1]	original	76.8%	76.2%	77.4%
	stems	67.6%	62.9%	73.1%
	n-gram seg.	75.1%	74.4%	75.9%
Ger[2]	original	59.2%	71.1%	50.7%
	stems	68.4%	68.1%	68.6%
	n-gram seg.	68.9%	73.7%	64.6%
Tur[1]	original	54.2%	72.9%	43.1%
	stems	61.8%	65.9%	58.2%
	n-gram seg.	64.2%	65.2%	63.3%
Fin[1]	original	47.1%	84.5%	32.6%
	stems	56.6%	74.1%	45.8%
	n-gram seg.	58.9%	76.1%	48.1%
	max-split*	61.3%	66.3%	56.9%

Table 2: Performance of the algorithm with the modifications on different languages.
[1]MorphoChallenge Data, [2]German CELEX

The algorithm is very efficient: When trained on the 240m tokens of the German TAZ corpus, it takes up less than 1 GB of memory. The training phase takes approx. 5 min on a 2.4GHz machine, and the segmentation of the 250k test words takes 3 min for the version that does the simple segmentation and about 8 min for the version that generates all possible segmentations and uses the language model.

5.1 Comparison to other systems

This modified version of the algorithm performs second best for English (after original RePortS) and ranks third for Turkish (after Bernhards algorithm with 65.3% F-measure and Morfessor-Categories-MAP with 70.7%). On German, our method significantly outperformed the other unsupervised algorithms, see Table 3. While most of the systems compared here were developed for languages other than German, (Bordag, 2006) describes a system initially built for German. When trained on the "Projekt Deutscher Wortschatz" corpus which comprises 24 million sentences, it achieves an F-score of 61% (precision 60%, recall 62%[2]) when evaluated on the full CELEX corpus.

best Morfessor 1.0	52.6%	70.9%	41.8%

Table 3: Evaluating rule-based and data-based systems for morphological segmentation with respect to CELEX manual morphological annotation.

Rule-based systems are currently the most common approach to morphological decomposition and perform better at segmenting words than state-of-the-art unsupervised algorithms (see Table 3 for performance of state-of-the-art rule-based systems evaluated on the same data). Both the ETI[3] and the SMOR (Schmid et al., 2004) systems rely on a large lexicon and a set of rules. The SMOR system returns a set of analyses that can be disambiguated in different ways. For details refer to pp. 29–33 in (Demberg, 2006).

5.2 Evaluation on Grapheme-to-Phoneme Conversion

Morphological segmentation is not of value in itself – the question is whether it can help improve results on an application. Performance improvements due to morphological information have been reported for example in MT, information retrieval, and speech recognition. For the latter task, morphological segmentations from the unsupervised systems presented here have been shown to improve accuracy (Kurimo et al., 2006).

Another motivation for evaluating the system on a task rather than on manually annotated data is that linguistically motivated morphological segmentation is not necessarily the best possible segmentation for a certain task. Evaluation against a manually annotated corpus prefers segmentations that are closest to linguistically motivated analyses. Furthermore, it might be important for a certain task to find a particular type of morpheme boundaries (e.g. boundaries between stems), but for another task it might be very important to find boundaries between stems and suffixes. The standard evaluation procedure does not differentiate between the types of mistakes made. Finally, only evaluation on a task can provide information as to whether high precision or high recall is more important, therefore, the decision as to which version of the algorithm should be chosen can only be taken given a specific task.

morphology	F-Meas. (CELEX)	PER (dt)
CELEX	100%	2.64%
ETI	79.5%	2.78%
SMOR-disamb2	83.0%	3.00%
SMOR-disamb1	71.8%	3.28%
RePortS-lm	68.8%	3.45%
no morphology		3.63%
orig. RePortS	59.2%	3.83%
Bernhard	63.5%	3.88%
RePortS-stem	68.4%	3.98%
Morfessor 1.0	52.6%	4.10%
Bordag	64.1%	4.38%

Table 4: F-measure for evaluation on manually annotated CELEX and phoneme error rate (PER) from g2p conversion using a decision tree (dt).

For these reasons we decided to evaluate the segmentation from the new versions of the RePortS algorithm on a German grapheme-to-phoneme (g2p) conversion task. The evaluation on this task is motivated by the fact that (Demberg, 2007) showed that good-quality morphological preprocessing can improve g2p conversion results. We here compare the effect of using our system's segmentations to a range of different morphological segmentations from other systems. We ran each of the rule-based systems (ETI, SMOR-disamb1, SMOR-disamb2) and the unsupervised algorithms (original RePortS, Bernhard, Morfessor 1.0, Bordag) on the CELEX data set and retrained our decision tree (an implementation based on (Lucassen and Mercer, 1984)) on the different morphological segmentations.

Table 4 shows the F-score of the different systems when evaluated on the manually annotated CELEX data (full data set) and the phoneme error rate (PER) for the g2p conversion algorithm when annotated with morphological boundaries (smaller test set, since the decision tree is a supervised method and needs training data). As we can see from the results, the distribution of precision and recall (see Table 3) has an important impact on the conversion quality: the RePortS version with higher precision signifi-

cantly outperforms the other version on the task, although their F-measures are almost identical. Remarkably, the RePortS version that uses the filtering step is the only unsupervised system that beats the no-morphology baseline ($p < 0.0001$). While all other unsupervised systems tested here make the system perform worse than it would without morphological information, this new version improves accuracy on g2p conversion.

6 Conclusions

A significant improvement in F-score was achieved by three simple modifications to the RePortS algorithm: generating an intermediary high-precision stem candidate list, using a language model to disambiguate between alternative segmentations, and learning patterns for regular stem variation, which can then also be exploited for segmentation. These modifications improved results on four different languages considered: English, German, Turkish and Finnish, and achieved the best results reported so far for an unsupervised system for morphological segmentation on German. We showed that the new version of the algorithm is the only unsupervised system among the systems evaluated here that achieves sufficient quality to improve transcription performance on a grapheme-to-phoneme conversion task.

Acknowledgments

I would like to thank Emily Pitler and Samarth Keshava for making available the code of the RePortS algorithm, and Stefan Bordag and Delphine Bernhard for running their algorithms on the German data. Many thanks also to Matti Varjokallio for evaluating the data on the MorphoChallenge test sets for Finnish, Turkish and English. Furthermore, I am very grateful to Christoph Zwirello and Gregor Möhler for training the decision tree on the new morphological segmentation. I also want to thank Frank Keller and the ACL reviewers for valuable and insightful comments.

Using Mazurkiewicz Trace Languages for Partition-Based Morphology

François Barthélemy

INRIA Atoll, domaine de Voluceau, 78153 Le Chesnay cedex (France)
barthe@cnam.fr

Abstract

Partition-based morphology is an approach of finite-state morphology where a grammar describes a special kind of regular relations, which split all the strings of a given tuple into the same number of substrings. They are compiled in finite-state machines. In this paper, we address the question of merging grammars using different partitionings into a single finite-state machine. A morphological description may then be obtained by parallel or sequential application of constraints expressed on different partition notions (e.g. morpheme, phoneme, grapheme). The theory of Mazurkiewicz Trace Languages, a well known semantics of parallel systems, provides a way of representing and compiling such a description.

1 Partition-Based Morphology

Finite-State Morphology is based on the idea that regular relations are an appropriate formalism to describe the morphology of a natural language. Such a relation is a set of pairs, the first component being an actual form called *surface form*, the second component being an abstract description of this form called *lexical form*. It is usually implemented by a finite-state transducer. Relations are not oriented, so the same transducer may be used both for analysis and generation. They may be non-deterministic, when the same form belongs to several pairs. Furthermore, finite state machines have interesting properties, they are composable and efficient.

There are two main trends in Finite-State Morphology: rewrite-rule systems and two-level rule systems. Rewrite-rule systems describe the morphology of languages using contextual rewrite rules which are easily applied in cascade. Rules are compiled into finite-state transducers and merged using transducer composition (Kaplan and Kay, 1994).

The other important trend of Finite-State Morphology is Two-Level Morphology (Koskenniemi, 1983). In this approach, not only pairs of lexical and surface strings are related, but there is a one-to-one correspondence between their symbols. It means that the two strings of a given pair must have the same length. Whenever a symbol of one side does not have an actual counterpart in the other string, a special symbol 0 is inserted at the relevant position in order to fulfill the same-length constraint. For example, the correspondence between the surface form `spies` and the morpheme concatenation `spy+s` is given as follows:

s	p	y	0	+	s
s	p	i	e	0	s

Same-length relations are closed under intersection, so two-level grammars describe a system as the simultaneous application of local constraints.

A third approach, Partition-Based Morphology, consists in splitting the strings of a pair into the same number of substrings. The same-length constraint does not hold on symbols but on substrings. For example, `spies` and `spy+s` may be partitioned as follows:

s	p	y	+	s
s	p	ie	ϵ	s

The partition-based approach was first proposed by (Black et al., 1987) and further improved by (Pulman and Hepple, 1993) and (Grimley-Evans et al.,

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 928–935,
Prague, Czech Republic, June 2007.

1996). It has been used to describe the morphology of Syriac (Kiraz, 2000), Akkadian (Barthélemy, 2006) and Arabic Dialects (Habash et al., 2005). These works use multi-tape transducers instead of usual two tape transducers, describing a special case of n-ary relations instead of binary relations.

Definition 1 *Partitioned n-relation*
A partitioned n-relation is a set of finite sequences of string n-tuples.

For instance, the n-tuple sequence of the example $(spy, spies)$ given above is $(s,s)(p,p)(y,ie)(+,\epsilon)(s,s)$. Of course, all the partitioned n-relations are not recognizable using a finite-state machine. Grimley-Evans and al. propose a partition-based formalism with a strong restriction: the string n-tuples used in the sequences belong to a finite set of such n-tuples (the centers of context-restriction rules). They describe an algorithm which compiles a set of contextual rules describing a partitioned n-relation into an epsilon-free letter transducer. (Barthélemy, 2005) proposed a more powerful framework, where the relations are defined by concatenating tuples of independent regular expressions and operations on partitioned n-relations such as intersection and complementation are considered.

In this paper, we propose to use Mazurkiewicz Trace Languages instead of partitioned relation as the semantics of partition-based morphological formalisms. The benefits are twofold: firstly, there is an extension of the formal power which allows the combination of morphological description using different partitionings of forms. Secondly, the compilation of such languages into finite-state machines has been exhaustively studied. Their closure properties provide operations useful for morphological purposes.

They include the concatenation (for instance for compound words), the intersection used to merge local constraints, the union (modular lexicon), the composition (cascading descriptions, form recognition and generation), the projection (to extract one level of the relation), the complementation and set difference, used to compile contextual rules following the algorithms in (Kaplan and Kay, 1994), (Grimley-Evans et al., 1996) and (Yli-Jyrä and Koskenniemi, 2004).

The use of the new semantics does not imply any change of the user-level formalisms, thanks to a straightforward homomorphism from partitioned n-relations to Mazurkiewicz Trace Languages.

2 Mazurkiewicz Trace Languages

Within a given n-tuple, there is no meaningful order between symbols of the different levels. Mazurkiewicz trace languages is a theory which expresses partial ordering between symbols. They have been defined and studied in the realm of parallel computing. In this section, we recall their definition and some classical results. (Diekert and Métivier, 1997) gives an exhaustive presentation on the subject with a detailed bibliography. It contains all the results mentioned here and refers to their original publication.

2.1 Definitions

A Partially Commutative Monoid is defined on an alphabet Σ with an independence binary relation I over $\Sigma \times \Sigma$ which is symmetric and irreflexive. Two independent symbols commute freely whereas non-independent symbols do not. I defines an equivalence relation $\sim_I$ on Σ^*: two words are equivalent if one is the result of a series of commutation of pairs of successive symbols which belong to I. The notation $[x]$ is used to denote the equivalence class of a string x with respect to $\sim_I$.

The Partially Commutative Monoid $M(\Sigma, I)$ is the quotient of the free monoid Σ^* by the equivalence relation $\sim_I$.

The binary relation $D = (\Sigma \times \Sigma) - I$ is called the dependence relation. It is reflexive and symmetric.

φ is the canonical homomorphism defined by:

$$\begin{array}{rccc} \varphi: & \Sigma^* & \rightarrow & M(\Sigma, I) \\ & x & \mapsto & [x] \end{array}$$

A Mazurkiewicz trace language (abbreviation: trace language) is a subset of a partially commutative monoid $M(\Sigma, I)$.

2.2 Recognizable Trace Languages

A trace language T is said *recognizable* if there exists an homomorphism ν from $M(\Sigma, I)$ to a finite monoid S such that $T = \nu^{-1}(F)$ for some $F \subseteq S$. A recognizable Trace Language may be implemented by a Finite-State Automaton.

A trace $[x]$ is said to be connected if the dependence relation restricted to the alphabet of $[x]$ is a connected graph. A trace language is connected if all its traces are connected.

A string x is said to be in lexicographic normal form if x is the smallest string of its equivalence class $[x]$ with respect to the lexicographic ordering induced by an ordering on Σ. The set of strings in lexicographic normal form is written $LexNF$. This set is a regular language which is described by the following regular expression:
$LexNF = \Sigma^* - \bigcup_{(a,b)\in I, a<b} \Sigma^* b (I(a))^* a \Sigma^*$
where $I(a)$ denotes the set of symbols independent from a.

Property 1 *Let $T \subseteq M(\Sigma, I)$ be a trace language. The following assertions are equivalent:*

- *T is recognizable*
- *T is expressible as a rational expression where the Kleene star is used only on connected languages.*
- *The set $Min(T) = \{x \in LexNF | [x] \in T\}$ is a regular language over Σ^*.*

Recognizability is closely related to the notion of iterative factor, which is the language-level equivalent of a loop in a finite-state machine. If two symbols a and b such that $a < b$ belong to a loop, and if the loop is traversed several times, then occurrences of a and b are interlaced. For such a string to be in lexicographic normal form, a dependent symbol must appear in the loop between b and a.

2.3 Operations and closure properties

Recognizable trace languages are closed under intersection and union. Furthermore, $\text{Min}(T_1) \cup \text{Min}(T_2) = \text{Min}(T_1 \cup T_2)$ and $\text{Min}(T_1) \cap \text{Min}(T_2) = \text{Min}(T_1 \cap T_2)$. It comes from the fact that intersection and union do not create new iterative factor. The property on lexicographic normal form comes from the fact that all the traces in the result of the operation belong to at least one of the operands which are in normal form.

Recognizable trace language are closed under concatenation. Concatenation do not create new iterative factors. The concatenation $\text{Min}(T_1)\text{Min}(T_2)$ is not necessarily in lexicographic normal form. For instance, suppose that $a > b$. Then $\{[a]\}.\{[b]\} = \{[ab]\}$, but $\text{Min}(\{[a]\}) = a, \text{Min}(\{[b]\}) = b$, and $\text{Min}(\{[ab]\}) = ba$.

Recognizable trace languages are closed under complementation.

Recognizable Trace Languages are not closed under Kleene star. For instance, $a < b$, $\text{Min}([ab]^*) = a^n b^n$ which is known not to be regular.

The projection on a subset S of Σ is the operation written π_S, which deletes all the occurrences of symbols in $\Sigma - S$ from the traces. Recognizable trace languages are not closed under projection. The reason is that the projection may delete symbols which makes the languages of loops connected.

3 Partitioned relations and trace languages

It is possible to convert a partitioned relation into a trace language as follows:

- represent the partition boundaries using a symbol ω not in Σ.
- distinguish the symbols according to the component (tape) of the n-tuple they belong to. For this purpose, we will use a subscript.
- define the dependence relation D by:
  - ω is dependent from all the other symbols
  - symbols in Σ sharing the same subscript are mutually dependent whereas symbols having different subscript are mutually independent.

For instance, the *spy* n-tuple sequence $(s,s)(p,p)(y,ie)(+,\epsilon)(s,s)$ is translated into the trace $\omega s_1 s_2 \omega p_1 p_2 \omega y_1 i_2 e_2 \omega +_1 \omega s_1 s_2 \omega$. The figure 1 gives the partial order between symbols of this trace.

The dependence relation is intuitively sound. For instance, in the third n-tuple, there is a dependency between i and e which cannot be permuted, but there is no dependency between i (resp. e) and y: i is neither before nor after y. There are three equivalent permutations: $y_1 i_2 e_2$, $i_2 y_1 e_2$ and $i_2 e_2 y_1$. In an implementation, one canonical representation must be chosen, in order to ensure that set operations, such as intersection, are correct. The notion of lexicographic normal form, based on any arbitrary but fixed order on symbols, gives such a canonical form.

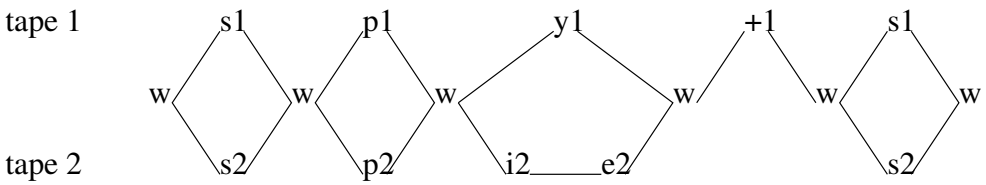

Figure 1: Partially ordered symbols

The compilation of the trace language into a finite-state automaton has been studied through the notion of recognizability. This automaton is very similar to an n-tape transducer. The Trace Language theory gives properties such as closure under intersection and soundness of the lexicographic normal form, which do not hold for usual transducers classes. It also provides a criterion to restrict the description of languages through regular expressions. This restriction is that the closure operator (Kleene star) must occur on connected languages only. In the translation of a partition-based regular expression, a star may appear either on a string of symbols of a given tape or on a string with at least one occurrence of ω.

Another benefit of Mazurkiewicz trace languages with respect to partitioned relations is their ability to represent the segmentation of the same form using two different partitionings. The example of figure 2 uses two partitionings of the form `spy+s`, one based on the notion of morpheme, the other on the notion of phoneme. The notation `<pos=noun>` and `<number=pl>` stands for two single symbols. Flat feature structures over (small) finite domains are easily represented by a string of such symbols. N-tuples are not very convenient to represent such a system.

Partition-based formalism are especially adapted to express relations between different representation such as feature structures and affixes, with respect to two-level morphology which imposes an artificial symbol-to-symbol mapping.

A multi-partitioned relation may be obtained by merging the translation of two partition-based grammars which share one or more common tapes. Such a merging is performed by the join operator of the relational algebra. Using a partition-based grammar for recognition or generation implies such an operation: the grammar is joined with a 1-tape machine without partitioning representing the form to be recognized (surface level) or generated (lexical level).

4 Multi-Tape Trace Languages

In this section, we define a subclass of Mazurkiewicz Trace Languages especially adapted to partition-based morphology, thanks to an explicit notion of tape partially synchronized by partition boundaries.

Definition 2 *A multi-tape partially commutative monoid is defined by a tuple* $(\Sigma, \Theta, \Omega, \mu)$ *where*

- Σ *is a finite set of symbols called the alphabet.*
- Θ *is a finite set of symbols called the tapes.*
- Ω *is a finite set of symbols which do not belong to* Σ*, called the partition boundaries.*
- μ *is a mapping from* $\Sigma \cup \Omega$ *to* 2^θ *such that* $\mu(x)$ *is a singleton for any* $x \in \Sigma$*.*

It is the Partially Commutative Monoid $M(\Sigma \cup \Omega, I_\mu)$ *where the independence relation is defined by* $I_\mu = \{(x, y) \in \Sigma \cup \Omega \times \Sigma \cup \Omega | \mu(x) \cap \mu(y) = \emptyset\}$. *Notation:* $MPM(\Sigma, \Theta, \Omega, \mu)$.

A Multi-Tape Trace Language is a subset of a Multi-Tape partially commutative monoid.

We now address the problem of relational operations over Recognizable Multi-Tape Trace Languages. Recognizable languages may be implemented by finite-state automata in lexicographic normal form, using the morphism φ^{-1}. Operations on trace languages are implemented by operations on finite-state automata. We are looking for implementations preserving the normal form property, because changing the order in regular languages is not a standard operation.

Some set operations are very simple to implement, namely union, intersection and difference.

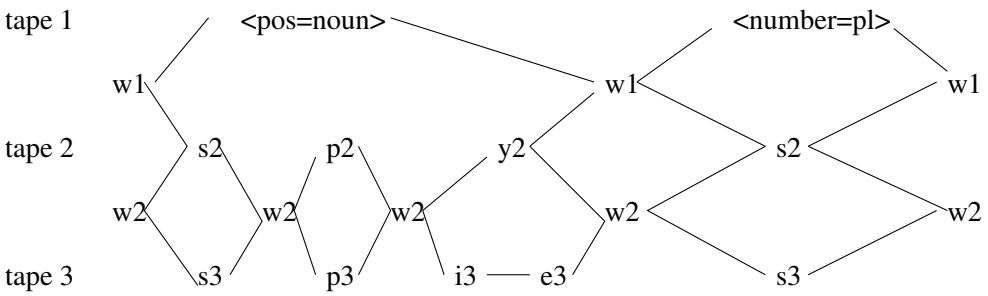

Figure 2: Two partitions of the same tape

The elements of the result of such an operation belongs to one or both operands, and are therefore in lexicographic normal form. If we write $Min(T)$ the set $Min(T) = \{x \in LexNF | [x] \in T\}$, where T is a Multi-Tape Trace Language, we have trivially the properties:

- $Min(T_1 \cup T_2) = Min(T_1) \cup Min(T_2)$
- $Min(T_1 \cap T_2) = Min(T_1) \cap Min(T_2)$
- $Min(T_1 - T_2) = Min(T_1) - Min(T_2)$

Implementing the complementation is not so straightforward because $Min(\overline{T})$ is usually not equal to $\overline{Min(T)}$. The later set contains strings not in lexical normal forms which may belong to the equivalence class of a member of T with respect to $\sim_I$. The complementation must not be computed with respect to regular languages but to LexNF.
$Min(\overline{T}) = LexNF - Min(T)$

As already mentioned, the concatenation of two regular languages in lexicographic normal form is not necessarily in normal form. We do not have a general solution to the problem but two partial solutions. Firstly, it is easy to test whether the result is actually in normal form or not. Secondly, the result is in normal form whenever a synchronization point belonging to all the levels is inserted between the strings of the two languages. Let $\omega_u \in \Omega, \mu(\omega_u) = \Theta$. Then, $Min(T_1.\{\omega_u\}.T_2) = Min(T_1).Min(\omega_u).Min(T_2)$.

The closure (Kleene star) operation creates a new iterative factor and therefore, the result may be a non recognizable trace language. Here again, concatenating a global synchronization point at the end of the language gives a trace language closed under Kleene star. By definition, such a language is connected. Furthermore, the result is in normal form.

So far, operations have operands and the result belonging to the same Multi-tape Monoid. It is not the case of the last two operations: projection and join.

We use the the operators Dom, Range, and the relations Id and Insert as defined in (Kaplan and Kay, 1994):

- Dom$(R) = \{x | \exists y, (x, y) \in R\}$
- Range$(R) = \{y | \exists x, (x, y) \in R\}$
- Id$(L) = \{(x, x) | x \in L\}$
- Insert$(S) = (\text{Id}(\Sigma) \cup (\{\epsilon\} \times S))^*$. It is used to insert freely symbols from S in a string from Σ^*. Conversely, Insert$(S)^{-1}$ removes all the occurrences of symbols from S, if $S \cap \Sigma = \emptyset$.

The result of a projection operation may not be recognizable if it deletes symbols making iterative factors connected. Furthermore, when the result is recognizable, the projection on $Min(T)$ is not necessarily in normal form. Both phenomena come from the deletion of synchronization points. Therefore, a projection which deletes only symbols from Σ is safe. The deletion of synchronization points is also possible whenever they do not synchronize anything more in the result of the projection because all but possibly one of its tapes have been deleted.

In the tape-oriented computation system, we are mainly interested in the projection which deletes some tapes and possibly some related synchronization points.

Property 2 *Projection*
Let T be a trace language over the MTM $M = (\Sigma, \Theta, w, \mu)$. Let $\Omega_1 \subset \Omega$ and $\Theta_1 \subset \Theta$. If

$\forall \omega \in \Omega - \Omega_1, |\mu(\omega) \cap \Theta_1| \leq 1$, *then* $Min(\pi_{\Theta_1,\Omega_1}(T)) = Range(Insert(\{x \in \Sigma | \mu(x) \notin \Theta_1\} \cup \Omega - \Omega_1)^{-1} \circ Min(T))$

The join operation is named by analogy with the operator of the relational algebra. It has been defined on finite-state transducers (Kempe et al., 2004).

Definition 3 *Multi-tape join*
Let $T_1 \subset MTM(\Sigma_1, \Theta_1, \Omega_1, \mu_1)$ *and* $T_2 \subset TM(\Sigma_2, \Theta_2, \Omega_2, \mu_2)$ *be two multi-tape trace languages.* $T_1 \bowtie T_2$ *is defined if and only if*

- $\forall \sigma \in \Sigma_1 \cap \Sigma_2, \mu_1(\sigma) \cap \Theta_2 = \mu_2(\sigma) \cap \Theta_1$
- $\forall \omega \in \Omega_1 \cap \Omega_2, \mu_1(\omega) \cap \Theta_2 = \mu_2(\omega) \cap \Theta_1$

The Multi-tape Trace Language $T_1 \bowtie T_2$ *is defined on the Multi-tape Partially Commutative Monoid* $MTM(\Sigma_1 \cup \Sigma_2, \Theta_1 \cup \Theta_2, \Omega_1 \cup \Omega_2, \mu)$ *where* $\mu(x) = \mu_1(x) \cup \mu_2(x)$. *It is defined by* $\pi_{\Sigma_1 \cup \Theta_1 \cup \Omega_1}(T_1 \bowtie T_2) = T_1$ *and* $\pi_{\Sigma_2 \cup \Theta_2 \cup \Omega_2}(T_1 \bowtie T_2) = T_2$.

If the two operands T_1 and T_2 belong to the same MTM, then $T_1 \bowtie T_2 = T_1 \cap T_2$. If the operands belong to disjoint monoids (which do not share any symbol), then the join is a Cartesian product.

The implementation of the join relies on the finite-state intersection algorithm. This algorithm works whenever the common symbols of the two languages appear in the same order in the two operands. The normal form does not ensure this property, because symbols in the common part of the join may be synchronized by tapes not in the common part, by transitivity, like in the example of the figure 3. In this example, `c` on tape 3 and `f` on tape 1 are ordered $c < f$ by transitivity using tape 2.

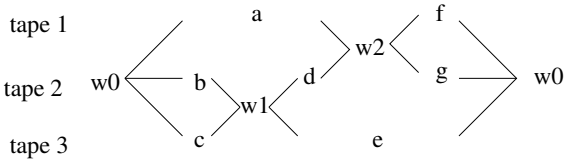

Figure 3: indirect tape synchronization

Let $T \subseteq MPM(\Sigma, \Theta, \Omega, \mu)$ a multi-partition trace language. Let G_T be the labeled graph where the nodes are the tape symbols from Θ and the edges are the set $\{(x, \omega, y) \in \Theta \times \Omega \times \Theta | x \in \mu(\omega)$ and $y \in \mu(\omega)\}$. Let Sync(Θ) be the set defined by Sync(Θ) = $\{\omega \in \Omega | \omega$ appears in G_T on a path between two tapes of $\Theta\}$.

The G_T graph for example of the figure 3 is given in figure 4 and Sync($\{1, 3\}$) = $\{\omega_0, \omega_1, \omega_2\}$.

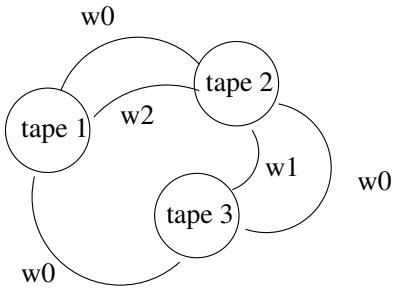

Figure 4: the G_T graph

Sync(Θ) is different from $\mu^{-1}(\Theta) \cap \Omega$ because some synchronization points may induce an order between two tapes by transitivity, using other tapes.

Property 3 *Let* $T_1 \subseteq MPM(\Sigma_1, \Theta_1, \Omega_1, \mu_1)$ *and* $T_2 \subseteq MPM(\Sigma_2, \Theta_2, \Omega_2, \mu_2)$ *be two multi-partition trace languages. Let* $\Sigma = \Sigma_1 \cap \Sigma_2$ *and* $\Omega = \Omega_1 \cap \Omega_2$. *If Sync*$(\Theta_1 \cap \Theta_2) \subseteq \Omega$, *then* $\pi_{\Sigma \cup \Omega}(Min(T_1)) \cap \pi_{\Sigma \cup \Omega}(Min(T_2)) = Min(\pi_{\Sigma \cup \Omega}(T_1) \cap \pi_{\Sigma \cup \Omega}(T_2)$

This property expresses the fact that symbols belonging to both languages appear in the same order in lexicographic normal forms whenever all the direct and indirect synchronization symbols belong to the two languages too.

Property 4 *Let* $T_1 \subseteq MPM(\Sigma_1, \Theta_1, \Omega_1, \mu_1)$ *and* $T_2 \subseteq MPM(\Sigma_2, \Theta_2, \Omega_2, \mu_2)$ *be two multi-partition trace languages. If* $\Theta_1 \cap \Theta_2$ *is a singleton* $\{\theta\}$ *and if* $\forall \omega \in \Omega_1 \cap \Omega_2, \theta \in \mu(\omega)$, *then* $\pi_{\Sigma \cup \Omega}(Min(T_1)) \cap \pi_{\Sigma \cup \Omega}(Min(T_2)) = Min(\pi_{\Sigma \cup \Omega}(T_1) \cap \pi_{\Sigma \cup \Omega}(T_2)$

This second property expresses the fact that symbols appear necessarily in the same order in the two operands if the intersection of the two languages is restricted to symbols of a single tape. This property is straightforward since symbols of a given tape are mutually dependent.

We now define a computation over $(\Sigma \cup \Omega)^*$ which computes $Min(T_1 \bowtie T_2)$.

Let $T_1 \subset MTM(\Sigma_1, \Theta_1, \omega_1, \mu_1)$ and $T_2 \subset MTM(\Sigma_2, \Theta_2, \Omega_2, \mu_2)$ be two recognizable multi-tape trace languages.
If Sync($\Theta_1 \cap \Theta_2$) $\subseteq \Omega$, then $Min(T_1 \bowtie T_2) =$ Range($Min(T_1 \circ$ Insert($\Sigma_2 - \Sigma_1) \circ$ Id(LexNF)) $\cap$ Range($Min(T_2) \circ$ Insert($\Sigma_1 - \Sigma_2) \circ$ Id(LexNF)).

5 A short example

We have written a morphological description of Turkish verbal morphology using two different partitionings. The first one corresponds to the notion of affix (morpheme). It is used to describe the morphotactics of the language using rules such as the following context-restriction rule:

```
(y?I4m,1 sing) ⇒
    (I?yor,prog)|(y?E2cE2k,future) __
```

In this rule, $y^?$ stands for an optional y, I^4 and E^2 for abstract vowels which realizations are subject to vowel harmony and $I^?$ is an optional occurrence of the first vowel. The rule may be read: the suffix $y^?I^4m$ denoting a first person singular may appear only after the suffix of progressive or the suffix of future[1]. Such rules describe simply affix order in verbal forms.

The second partitioning is a symbol-to-symbol correspondence similar to the one used in standard two-level morphology. This partitioning is more convenient to express the constraints of vowel harmony which occurs anywhere in the affixes and does not depend on affix boundaries.

Here are two of the rules implementing vowel harmony:

```
(I4,i) ⇒ (Vow,e|i) (Cons,Cons)* __
(I4,u) ⇒ (Vow,o|u) (Cons,Cons)* __
```

Vow and Cons denote respectively the sets of vowels and consonants. These rules may be read: *a symbol I^4 is realized as i (resp. u) whenever the closest preceding vowel is realized as e or i (resp. o or u).*

The realization or not of an optional letter may be expressed using one or the other partitioning. These optional letters always appear in the first position of an affix and depends only on the last letter of the preceding affix.

```
(y?,y) ⇒ (Vow,Vow) __
```

Here is an example of a verbal form given as a 3-tape relation partitioned using the two partitionings.

verbal root			prog				1 sing		
g	e	l	$I^?$	y	o	r	$Y^?$	I^4	m
g	e	l	i	y	o	r	ϵ	u	m

The translation of each rule into a Multi-tape Trace Language involves two tasks: introducing partition boundary symbols at each frontier between partitions. A different symbol is used for each kind of partitioning. Distinguishing symbols from different tapes in order to ensure that $\mu(x)$ is a singleton for each $x \in \Sigma$. Symbols of Σ are therefore pairs with the symbol appearing in the rule as first component and the tape identifier, a number, as second component.

Any complete order between symbols would define a lexicographic normal form. The order used by our system orders symbol with respect to tapes: symbols of the first tape are smaller than the symbols of tape 2, and so on. The order between symbols of a same tape is not important because these symbols are mutually dependent. The translation of a tuple $(a_1 \dots a_n, b_1 \dots b_m)$ is $(a_1, 1) \dots (a_n, 1)(b_1, 2) \dots (b_m, 2)\omega_1$. Such a string is in lexicographic normal form. Furthermore, this expression is connected, thanks to the partition boundary which synchronizes all the tapes, so its closure is recognizable. The concatenation too is safe.

All contextual rules are compiled following the algorithm in (Yli-Jyrä and Koskenniemi, 2004) [2]. Then all the rules describing affixes are intersected in an automaton, and all the rules describing surface transformation are intersected in another automaton. Then a join is performed to obtain the final machine. This join is possible because the intersection of the two languages consists in one tape (cf. property 4). Using it either for recognition or generation is also done by a join, possibly followed by a projection.

For instance, to recognize a surface form $geliyorum$, first compile it in the multi-tape trace language $(g, 3)(e, 3)(l, 3) \dots (m, 3)$, join it with the morphological description, and then project the result on tape 1 to obtain an abstract form `(verbal root,1)(prog,1)(1 sing,1)`. Finally extract the first component of each pair.

6 Conclusion

Partition-oriented rules are a convenient way to describe some of the constraints involved in the morphology of the language, but not all the constraints refer to the same partition notion. Describing a rule

[1] The actual rule has 5 other alternative tenses. It has been shortened for clarity.

[2] Two other compilation algorithm also work on the rules of this example (Kaplan and Kay, 1994), (Grimley-Evans et al., 1996). (Yli-Jyrä and Koskenniemi, 2004) is more general.

with an irrelevant one is sometimes difficult and inelegant. For instance, describing vowel harmony using a partitioning based on morphemes takes necessarily several rules corresponding to the cases where the harmony is within a morpheme or across several morphemes.

Previous partition-based formalisms use a unique partitioning which is used in all the contextual rules. Our proposition is to use several partitionings in order to express constraints with the proper granularity. Typically, these partitionings correspond to the notions of morphemes, phonemes and graphemes.

Partition-based grammars have the same theoretical power as two-level morphology, which is the power of regular languages. It was designed to remain finite-state and closed under intersection. It is compiled in finite-state automata which are formally equivalent to the epsilon-free letter transducers used by two-level morphology. It is simply more easy to use in some cases, just like two-level rules are more convenient than simple regular expressions for some applications.

Partition-Based morphology is convenient whenever the different levels use very different representations, like feature structures and strings, or different writing systems (e.g. Japanese hiragana and transcription). Two-level rules on the other hand are convenient whenever the related strings are variants of the same representation like in the example (spy+s,spies). Note that multi-partition morphology may use a one-to-one correspondence as one of its partitionings, and therefore is compatible with usual two-level morphology.

With respect to rewrite rule systems, partition-based morphology gives better support to parallel rule application and context definition may involve several levels. The counterpart is a risk of conflicts between contextual rules.

Much ado about nothing: A social network model of Russian paradigmatic gaps

Abstract

A number of Russian verbs lack 1sg non-past forms. These paradigmatic gaps are puzzling because they seemingly contradict the highly productive nature of inflectional systems. We model the persistence and spread of Russian gaps via a multi-agent model with Bayesian learning. We ran three simulations: no grammar learning, learning with arbitrary analogical pressure, and morphophonologically conditioned learning. We compare the results to the attested historical development of the gaps. Contradicting previous accounts, we propose that the persistence of gaps can be explained in the absence of synchronic competition between forms.

1 Introduction

Paradigmatic gaps present an interesting challenge for theories of inflectional structure and language learning. Wug tests, analogical change and children's overextensions of regular patterns demonstrate that inflectional morphology is highly productive. Yet lemmas sometimes have "missing" inflected forms. For example, in Russian the majority of verbs have first person singular (1sg) non-past forms (e.g., *posadit'* 'to plant', *posažu* 'I will plant'), but no 1sg form for a number of similar verbs (e.g., *pobedit'* 'to win', **pobežu* 'I will win'). The challenge lies in explaining this apparent contradiction. Given the highly productive nature of inflection, why do paradigmatic gaps arise? Why do they persist?

One approach explains paradigmatic gaps as a problem in generating an acceptable form. Under this hypothesis, gaps result from irreconcilable conflict between two or more inflectional patterns. For example, Albright (2003) presents an analysis of Spanish verbal gaps based on the Minimal Generalization Learner (Albright and Hayes 2002). In his account, competition between mid-vowel diphthongization (e.g., *s[e]ntir* 'to feel', *s[je]nto* 'I feel') and non-diphthongization (e.g., *p[e]dir* 'to ask', *p[i]do* 'I ask') leads to paradigmatic gaps in lexemes for which the applicability of diphthongization has low reliability (e.g., *abolir* 'to abolish, **ab[we]lo*, **ab[o]lo* 'I abolish').

However, this approach both overpredicts and underpredicts the existence of gaps cross-linguistically. First, it predicts that gaps should occur whenever the analogical forces determining word forms are contradictory and evenly weighted. However, variation between two inflectional patterns seems to more commonly result from such a scenario. Second, the model predicts that if the form-based conflict disappears, the gaps should also disappear. However, in Russian and probably in other languages, gaps persist even after the loss of competing inflectional patterns or other synchronic form-based motivation (Sims 2006).

By contrast, our approach operates at the level of inflectional property sets (IPS), or more properly, at the level of inflectional paradigms. We propose that once gaps are established in a language for whatever reason, they persist because learners infer the relative non-use of a given

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 936–943,
Prague, Czech Republic, June 2007.

combination of stem and IPS.[1] Put differently, we hypothesize that speakers possess at least two kinds of knowledge about inflectional structure: (1) knowledge of how to generate the appropriate form for a given lemma and IPS, and (2) knowledge of the probability with which that combination of lemma and property set is expressed, regardless of the form. Our approach differs from previous accounts in that persistence of gaps is attributed to the latter kind of knowledge, and does not depend on synchronic morphological competition.

We present a case study of the Russian verbal gaps, which are notable for their persistence. They arose between the mid 19th and early 20th century (Baerman 2007), and are still strongly attested in the modern language, but have no apparent synchronic morphological cause.

We model the persistence and spread of the Russian verbal gaps with a multi-agent model with Bayesian learning. Our model has two kinds of agents, adults and children. A model cycle consists of two phases: a production-perception phase, and a learning-maturation phase. In the production-perception phase, adults produce a batch of linguistic data (verb forms), and children listen to the productions from the adults they know. In the learning-maturation phase, children build a grammar based on the input they have received, then mature into adults. The existing adults die off, and the next generation of children is born.

Our model exhibits similar behavior to what is known about the development of Russian gaps.

2 The historical and distributional facts of Russian verbal gaps

2.1 Traditional descriptions

Grammars and dictionaries of Russian frequently cite paradigmatic gaps in the 1sg non-past. Nine major dictionaries and grammars, including Švedova (1982) and Zaliznjak (1977), yielded a combined list of 96 gaps representing 68 distinct stems. These verbal gaps fall almost entirely into the second conjugation class, and they overwhelmingly affect the subgroup of dental stems. Commonly cited gaps include: **galžu* 'I make a hubbub'; **očučus'* 'I come to be (REFL)'; 1SG **oščušču* 'I feel'; **pobežu* 'I will win'; and **ubežu* 'I will convince'.[2]

There is no satisfactory synchronic reason for the existence of the gaps. The grouping of gaps among 2nd conjugation dental stems is seemingly non-arbitrary because these are exactly the forms that would be subject to a palatalizing morphophonological alternation ($t^j \rightarrow tʃ$ or $ʃ^j$, $d^j \rightarrow ʒ$, $s^j \rightarrow ʃ$, $z^j \rightarrow ʒ$). Yet the Russian gaps do not meet the criteria for morphophonological competition as intended by Albright's (2003) model, because the alternations apply automatically in Contemporary Standard Russian. Analogical forces should thus heavily favor a single form, for example, *pobežu*.

Traditional explanations for the gaps, such as homophony avoidance (Švedova 1982) are also unsatisfactory since they can, at best, explain only a small percentage of the gaps.

Thus, the data suggest that gaps persist in Russian primarily because they are not uttered, and this non-use is learned by succeeding generations of Russian speakers.[3] The clustering of the gaps among 2nd conjugation dental stems most likely is partially a remnant of their original causes, and partially represents analogic extension of gaps along morphophonological lines (see 2.3 below).

2.2 Empirical evidence for and operational definition of gaps

When dealing with descriptions in semi-prescriptive sources such as dictionaries, we must always ask whether they accurately represent language use. In other words, is there empirical evidence that speakers fail to use these words?

We sought evidence of gaps from the Russian National Corpus (RNC).[4] The RNC is a balanced textual corpus with 77.6 million words consisting primarily of the contemporary Russian literary language. The content is prose, plays, memoirs and biographies, literary criticism, newspaper and magazine articles, school texts, religious and

[1] Paradigmatic gaps also probably serve a sociolinguistic purpose, for example as markers of education, but sociolinguistic issues are beyond the scope of this paper.

[2] We use here the standard Cyrillic transliteration used by linguists. It should not be considered an accurate phonological representation. Elsewhere, when phonological issues are relevant, we use IPA.

[3] See Manning (2003) and Zuraw (2003) on learning from implicit negative evidence.

[4] Documentation: http://ruscorpora.ru/corpora-structure.html Mirror site used for searching: http://corpus.leeds.ac.uk/ruscorpora.html.

philosophical materials, technical and scientific texts, judicial and governmental publications, etc.

We gathered token frequencies for the six non-past forms of 3,265 randomly selected second conjugation verb lemmas. This produced 11,729 inflected forms with non-zero frequency.[5] As described in Section 3 below, these 11,729 form frequencies became our model's seed data.

To test the claim that Russian has verbal gaps, we examined a subsample of 557 2nd conjugation lemmas meeting the following criteria: (a) total non-past frequency greater than 36 raw tokens, and (b) 3sg and 3pl constituting less than 85% of total non-past frequency.[6] These constraints were designed to select verbs for which all six person-number combinations should be robustly attested, and to minimize sampling errors by removing lemmas with low attestation.

We calculated the probability of the 1sg inflection by dividing the number of 1sg forms by the total number of non-past forms. The subset was bimodally distributed with one peak near 0%, a trough at around 2%, and the other peak at 13.3%. The first peak represents lemmas in which the 1sg form is basically not used – gaps. Accordingly, we define gaps as second conjugation verbs which meet criteria (a) and (b) above, and for which the 1sg non-past form constitutes less than 2% of total non-past frequency for that lemma (N=56).

In accordance with the grammatical descriptions, our criteria are disproportionately likely to identify dental stems as gaps. Still, only 43 of 412 dental stems (10.4%) have gaps, compared with 13 gaps among 397 examples of other stems (3.3%).

Second, not all dental stems are equally affected. There seems to be a weak prototypicality effect centered around stems ending in /dʲ/, from which /tʲ/ and /zʲ/ each differ by one phonological feature. There may also be some weak semantic factors that we do not consider here.

/**dʲ**/	/**tʲ**/	/**zʲ**/	/**sʲ**/	/**stʲ**/
13.3% (19/143)	12.4% (14/118)	11.9% (5/42)	4.8% (3/62)	4.3% (2/47)

Table 1. Distribution of Russian verbal gaps among dental stems

[5] We excluded 29 high-frequency lemmas for which the corpus did not provide accurate counts.

[6] Russian has a number of verbs for which only the 3sg and 3pl are regularly used.

2.3 Some relevant historical facts

A significant difference between the morphological competition approach and our statistical learning approach is that the former attempts to provide a single account for both the rise and the perpetuation of paradigmatic gaps. By contrast, our statistical learning model does not require that the morphological system provide synchronic motivation. The following question thus arises: Were the Russian gaps originally caused by forces which are no longer in play in the language?

Baerman and Corbett (2006) find evidence that the gaps began with a single root, *-bed-* (e.g., *pobedit'* 'to win'), and subsequently spread analogically within dental stems. Baerman (2007) expands on the historical evidence, finding that a conspiracy of several factors provided the initial push towards defective 1sg forms. Most important among these, many of the verbs with 1sg gaps in modern Russian are historically associated with aberrant morphophonological alternations. He argues that when these unusual alternations were eliminated in the language, some of the words failed to be integrated into the new morphological patterns, which resulted in lexically specified gaps.

Important to the point here is that the elimination of marginal alternations removed an earlier synchronic motivation for the gaps. Yet gaps have persisted and new gaps have arisen (e.g., *pylesosit'* 'to vacuum'). This persistence is the behavior that we seek to model.

3 Formal aspects of the model

We take up two questions: How much machinery do we need for gaps to persist? How much machinery do we need for gaps to spread to phonologically similar words? We model three scenarios.

In the first scenario there is no grammar learning. Adult agents produce forms by random sampling from the forms that heard as children, and child agents hear those forms. In the subsequent generation children become adults. In this scenario there is thus no analogical pressure. Any perseverance of gaps results from word-specific learning.

The second scenario is similar to the first, except that the learning process includes analogical pressure from a random set of words. Specifically, for a target concept, the estimated distribution of its IPS is influenced by the distribution of known words. This enables the learner to express a known

concept with a novel IPS. For example, imagine that a learner hears the present tense verb form *googles*, but not the past tense *googled*. By analogy with other verbs, learners can expect the past tense to occur with a certain frequency, even if they have not encountered it.

The third scenario builds upon the second. In this version, the analogical pressure is not completely random. Instead, it is weighted by morphophonological similarity – similar word forms contribute more to the analogical force on a target concept than do dissimilar forms. This addition to the model is motivated by the pervasive importance of stem shape in the Russian morphological system generally, and potentially provides an account for the phonological prototypicality effect among Russian gaps.

The three scenarios thus represent increasing machinery for the model, and we use them to explore the conditions necessary for gaps to persist and spread. We created a multi-agent network model with Bayesian learning component. In the following sections we describe the model's structure, and outline the criteria by which we evaluate its output under the various conditions.

3.1 Social structure

Our model includes two generations of agents. Adult agents output linguistic forms, which provide linguistic input for child agents. Output/input occurs in batches.[7] After each batch all adults die, all children mature into adults, and a new generation of children is born. Each run of the model included 10 generations of agents.

We model the social structure with a random network. Each adult produces 100,000 verb forms, and each child is exposed to every production from every adult to whom they are connected. Each generation consisted of 50 adult agents, and child agents are connected to adults with some probability *p*. On average, each child agent is connected to 10 adult agents, meaning that each child hears, on average, 1,000,000 tokens.

3.2 Linguistic events

Russian gaps are localized to second conjugation non-past verb forms, so productions of these forms are the focus of interest. Formally, we define a linguistic event as a concept-inflection-form (C,I,F) triple. The concept serves to connect the different forms and inflections of the same lemma.

3.3 Definition of grammar

A grammar is defined as a probability distribution over linguistic events. This gives rise to natural formulations of learning and production as statistical processes: learning is estimating a probability distribution from existing data, and production is sampling from a probability distribution. The grammar can be factored into modular components:

$$p(C, I, F) = p(C) \cdot p(I \mid C) \cdot p(F \mid C, I)$$

In this paper we focus on the probability distribution of concept-inflection pairs. In other words, we focus on the relative frequency of inflectional property sets (IPS) on a lemma-by-lemma basis, represented by the middle term above.

Accordingly, we made the simplest possible assumptions for the first and last terms. To calculate the probability of a concept, children use the sample frequency (e.g., if they hear 10 tokens of the concept 'eat', and 1,000 tokens total, then p('eat') = 10/1000 = .01). Learning of forms is perfect. That is, learners always produce the correct form for every concept-inflection pair.

3.4 Learning model

Although production in the real world is governed by semantics, we treat it here as a statistical process, much like rolling a six-sided die which may or may not be fair. When producing a Russian non-past verb, there are six possible combinations of inflectional properties (3 persons * 2 numbers). In our model, word learning involves estimating the probability distribution over the frequencies of the six forms on a lemma-by-lemma basis. A hypothetical example that introduces our variables:

jest'	**1sg**	**2sg**	**3sg**	**1pl**	**2pl**	**3pl**	**SUM**
D	15	5	45	5	5	25	100
d	0.15	0.05	0.45	0.05	0.05	0.25	1

Table 2. Hypothetical probability distribution

The first row indicates the concept and the inflections. The second row (**D**) indicates the

[7] See Niyogi (2006) for why batch learning is a reasonable approximation in this context.

hypothetical number of tokens of *jest'* 'eat' that the learner heard for each inflection (bolding indicates a six-vector). We use |D| to indicate the sum of this row (=100), which is the concept frequency. The third row (**d**) indicates the sample probability of that inflection, which is simply the second row divided by |D|.

The learner's goal is to estimate the distribution that generated this data. We assume the multinomial distribution, whose parameter is simply the vector of probabilities of each IPS. For each concept, the learner's task is to estimate the probability of each IPS, represented by **h** in the equations below. We begin with Bayes' rule:

$$p(\mathbf{h} \mid \mathbf{D}) \propto p(\mathbf{h}) \cdot \text{multinom}(\mathbf{D} \mid \mathbf{h})$$

The prior distribution constitutes the analogical pressure on the lemma. It is generated from the "expected" behavior, $\mathbf{h^0}$, which is an average of the known behavior from a random sample of other lemmas. The parameter κ determines the number of lemmas that are sampled for this purpose – it represents how many existing words affect a new word. To model the effect of morphophonological similarity (mpSim), in one variant of the model we weight this average by the similarity of the stem-final consonant.[8] For example, this has the effect that existing dental stems have more of an effect on dental stems. In this case, we define

$$\mathbf{h^0} = \Sigma_{c' \text{ in sample}} \mathbf{d}_{c'} \cdot \text{mpSim}(c, c') / \Sigma\, \text{mpSim}(c, c')$$

We use a featural definition of similarity, so that if the stem-final consonants differ by 0, 1, 2, or 3 or more phonological features, the resulting similarity is 1, 2/3, 1/3, or 0, respectively.

The prior distribution should assign higher probability to hypotheses that are "closer" to this expected behavior $\mathbf{h^0}$. Since the hypothesis is itself a probability distribution, the natural measure to use is the KL divergence. We used an exponentially distributed prior with parameter β:

$$p(\mathbf{h}) \propto \exp(-\beta \cdot \mathbf{h^0} \,||\, \mathbf{h})$$

As will be shown shortly, β has a natural interpretation as the relative strength of the prior with respect to the observed data.

The learner calculates their final grammar by taking the mode of the posterior distribution (MAP). It can be shown that this value is given by

$$\arg\max p(\mathbf{h} \mid \mathbf{D}) = (\beta \cdot \mathbf{h^0} + |D| \cdot \mathbf{d}) / (\beta + |D|)$$

Thus, the output of this learning rule is a probability vector **h** that represents the estimated probability of each of the six possible IPS's for that concept. As can be seen from the equation above, this probability vector is an average of the expected behavior $\mathbf{h^0}$ and the observed data **d**, weighted by β and the amount of observed data |D|, respectively.

Our approach entails that from the perspective of a language learner, gaps are not qualitatively distinct from productive forms. Instead, 1sg non-past gaps represent one extreme of a range of probabilities that the first person singular will be produced. In this sense, "gaps" represent an artificial boundary which we place on a gradient structure for the purpose of evaluating our model.

The contrast between our learning model and the account of gaps presented in Albright (2003) merits emphasis at this point. Generally speaking, learning a word involves at least two tasks: learning how to generate the appropriate phonological form for a given concept and inflectional property set, and learning the probability that a concept and inflectional property set will be produced at all. Albright's model focuses on the former aspect; our model focuses on the latter. In short, our account of gaps lies in the likelihood of a concept-IPS pair being expressed, not in the likelihood of a form being expressed.

3.5 Production model

We model language production as sampling from the probability distribution that is the output of the learning rule.

3.6 Seeding the model

The input to the first generation was sampled from the verbs identified in the corpus search (see 2.2). Each input set contained 1,000,000 tokens, which was the average amount of input for agents in all succeeding generations. This made the first

[8] In Russian, the stem-final consonant is important for morphological behavior generally. Any successful Russian learner would have to extract the generalization, completely apart from the issues posed by gaps.

generation's input as similar as possible to the input of all succeeding generations.

3.7 Parameter space in the three scenarios

In our model we manipulate two parameters – the strength of the analogical force on a target concept during the learning process (β), and the number of concepts which create the analogical force (κ), taken randomly from known concepts.

As discussed above, we model three scenarios. In the first scenario, there is no grammar learning, so there is only one condition (β = 0). For the second and third scenarios, we run the model with four values for β, ranging from weak to strong analogical force (0.05, 0.25, 1.25, 6.25), and two values for κ, representing influence from a small or large set of other words (30, 300).

4 Evaluating the output of the model

We evaluate the output of our model against the following question: How well do gaps persist?

We count as gaps any forms meeting the criteria outlined in 2.2 above, tabulating the number of gaps which exist for only one generation, for two total generations, etc. We define τ as the expected number of generations (out of 10) that a given concept meets the gap criteria. Thus, τ represents a gap's "life expectancy" (see Figure 1).

We found that this distribution is exponential – there are few gaps that exist for all ten generations, and lots of gaps that exist for only one, so we calculated τ with a log linear regression. Each value reported is an average over 10 runs.

As discussed above, our goal was to discover whether the model can exhibit the same qualitative behavior as the historical development of Russian gaps. Persistence across a handful of generations (so far) and spread to a limited number of similar forms should be reflected by a non-negligible τ.

5 Results

In this section we present the results of our model under the scenarios and parameter settings above.

Remember that in the first scenario there is no grammar learning. This run of the model represents the baseline condition – completely word-specific knowledge. Sampling results in random walks on form frequencies, so once a word form disappears it never returns to the sample. Word-specific learning is thus sufficient for the perseverance of existing paradigmatic gaps and the creation of new ones. With no analogical pressure, gaps are robustly attested (τ = 6.32). However, the new gaps are not restricted to the 1sg, and under this scenario, learners are unable to generalize to a novel pairing of lexeme + IPS.

The second scenario presents a more complicated picture. As shown in Table 3, as analogical pressure (β) increases, gap life expectancy (τ) decreases. In other words, high analogical pressure quickly eliminates atypical frequency distributions, such as those exhibited by gaps. The runs with low values of β are particularly interesting because they represent an approximate balance between elimination of gaps as a general behavior, and the short-term persistence and even spread of gaps due to sampling artifacts and the influence of existing gaps. Thus, although the limit behavior is for gaps to disappear, this scenario retains the ability to explain persistence of gaps due to word-specific learning when there is weak analogical force.

At the same time, the facts of Russian differ from the behavior of the model in that the Russian gaps spread to morphophonologically similar forms, not random ones. The third version of our model weights the analogical strength of different concepts based upon morphophonological similarity to the target.

κ	**β**	**τ (random)**	**τ (phono.)**
--	0	6.32	
30	0.05	4.95	5.77
30	0.25	3.46	5.28
30	1.25	1.91	3.07
30	6.25	2.59	1.87
300	0.05	4.97	5.99
300	0.25	3.72	5.14
300	1.25	1.90	3.10
300	6.25	2.62	1.84

Table 3. Life expectancy of gaps, as a function of the strength of random analogical forces

Under these conditions we get two interesting results, presented in Table 3 above. First, gaps persist slightly better overall in scenario 3 than in

scenario 2 for all levels of κ and β.[9] Compare the τ values for random analogical force (scenario 2) with the τ values for morphophonologically weighted analogical force (scenario 3).

Second, strength of analogical force matters. When there is weak analogical pressure, weighting for morphophonological similarity has little effect on the persistence and spread of gaps. However, when there is relatively strong analogical pressure, morphophonological similarity helps atypical frequency distributions to persist, as shown in Figure 1. This results from the fact that there is a prototypicality effect for gaps. Since dental stems are more likely to be gaps, incorporating sensitivity to stem shape causes the analogical pressure on target dental stems to be relatively stronger from words that are gaps. Correspondingly, the analogical pressure on non-dental stems is relatively stronger from words that are not gaps. The prototypical stem shape for a gap is thereby perpetuated and gaps spread to new dental stems.

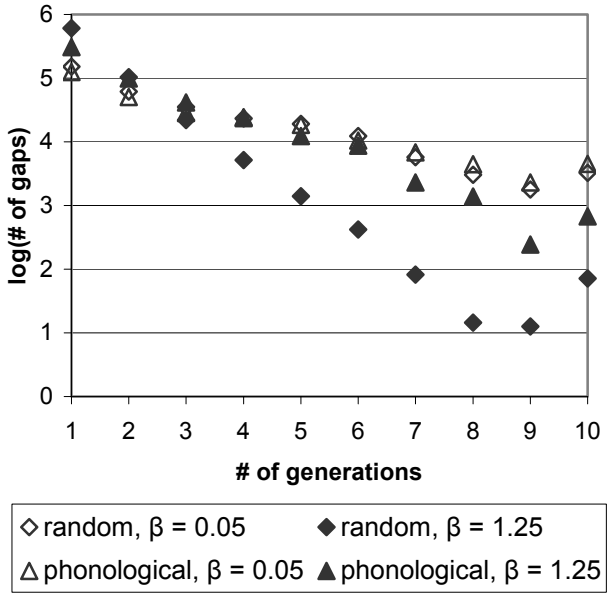

Figure 1. Gap life expectancy (β=0.05, κ=30)

[9] The apparent increase in gap half-life when β=6.25 is an artifact of the regression model. There were a few well-entrenched gaps whose high lemma frequency enables them to resist even high levels of analogical pressure over 10 generations. These data points skewed the regression, as shown by a much lower R^2 (0.5 vs. 0.85 or higher for all the other conditions).

6 Discussion

In conclusion, our model has in many respects succeeded in getting gaps to perpetuate and spread. With word-specific learning alone, well-entrenched gaps can be maintained across multiple generations. More significantly, weak analogical pressure, especially if weighted for morpho-phonological similarity, results in the perseverance and short-term growth of gaps. This is essentially the historical pattern of the Russian verbal gaps.

These results highlight several issues regarding both the nature of paradigmatic gaps and the structure of inflectional systems generally.

We claim that it is not necessary to posit an irreconcilable conflict in the generation of inflected forms in order to account for gaps. Remember that in our model, agents face no conflict in terms of which form to produce – there is only one possibility. Yet the gaps persist in part because of analogical pressure from existing gaps. Albright (2003) himself is agnostic on the issue of whether form-based competition is *necessary* for the existence and persistence of gaps, but Hudson (2000), among others, claims that gaps could not exist in the absence of it. We have presented evidence that this claim is unfounded.

But why would someone assume that grammar competition is necessary? Hudson's claim arises from a confusion of two issues. Discussing the English paradigmatic gap *amn't*, Hudson states that "a simple application of [the usage-based learning] principle would be to say that the gap exists simply because nobody says *amn't*... But this explanation is too simple... There are many inflected words that may never have been uttered, but which we can nevertheless imagine ourselves using, given the need; we generate them by generalization" (Hudson 2000:300). By his logic, there must therefore be some source of grammar conflict which prevents speakers from generalizing.

However, there is a substantial difference between having no information about a word, and having information about the non-usage of a word. We do not dispute learners' ability to generalize. We only claim that information of non-usage is sufficient to block such generalizations. When confronted with a new word, speakers will happily generalize a word form, but this is not the same task that they perform when faced with gaps.

The perseverance of gaps in the absence of form-based competition shows that a different, non-form level of representation is at issue. Generating inflectional morphology involves at least two different types of knowledge: knowledge about the appropriate word form to express a given concept and IPS on the one hand, and knowledge of how often that concept and IPS is expressed on the other. The emergence of paradigmatic gaps may be closely tied to the first type of knowledge, but the Russian gaps, at least, persist because of the second type of knowledge. We therefore propose that morphology may be defective at the morphosyntactic level.

This returns us to the question that we began this paper with – how paradigmatic gaps can persist in light of the overwhelming productivity of inflectional morphology. Our model suggests that the apparent contradiction is, at least in some cases, illusory. Productivity refers to the likelihood of a given inflectional pattern applying to a given combination of stem and IPS. Our account is based in the likelihood of the stem and inflectional property set being expressed at all, regardless of the form. In short, the Russian paradigmatic gaps represent an issue which is orthogonal to productivity. The two issues are easily confused, however. An unusual frequency distribution can make it *appear* that there is in fact a problem at the level of form, even when there may not be.

Finally, our simulations raise the question of whether the 1sg non-past gaps in Russian will persist in the language in the long term. In our model, analogical forces delay convergence to the mean, but the limit behavior is that all gaps disappear. Although there is evidence in Russian that words can develop new gaps, we do not know with any great accuracy whether the set of gaps is currently expanding, contracting, or approximately stable. Our model predicts that in the long run, the gaps will disappear under general analogical pressure. However, another possibility is that our model includes only enough factors (e.g., morphophonological similarity) to approximate the short-term influences on the Russian gaps and that we would need more factors, such as semantics, to successfully model their long-term development. This remains an open question.

Substring-Based Transliteration

Abstract

Transliteration is the task of converting a word from one alphabetic script to another. We present a novel, substring-based approach to transliteration, inspired by phrase-based models of machine translation. We investigate two implementations of substring-based transliteration: a dynamic programming algorithm, and a finite-state transducer. We show that our substring-based transducer not only outperforms a state-of-the-art letter-based approach by a significant margin, but is also orders of magnitude faster.

1 Introduction

A significant proportion of out-of-vocabulary words in machine translation models or cross language information retrieval systems are named entities. If the languages are written in different scripts, these names must be transliterated. Transliteration is the task of converting a word from one writing script to another, usually based on the phonetics of the original word. If the target language contains all the phonemes used in the source language, the transliteration is straightforward. For example, the Arabic transliteration of *Amanda* is أماندا, which is essentially pronounced in the same way. However, if some of the sounds are missing in the target language, they are generally mapped to the most phonetically similar letter. For example, the sound [p] in the name *Paul*, does not exist in Arabic, and the phonotactic constraints of Arabic disallow the sound [ɑ] in this context, so the word is transliterated as بول, pronounced [bul].

The information loss inherent in the process of transliteration makes back-transliteration, which is the restoration of a previously transliterated word, a particularly difficult task. Any phonetically reasonable forward transliteration is essentially correct, although occasionally there is a standard transliteration (e.g. *Omar Sharif*). In the original script, however, there is usually only a single correct form. For example, both *Naguib Mahfouz* and *Najib Mahfuz* are reasonable transliterations of نجيب محفوظ, but *Tsharlz Dykens* is certainly not acceptable if one is referring to the author of *Oliver Twist*.

In a statistical approach to machine transliteration, given a foreign word F, we are interested in finding the English word $\hat{E}$ that maximizes $P(E|F)$. Using Bayes' rule, and keeping in mind that F is constant, we can formulate the task as follows:

$$\hat{E} = \arg\max_E \frac{P(F|E)P(E)}{P(F)}$$

$$= \arg\max_E P(F|E)P(E)$$

This is known as the noisy channel approach to machine transliteration, which splits the task into two parts. The language model provides an estimate of the probability $P(E)$ of an English word, while the transliteration model provides an estimate of the probability $P(F|E)$ of a foreign word being a transliteration of an English word. The probabilities assigned by the transliteration and language models counterbalance each other. For example, simply concatenating the most common mapping for each letter in the Arabic string مايكل, produces the string *maykl*, which is barely pronounceable. In order to generate the correct $Michael$, a model needs

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 944–951,
Prague, Czech Republic, June 2007.

to know the relatively rare letter relationships *ch*/ﭺ and *ae*/ϵ, and to balance their unlikelihood against the probability of the correct transliteration being an actual English name.

The search for the optimal English transliteration $\hat{E}$ for a given foreign name F is referred to as decoding. An efficient approach to decoding is dynamic programming, in which solutions to subproblems are maintained in a table and used to build up the global solution in a bottom-up approach. Dynamic programming approaches are optimal as long as the dynamic programming invariant assumption holds. This assumption states that if the optimal path through a graph happens to go through state *q*, then this optimal path must include the best path up to and including *q*. Thus, once an optimal path to state *q* is found, all other paths to *q* can be eliminated from the search. The validity of this assumption depends on the state space used to define the model. Typically, for problems related to word comparison, a dynamic programming approach will define states as positions in the source and target words. As will be shown later, however, not all models can be represented with such a state space.

The phrase-based approach developed for statistical machine translation (Koehn et al., 2003) is designed to overcome the restrictions on many-to-many mappings in word-based translation models. This approach is based on learning correspondences between phrases, rather than words. Phrases are generated on the basis of a word-to-word alignment, with the constraint that no words within the phrase pair are linked to words outside the phrase pair.

In this paper, we propose to apply phrase-based translation methods to the task of machine transliteration, in an approach we refer to as substring-based transliteration. We consider two implementations of these models. The first is an adaptation of the monotone search algorithm outlined in (Zens and Ney, 2004).The second encodes the substring-based transliteration model as a transducer. The results of experiments on Arabic-to-English transliteration show that the substring-based transducer outperforms a state-of-the-art letter-based transducer, while at the same time being orders of magnitude smaller and faster.

The remainder of the paper is organized as follows. Section 2 discusses previous approaches to machine transliteration. Section 3 presents the letter-based transducer approach to Arabic-English transliteration proposed in (Al-Onaizan and Knight, 2002), which we use as the main point of comparison for our substring-based models. Section 4 presents our substring-based approaches to transliteration. In Section 5, we outline the experiments used to evaluate the models and present their results. Finally, Section 6 contains our overall impressions and conclusions.

2 Previous Work

Arababi et al. (1994) propose to model forward transliteration through a combination of neural net and expert systems. Their main task was to vowelize the Arabic names as a preprocessing step for transliteration. Their method is Arabic-specific and requires that the Arabic names have a regular pattern of vowelization.

Knight and Graehl (1998) model the transliteration of Japanese syllabic *katakana* script into English with a sequence of finite-state transducers. After performing a conversion of the English and katakana sequences to their phonetic representations, the correspondences between the English and Japanese phonemes are learned with the expectation maximization (EM) algorithm. Stalls and Knight (1998) adapt this approach to Arabic, with the modification that the English phonemes are mapped directly to Arabic letters. Al-Onaizan and Knight (2002) find that a model mapping directly from English to Arabic letters outperforms the phoneme-to-letter model.

AbdulJaleel and Larkey (2003) model forward transliteration from Arabic to English by treating the words as sentences and using a statistical word alignment model to align the letters. They select common English n-grams based on cases when the alignment links an Arabic letter to several English letters, and consider these n-grams as single letters for the purpose of training. The English transliterations are produced using probabilities, learned from the training data, for the mappings between Arabic letters and English letters/n-grams.

Li et al. (2004) propose a letter-to-letter n-gram transliteration model for Chinese-English transliteration in an attempt to allow for the encoding of more

contextual information. The model isolates individual mapping operations between training pairs, and then learns n-gram probabilities for sequences of these mapping operations. Ekbal et al. (2006) adapt this model to the transliteration of names from Bengali to English.

3 Letter-based Transliteration

The main point of comparison for the evaluation of our substring-based models of transliteration is the letter-based transducer proposed by (Al-Onaizan and Knight, 2002). Their model is a composition of a transliteration transducer and a language transducer. Mappings in the transliteration transducer are defined between 1-3 English letters and 0-2 Arabic letters, and their probabilities are learned by EM. The transliteration transducer is split into three states to allow mapping probabilities to be learned separately for letters at the beginning, middle and end of a word. Unlike the transducers proposed in (Stalls and Knight, 1998) and (Knight and Graehl, 1998) no attempt is made to model the pronunciation of words. Although names are generally transliterated based on how they sound, not how they look, the letter-phoneme conversion itself is problematic as it is not a trivial task. Many transliterated words are proper names, whose pronunciation rules may vary depending on the language of origin (Li et al., 2004). For example, ch is generally pronounced as either [ʧ] or [k] in English names, but as [ʃ] in French names.

The language model is implemented as a finite state acceptor using a combination of word unigram and letter trigram probabilities. Essentially, the word unigram model acts as a probabilistic lookup table, allowing for words seen in the training data to be produced with high accuracy, while the letter trigram probabilities are used model words not seen in the training data.

4 Substring-based Transliteration

Our substring-based transliteration approach is an adaptation of phrase-based models of machine translation to the domain of transliteration. In particular, our methods are inspired by the monotone search algorithm proposed in (Zens and Ney, 2004). We introduce two models of substring-based transliteration: the Viterbi substring decoder and the substring-based transducer. Table 1 presents a comparison of the substring-based models to the letter-based model discussed in Section 3.

4.1 The Monotone Search Algorithm

Zens and Ney (2004) propose a linear-time decoding algorithm for phrase-based machine translation. The algorithm requires that the translation of phrases be sequential, disallowing any phrase reordering in the translation.

Starting from a word-based alignment for each pair of sentences, the training for the algorithm accepts all contiguous bilingual phrase pairs (up to a predetermined maximum length) whose words are only aligned with each other (Koehn et al., 2003). The probabilities $P(\tilde{f}|\tilde{e})$ for each foreign phrase $\tilde{f}$ and English phrase $\tilde{e}$ are calculated on the basis of counts gleaned from a bitext. Since the counting process is much simpler than trying to learn the phrases with EM, the maximum phrase length can be made arbitrarily long with minimal jumps in complexity. This allows the model to actually encode contextual information into the translation model instead of leaving it completely to the language model. There are no null (ϵ) phrases so the model does not handle insertions or deletions explicitly. They can be handled implicitly, however, by including inserted or deleted words as members of a larger phrase.

Decoding in the monotone search algorithm is performed with a Viterbi dynamic programming approach. For a foreign sentence of length J and a phrase length maximum of M, a table is filled with a row j for each position in the input foreign sentence, representing a translation sequence ending at that foreign word, and each column e represents possible final English words for that translation sequence. Each entry in the table Q is filled according to the following recursion:

$$\begin{aligned} Q(0,\$) &= 1 \\ Q(j,e) &= \max_{e',\tilde{e},\tilde{f}} P(\tilde{f}|\tilde{e})P(\tilde{e}|e')Q(j',e') \\ Q(J+1,\$) &= \max_{e'} Q(J,e')P(\$|e') \end{aligned}$$

where $\tilde{f}$ is a foreign phrase beginning at $j'+1$, ending at j and consisting of up to M words. The '$' symbol is the sentence boundary marker.

	Letter Transducer	Viterbi Substring	Substring Transducer
Model Type	Transducer	Dynamic Programming	Transducer
Transliteration Model	Letter	Substring	Substring
Language Model	Word/Letter	Substring/Letter	Word/Letter
Null Symbols	Yes	No	No
Alignments	All	Most Probable	Most Probable

Table 1: Comparison of statistical transliteration models.

In the above recursion, the language model is represented as $P(\tilde{e}|e')$, the probability of the English phrase given the previous English word. Because of data sparseness issues in the context of word phrases, the actual implementation approximates this probability using word n-grams.

4.2 Viterbi Substring Decoder

We propose to adapt the monotone search algorithm to the domain of transliteration by substituting letters and substrings for the words and phrases of the original model. There are, in fact, strong indications that the monotone search algorithm is better suited to transliteration than it is to translation. Unlike machine translation, where the constraint on reordering required by monotone search is frequently violated, transliteration is an inherently sequential process. Also, the sparsity issue in training the language model is much less pronounced, allowing us to model $P(\tilde{e}|e')$ directly.

In order to train the model, we extract the one-to-one Viterbi alignment of a training pair from a stochastic transducer based on the model outlined in (Ristad and Yianilos, 1998). Substrings are then generated by iteratively appending adjacent links or unlinked letters to the one-to-one links of the alignment. For example, assuming a maximum substring length of 2, the <*r*, ر> link in the alignment presented in Figure 1 would participate in the following substring pairs: <*r*, ر>, <*ur*, ر>, and <*ra*, را>.

The fact that the Viterbi substring decoder employs a dynamic programming search through the source/target letter state space described in Section 1 renders the use of a word unigram language model impossible. This is due to the fact that alternate paths to a given source/target letter pair are being eliminated as the search proceeds. For example, suppose the Viterbi substring decoder were given the

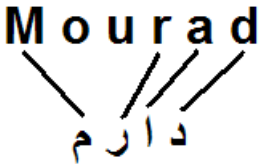

Figure 1: A one-to-one alignment of *Mourad* and مراد. For clarity the Arabic name is written left to right.

Arabic string كريم, and there are two valid English names in the language model, *Karim* (the correct transliteration of the input) and *Kristine* (the Arabic transliteration of which would be كرستين). The optimal path up to the second letter might go through <ك,*k*>, <ر,*r*>. At this point, it is transliterating into the name *Kristine*, but as soon as it hits the third letter (ي), it is clear that this is the incorrect choice. In order to recover from the error, the search would have to backtrack to the beginning and return to state <ر,*r*> from a different path, but this is an impossibility since all other paths to that state have been eliminated from the search.

4.3 Substring-based Transducer

The major advantage the letter-based transducer presented in Section 3 has over the Viterbi substring decoder is its word unigram language model, which allows it to reproduce words seen in the training data with high accuracy. On the other hand, the Viterbi substring decoder is able to encode contextual information in the transliteration model because of its ability to consider larger many-to-many mappings. In a novel approach presented here, we propose a substring-based transducer that draws on both advantages. The substring transliteration model learned for the Viterbi substring decoder is encoded as a transducer, thus allowing it to use a word uni-

gram language model. Our model, which we refer to as the substring-based transducer, has several advantages over the previously presented models.

- The substring-based transducer can be composed with a word unigram language model, allowing it to transliterate names seen in training for the language model with greater accuracy.
- Longer many-to-many mappings enable the transducer to encode contextual information into the transliteration model. Compared to the letter-based transducer, it allows for the generation of longer well-formed substrings (or potentially even entire words).
- The letter-based transducer considers all possible alignments of the training examples, meaning that many low-probability mappings are encoded into the model. This issue is even more pronounced in cases where the desired transliteration is not in the word unigram model, and it is guided by the weaker letter trigram model. The substring-based transducer can eliminate many of these low-probability mappings because of its commitment to a single high-probability one-to-one alignment during training.
- A major computational advantage this model has over the letter-based transducer is the fact that null characters (ϵ) are not encoded explicitly. Since the Arabic input to the letter-based transducer could contain an arbitrary number of nulls, the potential number of output strings from the transliteration transducer is infinite. Thus, the composition with the language transducer must be done in such a way that there is a valid path for all of the strings output by the transliteration transducer that have a positive probability in the language model. This leads to prohibitively large transducers. On the other hand, the substring-based transducer handles nulls implicitly (e.g. the mapping *ke*:ك implicitly represents *e*:ϵ after a *k*), so the transducer itself is not required to deal with them.

5 Experiments

In this section, we describe the evaluation of our models on the task of Arabic-to-English transliteration.

5.1 Data

For our experiments, we required bilingual name pairs for testing and development data, as well as for the training of the transliteration models. To train the language models, we simply needed a list of English names. Bilingual data was extracted from the Arabic-English Parallel News part 1 (approx. 2.5M words) and the Arabic Treebank Part 1-10k word English Translation. Both bitexts contain Arabic news articles and their English translations. The English name list for the language model training was extracted from the English-Arabic Treebank v1.0 (approx. 52k words)[1]. The language model training set consisted of all words labeled as proper names in this corpus along with all the English names in the transliteration training set. Any names in any of the data sets that consisted of multiple words (e.g. first name/last name pairs) were split and considered individually. Training data for the transliteration model consisted of 2844 English-Arabic pairs. The language model was trained on a separate set of 10991 (4494 unique) English names. The final test set of 300 English-Arabic transliteration pairs contained no overlap with the set that was used to induce the transliteration models.

5.2 Evaluation Methodology

For each of the 300 transliteration pairs in the test set, the name written in Arabic served as input to the models, while its English counterpart was considered a gold standard transliteration for the purpose of evaluation. Two separate tests were performed on the test set. In the first, the 300 English words in the test set were added to the training data for the language models (the *seen* test), while in the second, all English words in the test set were removed from the language model's training data (the *unseen* test). Both tests were run on the same set of words to ensure that variations in performance for *seen* and *unseen* words were solely due to whether or not they appear in the language model (and not, for example, their language of origin). The *seen* test is similar to tests run in (Knight and Graehl, 1998) and (Stalls and Knight, 1998) where the models could not produce any words not included in the language

[1] All corpora are distributed by the Linguistic Data Consortium. Despite the name, the English-Arabic Treebank v1.0 contains only English data.

model training data. The models were evaluated on the *seen* test set in terms of exact matches to the gold standard. Because the task of generating transliterations for the *unseen* test set is much more difficult, exact match accuracy will not provide a meaningful metric for comparison. Thus, a softer measure of performance was required to indicate how close the generated transliterations are to the gold standard. We used Levenshtein distance: the number of insertions, deletions and substitutions required to convert one string into another. We present the results separately for names of Arabic origin and for those of non-Arabic origin.

We also performed a third test on words that appear in both the transliteration and language model training data. This test was not indicative of the overall strength of the models but was meant to give a sense of how much each model depends on its language model versus its transliteration model.

5.3 Setup

Five approaches were evaluated on the Arabic-English transliteration task.

- **Baseline:** As a baseline for our experiments, we used a simple deterministic mapping algorithm which maps Arabic letters to the most likely letter or sequence of letters in English.
- **Letter-based Transducer:** Mapping probabilities were learned by running the forward-backward algorithm until convergence. The language model is a combination of word unigram and letter trigram models and selects a word unigram or letter trigram modeling of the English word depending on whichever one assigns the highest probability. The letter-based transducer was implemented in Carmel[2].
- **Viterbi Substring Decoder:** We experimented with maximum substring lengths between 3 and 10 on the development set, and found that a maximum length of 6 was optimal.
- **Substring-based Transducer:** The substring-based transducer was also implemented in Carmel. We found that this model worked best with a maximum substring length of 4.

[2]Carmel is a finite-state transducer package written by Jonathan Graehl. It is available at http://www.isi.edu/licensed-sw/carmel/.

Method	Arabic	Non-Arabic	All
Baseline	1.9	2.1	2.0
Letter trans.	45.9	64.3	54.7
Viterbi substring	15.9	30.1	22.7
Substring trans.	**59.9**	**81.1**	**70.0**
Human	33.1	40.6	36.7

Method	Arabic	Non-Arabic	All
Baseline	2.32	2.80	2.55
Letter trans.	2.46	2.63	2.54
Viterbi substring	**1.90**	**2.13**	**2.01**
Substring trans.	1.92	2.41	2.16
Human	1.24	1.42	1.33

Table 3: Average Levenshtein distance on the *unseen* test set for various methods.

- **Human:** For the purpose of comparison, we allowed an independent human subject (fluent in Arabic, but a native speaker of English) to perform the same task. The subject was asked to transliterate the Arabic words in the test set without any additional context. No additional resources or collaboration were allowed.

5.4 Results on the Test Set

Table 2 presents the word accuracy performance of each transliterator when the test set is available to the language models. Table 3 shows the average Levenshtein distance results when the test set is unavailable to the language models. Exact match performance by the automated approaches on the *unseen* set did not exceed 10.3% (achieved by the Viterbi substring decoder). Results on the *seen* test suggest that non-Arabic words (back transliterations) are easier to transliterate exactly, while results for the *unseen* test suggest that errors on Arabic words (forward transliterations) tend to be closer to the gold standard.

Overall, our substring-based transducer clearly outperforms the letter-based transducer. Its performance is better in both tests, but its advantage is particularly pronounced on words it has seen in the training data for the language model (the task

	Arabic	LBT	SBT	Correct
1	عثمان	Uthman	Uthman	Othman
2	اشرف	Asharf	Asharf	Ashraf
3	رفعت	Rafeet	Arafat	Refaat
4	اسامة	Istamaday	Asuma	Usama
5	ايمان	Erdman	Aliman	Iman
6	ووتش	Wortch	Watch	Watch
7	ميلز	Mellis	Mills	Mills
8	فيراري	February	Firari	Ferrari

Table 4: A sample of the errors made by the letter-based (LBT) and segment-based (SBT) transducers.

for which the letter-based transducer was originally designed). Since both transducers use exactly the same language model, the fact that the substring-based transducer outperforms the letter-based transducer indicates that it learns a stronger transliteration model.

The Viterbi substring decoder seems to struggle when it comes to recreating words seen the language training data, as evidenced by its weak performance on the *seen* test. Obviously, its substring/letter bigram language model is no match for the word unigram model used by the transducers on this task. On the other hand, its stronger performance on the *unseen* test set suggests that its language model is stronger than the letter trigram used by the transducers when it comes to generating completely novel words.

A sample of the errors made by the letter- and substring-based transducers is presented in Table 4. In general, when both models err, the substring-based transducer tends toward more phonetically reasonable choices. The most common type of error is simply correct alternate English spellings of an Arabic name (error 1). Error 2 is an example of a learned mapping being misplaced (the deleted *a*). Error 3 indicates that the letter-based transducer is able to avoid these misplaced mappings at the beginning or end of a word because of its three-state transliteration transducer (i.e. it learns not to allow vowel deletions at the beginning of a word). Errors 4 and 5 are cases where the letter-based transducer produced particularly awkward transliterations. Errors 6 and 7 are names that actually appear in the word unigram model but were missed by the letter-based transducer, while error 8 is an example of the letter-based transducer incorrectly choosing a name from the word unigram model. As discussed in Section 4.3, this is likely due to mappings learned from low-probability alignments.

Method	Exact match	Avg Lev.
Letter transducer	81.2	0.46
Viterbi substring	83.2	0.24
Substring transducer	**94.4**	**0.09**

Table 5: Results for testing on the transliteration training set.

5.5 Results on the Training Set

The substring-based approaches encode a great deal of contextual information into the transliteration model. In order to assess how much the performance of each approach depends on its language model versus its transliteration model, we tested the three statistical models on the set of 2844 names seen in both the transliteration and language model training. The results of this experiment are presented in Table 5. The Viterbi substring decoder receives the biggest boost, outperforming the letter-based transducer, which indicates that its strength lies mainly in its transliteration modeling as opposed to its language modeling. The substring-based transducer, however, still outperforms it by a large margin, achieving near-perfect results. Most of the remaining errors can be attributed to names with alternate correct spellings in English.

The results also suggest that the substring-based transducer practically subsumes a naive "lookup table" approach. Although the accuracy achieved is less than 100%, the substring-based transducer has the great advantage of being able to handle noise in the input. In other words, if the spelling of an input word does not match an Arabic word from the training data, a lookup table will generate nothing, while the substring-based transducer could still search for the correct transliteration.

5.6 Computational Considerations

Another point of comparison between the models is complexity. The letter-based transducer encodes 56144 mappings while the substring-based transducer encodes 13948, but as shown in Table 6, once

Method	Size (states/arcs)
Letter transducer	86309/547184
Substring transducer	759/2131

Table 6: Transducer sizes for composition with the word حلمي (*Helmy*).

Method	Time
Letter transducer	5h52min
Viterbi substring	3 sec
Substring transducer	11 sec

Table 7: Running times for the 300 word test set.

the transducers are fully composed, the difference becomes even more pronounced. As discussed in Section 4.3, the reason for the size explosion factor in the letter-based transducer is the possibility of null characters in the input word.

The running times for the statistical approaches on the 300 word test set are presented in Table 7. The huge computational advantage of the substring-based approach makes it a much more attractive option for any real-world application. Tests were performed on an AMD Athlon 64 3500+ machine with 2GB of memory running Red Hat Enterprise Linux release 4.

6 Conclusion

In this paper, we presented a new substring-based approach to modeling transliteration inspired by phrase-based models of machine translation. We tested both dynamic programming and finite-state transducer implementations, the latter of which enabled us to use a word unigram language model to improve the accuracy of generated transliterations. The results of evaluation on the task of Arabic-English transliteration indicate that the substring-based approach not only improves performance over a state-of-the-art letter-based model, but also leads to major gains in efficiency. Since no language-specific information was encoded directly into the models, they can also be used for transliteration between other language pairs.

In the future, we plan to consider more complex language models in order to improve the results on unseen words, which should certainly be feasible for the substring-based transducer because of its efficient memory usage. Another feature of the substring-based transducer that we have not yet explored is its ability to easily produce an n-best list of transliterations. We plan to investigate whether using methods like discriminative reranking (Och and Ney, 2002) on such an n-best list could improve performance.

Pipeline Iteration

Abstract

This paper presents pipeline iteration, an approach that uses output from later stages of a pipeline to constrain earlier stages of the same pipeline. We demonstrate significant improvements in a state-of-the-art PCFG parsing pipeline using base-phrase constraints, derived either from later stages of the parsing pipeline or from a finite-state shallow parser. The best performance is achieved by reranking the union of unconstrained parses and relatively heavily-constrained parses.

1 Introduction

A "pipeline" system consists of a sequence of processing stages such that the output from one stage provides the input to the next. Each stage in such a pipeline identifies a subset of the possible solutions, and later stages are constrained to find solutions within that subset. For example, a part-of-speech tagger could constrain a "base phrase" chunker (Ratnaparkhi, 1999), or the n-best output of a parser could constrain a reranker (Charniak and Johnson, 2005). A pipeline is typically used to reduce search complexity for rich models used in later stages, usually at the risk that the best solutions may be pruned in early stages.

Pipeline systems are ubiquitous in natural language processing, used not only in parsing (Ratnaparkhi, 1999; Charniak, 2000), but also machine translation (Och and Ney, 2003) and speech recognition (Fiscus, 1997; Goel et al., 2000), among others. Despite the widespread use of pipelines, they have been understudied, with very little work on general techniques for designing and improving pipeline systems (although *cf.* Finkel et al. (2006)). This paper presents one such general technique, here applied to stochastic parsing, whereby output from later stages of a pipeline is used to constrain earlier stages of the same pipeline. To our knowledge, this is the first time such a pipeline architecture has been proposed.

It may seem surprising that later stages of a pipeline, already constrained to be consistent with the output of earlier stages, can profitably inform the earlier stages in a second pass. However, the richer models used in later stages of a pipeline provide a better distribution over the subset of possible solutions produced by the early stages, effectively resolving some of the ambiguities that account for much of the original variation. If an earlier stage is then constrained in a second pass not to vary with respect to these resolved ambiguities, it will be forced to find other variations, which may include better solutions than were originally provided.

To give a rough illustration, consider the Venn diagram in Fig. 1(i). Set A represents the original subset of possible solutions passed along by the earlier stage, and the dark shaded region represents high-probability solutions according to later stages. If some constraints are then extracted from these high-probability solutions, defining a subset of solutions (S) that rule out some of A, the early stage will be forced to produce a different set (B). Constraints derived from later stages of the pipeline focus the search in an area believed to contain high-quality candidates.

Another scenario is to use a different model altogether to constrain the pipeline. In this scenario,

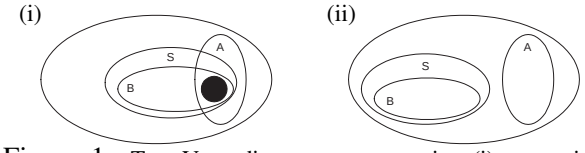

Figure 1: Two Venn diagrams, representing (i) constraints derived from later stages of an iterated pipelined system; and (ii) constraints derived from a different model.

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 952–959,
Prague, Czech Republic, June 2007.

represented in Fig. 1(ii), the other model constrains the early stage to be consistent with some subset of solutions (S), which may be largely or completely disjoint from the original set A. Again, a different set (B) results, which may include better results than A. Whereas when iterating we are guaranteed that the new subset S will overlap at least partially with the original subset A, that is not the case when making use of constraints from a separately trained model.

In this paper, we investigate pipeline iteration within the context of the Charniak and Johnson (2005) parsing pipeline, by constraining parses to be consistent with a base-phrase tree. We derive these base-phrase constraints from three sources: the reranking stage of the parsing pipeline; a finite-state shallow parser (Hollingshead et al., 2005); and a combination of the output from these two sources. We compare the relative performance of these three sources and find the best performance improvements using constraints derived from a weighted combination of shallow parser output and reranker output.

The Charniak parsing pipeline has been extensively studied over the past decade, with a number of papers focused on improving early stages of the pipeline (Charniak et al., 1998; Caraballo and Charniak, 1998; Blaheta and Charniak, 1999; Hall and Johnson, 2004; Charniak et al., 2006) as well as many focused on optimizing final parse accuracy (Charniak, 2000; Charniak and Johnson, 2005; McClosky et al., 2006). This focus on optimization has made system improvements very difficult to achieve; yet our relatively simple architecture yields statistically significant improvements, making pipeline iteration a promising approach for other tasks.

2 Approach

Our approach uses the Charniak state-of-the-art parsing pipeline. The well-known Charniak (2000) coarse-to-fine parser is a two-stage parsing pipeline, in which the first stage uses a vanilla PCFG to populate a chart of parse constituents. The second stage, constrained to only those items in the first-stage chart, uses a refined grammar to generate an n-best list of parse candidates. Charniak and Johnson (2005) extended this pipeline with a discriminative maximum entropy model to rerank the n-best parse candidates, deriving a significant benefit from the richer model employed by the reranker.

For our experiments, we modified the parser[1] to allow us to optionally provide base-phrase trees to constrain the first stage of parsing.

Parser		Base Phrases	Shallow Phrases
Charniak	parser-best	91.9	94.4
	reranker-best	92.8	94.8
Finite-state shallow parser		91.7	94.3

Table 1: F-scores on WSJ section 24 of output from two parsers on the similar tasks of base-phrase parsing and shallow-phrase parsing. For evaluation, base and shallow phrases are extracted from the Charniak/Johnson full-parse output.

2.1 Base Phrases

Following Ratnaparkhi (1999), we define a *base phrase* as any parse node with only preterminal children. Unlike the shallow phrases defined for the CoNLL-2000 Shared Task (Tjong Kim Sang and Buchholz, 2000), base phrases correspond directly to constituents that appear in full parses, and hence can provide a straightforward constraint on edges within a chart parser. In contrast, shallow phrases collapse certain non-constituents—such as auxiliary chains—into a single phrase, and hence are not directly applicable as constraints on a chart parser.

We have two methods for deriving base-phrase annotations for a string. First, we trained a finite-state shallow parser on base phrases extracted from the Penn Wall St. Journal (WSJ) Treebank (Marcus et al., 1993). The treebank trees are pre-processed identically to the procedure for training the Charniak parser, e.g., empty nodes and function tags are removed. The shallow parser is trained using the perceptron algorithm, with a feature set nearly identical to that from Sha and Pereira (2003), and achieves comparable performance to that paper. See Hollingshead et al. (2005) for more details. Second, base phrases can be extracted from the full-parse output of the Charniak and Johnson (2005) reranker, via a simple script to extract nodes with only preterminal children.

Table 1 shows these systems' bracketing accuracy on both the base-phrase and shallow parsing tasks for WSJ section 24; each system was trained on WSJ sections 02-21. From this table we can see that base phrases are substantially more difficult than shallow phrases to annotate. Output from the finite-state shallow parser is roughly as accurate as output extracted from the Charniak parser-best trees, though a fair amount below output extracted from the reranker-best trees.

In addition to using base phrase constraints from these two sources independently, we also looked at

combining the predictions of both to obtain more reliable constraints. We next present a method of combining output from multiple parsers based on combined precision and recall optimization.

2.2 Combining Parser n-best Lists

In order to select high-likelihood constraints for the pipeline, we may want to extract annotations with high levels of agreement ("consensus hypotheses") between candidates. In addition, we may want to favor precision over recall to avoid erroneous constraints within the pipeline as much as possible. Here we discuss how a technique presented in Goodman's thesis (1998) can be applied to do this.

We will first present this within a general chart parsing approach, then move to how we use it for n-best lists. Let $\mathcal{T}$ be the set of trees for a particular input, and let a parse $T \in \mathcal{T}$ be considered as a set of labeled spans. Then, for all labeled spans $X \in T$, we can calculate the posterior probability $\gamma(X)$ as follows:

$$\gamma(X) \quad = \quad \sum_{T \in \mathcal{T}} \frac{\mathrm{P}(T)[\![X \in T]\!]}{\sum_{T' \in \mathcal{T}} \mathrm{P}(T')} \qquad (1)$$

where $[\![X \in T]\!] = \begin{cases} 1 & \text{if } X \in T \\ 0 & \text{otherwise.} \end{cases}$

Goodman (1996; 1998) presents a method for using the posterior probability of constituents to maximize the expected labeled recall of binary branching trees, as follows:

$$\widehat{T} \quad = \quad \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{X \in T} \gamma(X) \qquad (2)$$

Essentially, find the tree with the maximum sum of the posterior probabilities of its constituents. This is done by computing the posterior probabilities of constituents in a chart, typically via the Inside-Outside algorithm (Baker, 1979; Lari and Young, 1990), followed by a final CYK-like pass to find the tree maximizing the sum.

For non-binary branching trees, where precision and recall may differ, Goodman (1998, Ch.3) proposes the following combined metric for balancing precision and recall:

$$\widehat{T} \quad = \quad \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{X \in T} (\gamma(X) - \lambda) \qquad (3)$$

where λ ranges from 0 to 1. Setting λ=0 is equivalent to Eq. 2 and thus optimizes recall, and setting λ=1 optimizes precision; Appendix 5 at the end of this paper presents brief derivations of these metrics.[2] Thus, λ functions as a mixing factor to balance recall and precision.

This approach also gives us a straightforward way to combine n-best outputs of multiple systems. To do this, we construct a chart of the constituents in the trees from the n-best lists, and allow any combination of constituents that results in a tree – even one with no internal structure. In such a way, we can produce trees that only include a small number of high-certainty constituents, and leave the remainder of the string unconstrained, even if such trees were not candidates in the original n-best lists.

For simplicity, we will here discuss the combination of two n-best lists, though it generalizes in the obvious way to an arbitrary number of lists. Let $\mathcal{T}$ be the union of the two n-best lists. For all trees $T \in \mathcal{T}$, let $\mathrm{P}_1(T)$ be the probability of T in the first n-best list, and $\mathrm{P}_2(T)$ the probability of T in the second n-best list. Then, we define $\mathrm{P}(T)$ as follows:

$$\mathrm{P}(T) \quad = \quad \alpha \frac{\mathrm{P}_1(T)}{\sum_{T' \in \mathcal{T}} \mathrm{P}_1(T')} + \frac{\mathrm{P}_2(T)}{\sum_{T' \in \mathcal{T}} \mathrm{P}_2(T')} \qquad (4)$$

where the parameter α dictates the relative weight of P_1 versus P_2 in the combination.[3]

For this paper, we combined two n-best lists of base-phrase trees. Although there is no hierarchical structure in base-phrase annotations, they can be represented as flat trees, as shown in Fig. 2(a). We constructed a chart from the two lists being combined, using Eq. 4 to define $\mathrm{P}(T)$ in Eq. 1. We wish to consider every possible combination of the base phrases, so for the final CYK-like pass to find the argmax tree, we included rules for attaching each preterminal directly to the root of the tree, in addition to rules permitting any combination of hypothesized base phrases.

Consider the trees in Fig. 2. Figure 2(a) is a shallow parse with three NP base phrases; Figure 2(b) is the same parse where the ROOT production has been binarized for the final CYK-like pass, which requires binary productions. If we include productions of the form 'ROOT → X ROOT' and 'ROOT → X Y' for all non-terminals X and Y (including POS tags), then any tree-structured combination of base phrases hypothesized in either n-

[2] Our notation differs slightly from that in Goodman (1998), though the approaches are formally equivalent.

[3] Note that P_1 and P_2 are normalized in eq. 4, and thus are not required to be true probabilities. In turn, P is normalized when used in eq. 1, such that the posterior probability γ is a true probability. Hence P need not be normalized in eq. 4.

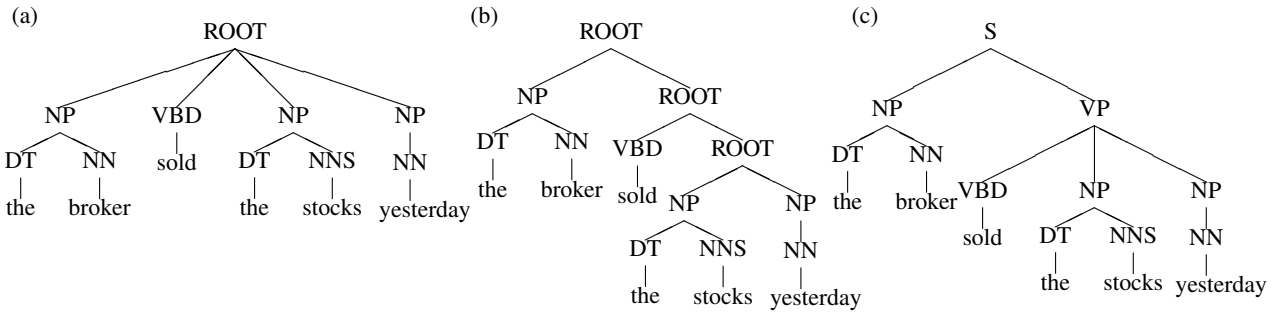

Figure 2: Base-phrase trees (a) as produced for an n-best list and (b) after root-binarization for n-best list combination. Full-parse tree (c) consistent with constraining base-phrase tree (a).

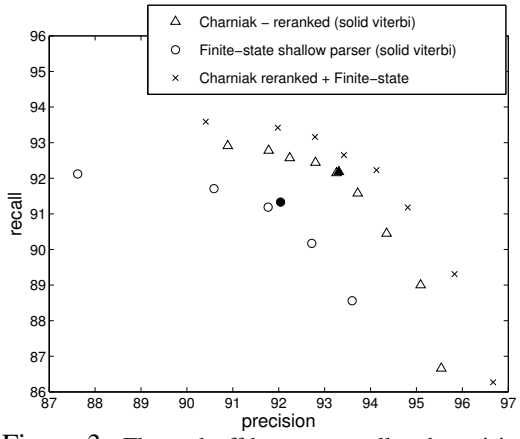

Figure 3: The tradeoff between recall and precision using a range of λ values (Eq. 3) to select high-probability annotations from an n-best list. Results are shown on 50-best lists of base-phrase parses from two parsers, and on the combination of the two lists.

best list is allowed, including the one with no base phrases at all. Note that, for the purpose of finding the argmax tree in Eq. 3, we only sum the posterior probabilities of base-phrase constituents, and not the ROOT symbol or POS tags.

Figure 3 shows the results of performing this combined precision/recall optimization on three separate n-best lists: the 50-best list of base-phrase trees extracted from the full-parse output of the Charniak and Johnson (2005) reranker; the 50-best list output by the Hollingshead et al. (2005) finite-state shallow parser; and the weighted combination of the two lists at various values of λ in Eq. 3. For the combination, we set α=2 in Eq. 4, with the Charniak and Johnson (2005) reranker providing P_1, effectively giving the reranker twice the weight of the shallow parser in determining the posteriors. The shallow parser has perceptron scores as weights, and the distribution of these scores after a softmax normalization was too peaked to be of utility, so we used the normalized reciprocal rank of each candidate as P_2 in Eq. 4.

We point out several details in these results. First, using this method does not result in an F-measure improvement over the Viterbi-best base-phrase parses (shown as solid symbols in the graph) for either the reranker or shallow parser. Also, using this model effects a greater improvement in precision than in recall, which is unsurprising with these non-hierarchical annotations; unlike full parsing (where long sequences of unary productions can improve recall arbitrarily), in base-phrase parsing, any given span can have only one non-terminal. Finally, we see that the combination of the two n-best lists improves over either list in isolation.

3 Experimental Setup

For our experiments we constructed a simple parsing pipeline, shown in Fig. 4. At the core of the pipeline is the Charniak and Johnson (2005) coarse-to-fine parser and MaxEnt reranker, described in Sec. 2. The parser constitutes the first and second stages of our pipeline, and the reranker the final stage. Following Charniak and Johnson (2005), we set the parser to output 50-best parses for all experiments described here. We constrain only the first stage of the parser: during chart construction, we disallow any constituents that conflict with the constraints, as described in detail in the next section.

3.1 Parser Constraints

We use base phrases, as defined in Sec. 2.1, to constrain the first stage of our parsing pipeline. Under these constraints, full parses must be consistent with the base-phrase tree provided as input to the parser, i.e., any valid parse must contain all of the base-phrase constituents in the constraining tree. The full-parse tree in Fig. 2(c), for example, is consistent with the base-phrase tree in Fig. 2(a).

Implementing these constraints in a parser is straightforward, one of the advantages of using base phrases as constraints. Since the internal structure of base phrases is, by definition, limited to preterminal children, we can constrain the entire parse by constraining the parents of the appropriate preterminal nodes. For any preterminal that occurs within the span of a constraining base phrase, the only valid parent is a node matching both the *span* (start and end points) and the *label* of the provided base

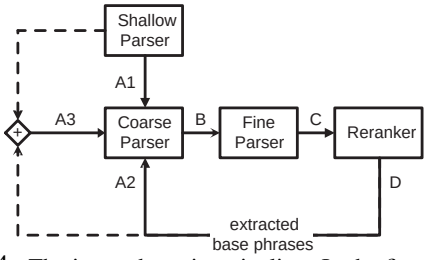

Figure 4: The iterated parsing pipeline. In the first iteration, the coarse parser may be either unconstrained, or constrained by base phrases from the shallow parser (A1). In the second iteration, base phrase constraints may be extracted either from reranker output (A2) or from a weighted combination of shallow parser output and reranker output (A3). Multiple sets of n-best parses, as output by the coarse-to-fine parser under different constraint conditions, may be joined in a set union (C).

phrase. All other proposed parent-nodes are rejected. In such a way, for any parse to cover the entire string, it would have to be consistent with the constraining base-phrase tree.

Words that fall outside of any base-phrase constraint are unconstrained in how they attach within the parse; hence, a base-phrase tree with few words covered by base-phrase constraints will result in a larger search space than one with many words covered by base phrases. We also put no restrictions on the preterminal labels, even within the base phrases. We normalized for punctuation. If the parser fails to find a valid parse with the constraints, then we lift the constraints and allow any parse constituent originally proposed by the first-stage parser.

3.2 Experimental Conditions

Our experiments will demonstrate the effects of constraining the Charniak parser under several different conditions. The baseline system places no constraints on the parser. The remaining experimental conditions each consider one of three possible sources of the base phrase constraints: (1) the base phrases output by the finite-state shallow parser; (2) the base phrases extracted from output of the reranker; and (3) a combination of the output from the shallow parser and the reranker, which is produced using the techniques outlined in Sec. 2.2. Constraints are enforced as described in Sec. 3.1.

Unconstrained For our baseline system, we run the Charniak and Johnson (2005) parser and reranker with default parameters. The parser is provided with treebank-tokenized text and, as mentioned previously, outputs 50-best parse candidates to the reranker.

FS-constrained The FS-constrained condition provides a comparison point of non-iterated constraints. Under this condition, the one-best base-phrase tree output by the finite-state shallow parser is input as a constraint to the Charniak parser. We run the parser and reranker as before, under constraints from the shallow parser. The accuracy of the constraints used under this condition is shown in the first row of Table 2. Note that this condition is *not* an instance of pipeline iteration, but is included to show the performance levels that can be achieved without iteration.

System	LR	LP	F
Finite-state shallow parser	91.3	92.0	91.7
Charniak reranker-best	92.2	93.3	92.8
Combination (λ=0.5)	92.2	94.1	93.2
Combination (λ=0.9)	81.0	97.4	88.4

Table 2: Labeled recall (LR), precision (LP), and F-scores on WSJ section 24 of base-phrase trees produced by the three possible sources of constraints.

Reranker-constrained We will use the reranker-constrained condition to examine the effects of pipeline iteration, with no input from other models outside the pipeline. We take the reranker-best full-parse output under the condition of unconstrained search, and extract the corresponding base-phrase tree. We run the parser and reranker as before, now with constraints from the reranker. The accuracy of the constraints used under this condition is shown in the second row of Table 2.

Combo-constrained The combo-constrained conditions are designed to compare the effects of generating constraints with different combination parameterizations, i.e., different λ parameters in Eq. 3. For this experimental condition, we extract base-phrase trees from the n-best full-parse trees output by the reranker. We combine this list with the n-best list output by the finite-state shallow parser, exactly as described in Sec. 2.2, again with the reranker providing P_1 and α=2 in Eq. 4. We examined a range of operating points from λ=0.4 to λ=0.9, and report two points here (λ=0.5 and λ=0.9), which represent the highest overall accuracy and the highest precision, respectively, as shown in Table 2.

Constrained and Unconstrained Union When iterating this pipeline, the original n-best list of full parses output from the unconstrained parser is available at no additional cost, and our final set of experimental conditions investigate taking the union of constrained and unconstrained n-best lists. The imposed constraints can result in candidate sets that are largely (or completely) disjoint from the unconstrained sets, and it may be that the unconstrained set is in many cases superior to the constrained set.

Constraints	Parser-best	Reranker-best	Oracle-best	# Candidates
Baseline (Unconstrained, 50-best)	88.92	90.24	95.95	47.9
FS-constrained	88.44	89.50	94.10	46.2
Reranker-constrained	89.60	90.46	95.07	46.9
Combo-constrained (λ=0.5)	89.81	90.74	95.41	46.3
Combo-constrained (λ=0.9)	89.34	90.43	95.91	47.5

Table 3: Full-parse F-scores on WSJ section 24. The unconstrained search (first row) provides a baseline comparison for the effects of constraining the search space. The last four rows demonstrate the effect of various constraint conditions.

Even our high-precision constraints did not reach 100% precision, attesting to the fact that there was some error in all constrained conditions. By constructing the union of the two n-best lists, we can take advantage of the new constrained candidate set without running the risk that the constraints have resulted in a worse n-best list. Note that the parser probabilities are produced from the same model in both passes, and are hence directly comparable.

The output of the second pass of the pipeline could be used to constrain a third pass, for multiple pipeline iterations. However, we found that further iterations provided no additional improvements.

3.3 Data

Unless stated otherwise, all reported results will be F-scores on WSJ section 24 of the Penn WSJ Treebank, which was our development set. Training data was WSJ sections 02-21, with section 00 as held-out data. Crossfold validation (20-fold with 2,000 sentences per fold) was used to train the reranker for every condition. Evaluation was performed using `evalb` under standard parameterizations. WSJ section 23 was used only for final testing.

4 Results & Discussion

We evaluate the one-best parse candidates before and after reranking (*parser-best* and *reranker-best*, respectively). We additionally provide the best-possible F-score in the n-best list (*oracle-best*) and the number of unique candidates in the list.

Table 3 presents trials showing the effect of constraining the parser under various conditions. Constraining the parser to the base phrases produced by the finite-state shallow parser (FS-constrained) hurts performance by half a point. Constraining the parser to the base phrases produced by the reranker, however, provides a 0.7 percent improvement in the parser-best accuracy, and a 0.2 percent improvement after reranking. Combining the two base-phrase n-best lists to derive the constraints provides further improvements when λ=0.5, to a total improvement of 0.9 and 0.5 percent over parser-best and reranker-best accuracy, respectively. Performance degrades at λ=0.9 relative to λ=0.5, indicating that, even at a lower precision, more constraints are beneficial.

The oracle rate decreases under all of the constrained conditions as compared to the baseline, demonstrating that the parser was prevented from finding some of the best solutions that were originally found. However, the improvement in F-score shows that the constraints assisted the parser in achieving high-quality solutions despite this degraded oracle accuracy of the lists.

Table 4 shows the results when taking the union of the constrained and unconstrained lists prior to reranking. Several interesting points can be noted in this table. First, despite the fact that the FS-constrained condition hurts performance in Table 3, the union provides a 0.5 percent improvement over the baseline in the parser-best performance. This indicates that, in some cases, the Charniak parser is scoring parses in the constrained set higher than in the unconstrained set, which is evidence of search errors in the unconstrained condition. One can see from the number of candidates that the FS-constrained condition provides the set of candidates most disjoint from the original unconstrained parser, leading to the largest number of candidates in the union. Surprisingly, even though this set provided the highest parser-best F-score of all of the union sets, it did not lead to significant overall improvements after reranking.

In all other conditions, taking the union decreases the parser-best accuracy when compared to the corresponding constrained output, but improves the reranker-best accuracy in all but the combo-constrained λ=0.9 condition. One explanation for the lower performance at λ=0.9 versus λ=0.5 is seen in the number of candidates, about 7.5 fewer than in the λ=0.5 condition. There are fewer constraints in the high-precision condition, so the resulting n-best lists do not diverge as much from the original lists, leading to less diversity in their union.

The gains in performance should not be attributed to increasing the number of candidates nor to allow-

Constraints	Parser-best	Reranker-best	Oracle-best	# Candidates
Baseline (Unconstrained, 50-best)	88.92	90.24	95.95	47.9
Unconstrained ∪ FS-constrained	89.39	90.27	96.61	74.9
Unconstrained ∪ Reranker-constrained	89.23	90.59	96.48	70.3
Unconstrained ∪ Combo (λ=0.5)	89.28	90.78	96.53	69.7
Unconstrained ∪ Combo (λ=0.9)	89.03	90.44	96.40	62.1
Unconstrained (100-best)	88.82	90.13	96.38	95.2
Unconstrained (50-best, beam×2)	89.01	90.45	96.13	48.1

Table 4: Full-parse F-scores on WSJ section 24 after taking the set union of unconstrained and constrained parser output under the 4 different constraint conditions. Also, F-score for 100-best parses, and 50-best parses with an increased beam threshold, output by the Charniak parser under the unconstrained condition.

Constraints	F-score
Baseline (Unconstrained, 50-best)	91.06
Unconstrained ∪ Combo (λ=0.5)	91.48

Table 5: Full-parse F-scores on WSJ section 23 for our best-performing system on WSJ section 24. The 0.4 percent F-score improvement is significant at $p < 0.001$.

ing the parser more time to generate the parses. The penultimate row in Table 4 shows the results with 100-best lists output in the unconstrained condition, which does not improve upon the 50-best performance, despite an improved oracle F-score. Since the second iteration through the parsing pipeline clearly increases the overall processing time by a factor of two, we also compare against output obtained by doubling the coarse-parser's beam threshold. The last row in Table 4 shows that the increased threshold yields an insignificant improvement over the baseline, despite a very large processing burden.

We applied our best-performing model (Unconstrained ∪ Combo, λ=0.5) to the test set, WSJ section 23, for comparison against the baseline system. Table 5 shows a 0.4 percent F-score improvement over the baseline for that section, which is statistically significant at $p < 0.001$, using the stratified shuffling test (Yeh, 2000).

5 Conclusion & Future Work

In summary, we have demonstrated that pipeline iteration can be useful in improving system performance, by constraining early stages of the pipeline with output derived from later stages. While the current work made use of a particular kind of constraint—base phrases—many others could be extracted as well. Preliminary results extending the work presented in this paper show parser accuracy improvements from pipeline iteration when using constraints based on an unlabeled partial bracketing of the string. Higher-level phrase segmentations or fully specified trees over portions of the string might also prove to be effective constraints. The techniques shown here are by no means limited to parsing pipelines, and could easily be applied to other tasks making use of pipeline architectures.

Appendix A Combined Precision/Recall Decoding

Recall that $\mathcal{T}$ is the set of trees for a particular input, and each $T \in \mathcal{T}$ is considered as a set of labeled spans. For all labeled spans $X \in T$, we can calculate the posterior probability $\gamma(X)$ as follows:

$$\gamma(X) \;=\; \sum_{T \in \mathcal{T}} \frac{\mathrm{P}(T)[\![X \in T]\!]}{\sum_{T' \in \mathcal{T}} \mathrm{P}(T')}$$

where $[\![X \in T]\!] = \begin{cases} 1 & \text{if } X \in T \\ 0 & \text{otherwise.} \end{cases}$

If τ is the reference tree, the labeled precision (LP) and labeled recall (LR) of a T relative to τ are defined as

$$\mathrm{LP} \;=\; \frac{|T \cap \tau|}{|T|} \qquad \mathrm{LR} \;=\; \frac{|T \cap \tau|}{|\tau|}$$

where $|T|$ denotes the size of the set T.

A metric very close to LR is $|T \cap \tau|$, the number of nodes in common between the tree and the reference tree. To maximize the expected value ($\mathcal{E}$) of this metric, we want to find the tree $\widehat{T}$ as follows:

$$\begin{aligned}
\widehat{T} &= \operatorname*{argmax}_{T \in \mathcal{T}} \mathcal{E}\left[|T \bigcap \tau|\right] \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{T' \in \mathcal{T}} \frac{\mathrm{P}(T')\left[|T \bigcap T'|\right]}{\sum_{T'' \in \mathcal{T}} \mathrm{P}(T'')} \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{T' \in \mathcal{T}} \frac{\mathrm{P}(T') \sum_{X \in T} [\![X \in T']\!]}{\sum_{T'' \in \mathcal{T}} \mathrm{P}(T'')} \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{X \in T} \sum_{T' \in \mathcal{T}} \frac{\mathrm{P}(T')[\![X \in T']\!]}{\sum_{T'' \in \mathcal{T}} \mathrm{P}(T'')} \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{X \in T} \gamma(X) \qquad (5)
\end{aligned}$$

This exactly maximizes the expected LR in the case of binary branching trees, and is closely related to LR for non-binary branching trees. Similar to maximizing the expected number of matching nodes, we can minimize the expected number of non-matching nodes, for a metric related to LP:

$$\begin{aligned}
\widehat{T} &= \operatorname*{argmin}_{T \in \mathcal{T}} \mathcal{E}\left[|T| - |T \bigcap \tau|\right] \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \mathcal{E}\left[|T \bigcap \tau| - |T|\right] \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{T' \in \mathcal{T}} \frac{\mathrm{P}(T')\left[|T \bigcap T'| - |T|\right]}{\sum_{T'' \in \mathcal{T}} \mathrm{P}(T'')} \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{T' \in \mathcal{T}} \frac{\mathrm{P}(T') \sum_{X \in T} ([\![X \in T']\!] - 1)}{\sum_{T'' \in \mathcal{T}} \mathrm{P}(T'')} \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{X \in T} \sum_{T' \in \mathcal{T}} \frac{\mathrm{P}(T')([\![X \in T']\!] - 1)}{\sum_{T'' \in \mathcal{T}} \mathrm{P}(T'')} \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{X \in T} (\gamma(X) - 1) \qquad (6)
\end{aligned}$$

Finally, we can combine these two metrics in a linear combination. Let λ be a mixing factor from 0 to 1. Then we can optimize the weighted sum:

$$\begin{aligned}
\widehat{T} &= \operatorname*{argmax}_{T \in \mathcal{T}} \mathcal{E}\left[(1-\lambda)|T \bigcap \tau| + \lambda(|T \bigcap \tau| - |T|)\right] \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} (1-\lambda)\mathcal{E}\left[|T \bigcap \tau|\right] + \lambda\mathcal{E}\left[|T \bigcap \tau| - |T|\right] \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \left[(1-\lambda) \sum_{X \in T} \gamma(X)\right] + \left[\lambda \sum_{X \in T} (\gamma(X) - 1)\right] \\
&= \operatorname*{argmax}_{T \in \mathcal{T}} \sum_{X \in T} (\gamma(X) - \lambda) \qquad (7)
\end{aligned}$$

The result is a combined metric for balancing precision and recall. Note that, if λ=0, Eq. 7 is the same as Eq. 5 and thus maximizes the LR metric; and if λ=1, Eq. 7 is the same as Eq. 6 and thus maximizes the LP metric.

Learning Synchronous Grammars for Semantic Parsing with Lambda Calculus

Yuk Wah Wong and Raymond J. Mooney
Department of Computer Sciences
The University of Texas at Austin
{ywwong,mooney}@cs.utexas.edu

Abstract

This paper presents the first empirical results to our knowledge on learning synchronous grammars that generate logical forms. Using statistical machine translation techniques, a semantic parser based on a synchronous context-free grammar augmented with λ-operators is learned given a set of training sentences and their correct logical forms. The resulting parser is shown to be the best-performing system so far in a database query domain.

1 Introduction

Originally developed as a theory of compiling programming languages (Aho and Ullman, 1972), synchronous grammars have seen a surge of interest recently in the *statistical machine translation* (SMT) community as a way of formalizing syntax-based translation models between natural languages (NL). In generating multiple parse trees in a single derivation, synchronous grammars are ideal for modeling syntax-based translation because they describe not only the hierarchical structures of a sentence and its translation, but also the exact correspondence between their sub-parts. Among the grammar formalisms successfully put into use in syntax-based SMT are synchronous context-free grammars (SCFG) (Wu, 1997) and synchronous tree-substitution grammars (STSG) (Yamada and Knight, 2001). Both formalisms have led to SMT systems whose performance is state-of-the-art (Chiang, 2005; Galley et al., 2006).

Synchronous grammars have also been used in other NLP tasks, most notably *semantic parsing*, which is the construction of a complete, formal *meaning representation* (MR) of an NL sentence. In our previous work (Wong and Mooney, 2006), semantic parsing is cast as a machine translation task, where an SCFG is used to model the translation of an NL into a formal meaning-representation language (MRL). Our algorithm, WASP, uses statistical models developed for syntax-based SMT for lexical learning and parse disambiguation. The result is a robust semantic parser that gives good performance in various domains. More recently, we show that our SCFG-based parser can be inverted to produce a state-of-the-art NL generator, where a formal MRL is translated into an NL (Wong and Mooney, 2007).

Currently, the use of learned synchronous grammars in semantic parsing and NL generation is limited to simple MRLs that are free of logical variables. This is because grammar formalisms such as SCFG do not have a principled mechanism for handling logical variables. This is unfortunate because most existing work on computational semantics is based on predicate logic, where logical variables play an important role (Blackburn and Bos, 2005). For some domains, this problem can be avoided by transforming a logical language into a variable-free, functional language (e.g. the GEOQUERY functional query language in Wong and Mooney (2006)). However, development of such a functional language is non-trivial, and as we will see, logical languages can be more appropriate for certain domains.

On the other hand, most existing methods for mapping NL sentences to logical forms involve substantial hand-written components that are difficult to maintain (Joshi and Vijay-Shanker, 2001; Bayer et al., 2004; Bos, 2005). Zettlemoyer and Collins (2005) present a statistical method that is consider-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 960–967,
Prague, Czech Republic, June 2007.

ably more robust, but it still relies on hand-written rules for lexical acquisition, which can create a performance bottleneck.

In this work, we show that methods developed for SMT can be brought to bear on tasks where logical forms are involved, such as semantic parsing. In particular, we extend the WASP semantic parsing algorithm by adding variable-binding λ-operators to the underlying SCFG. The resulting synchronous grammar generates logical forms using λ-calculus (Montague, 1970). A semantic parser is learned given a set of sentences and their correct logical forms using SMT methods. The new algorithm is called λ-WASP, and is shown to be the best-performing system so far in the GEOQUERY domain.

2 Test Domain

In this work, we mainly consider the GEOQUERY domain, where a query language based on Prolog is used to query a database on U.S. geography (Zelle and Mooney, 1996). The query language consists of logical forms augmented with meta-predicates for concepts such as *smallest* and *count*. Figure 1 shows two sample logical forms and their English glosses. Throughout this paper, we use the notation $x_1, x_2, \ldots$ for logical variables.

Although Prolog logical forms are the main focus of this paper, our algorithm makes minimal assumptions about the target MRL. The only restriction on the MRL is that it be defined by an unambiguous context-free grammar (CFG) that divides a logical form into subformulas (and terms into subterms). Figure 2(a) shows a sample parse tree of a logical form, where each CFG production corresponds to a subformula.

3 The Semantic Parsing Algorithm

Our work is based on the WASP semantic parsing algorithm (Wong and Mooney, 2006), which translates NL sentences into MRs using an SCFG. In WASP, each SCFG production has the following form:

$$A \rightarrow \langle \alpha, \beta \rangle \tag{1}$$

where α is an NL phrase and β is the MR translation of α. Both α and β are strings of terminal and non-terminal symbols. Each non-terminal in α appears in β exactly once. We use indices to show the correspondence between non-terminals in α and β. All derivations start with a pair of co-indexed start symbols, $\langle S_{\boxed{1}}, S_{\boxed{1}} \rangle$. Each step of a derivation involves the rewriting of a pair of co-indexed non-terminals by the same SCFG production. The yield of a derivation is a pair of terminal strings, $\langle \mathbf{e}, \mathbf{f} \rangle$, where $\mathbf{e}$ is an NL sentence and $\mathbf{f}$ is the MR translation of $\mathbf{e}$. For convenience, we call an SCFG production a *rule* throughout this paper.

While WASP works well for target MRLs that are free of logical variables such as CLANG (Wong and Mooney, 2006), it cannot easily handle various kinds of logical forms used in computational semantics, such as predicate logic. The problem is that WASP lacks a principled mechanism for handling logical variables. In this work, we extend the WASP algorithm by adding a variable-binding mechanism based on λ-calculus, which allows for compositional semantics for logical forms.

This work is based on an extended version of SCFG, which we call λ-SCFG, where each rule has the following form:

$$A \rightarrow \langle \alpha, \lambda x_1 \ldots \lambda x_k.\beta \rangle \tag{2}$$

where α is an NL phrase and β is the MR translation of α. Unlike (1), β is a string of terminals, non-terminals, and *logical variables*. The variable-binding operator λ binds occurrences of the logical variables $x_1, \ldots, x_k$ in β, which makes $\lambda x_1 \ldots \lambda x_k.\beta$ a λ-*function* of arity k. When applied to a list of arguments, $(x_{i_1}, \ldots, x_{i_k})$, the λ-function gives $\beta\sigma$, where σ is a substitution operator, $\{x_1/x_{i_1}, \ldots, x_k/x_{i_k}\}$, that replaces all bound occurrences of x_j in β with x_{i_j}. If any of the arguments x_{i_j} appear in β as a free variable (i.e. not bound by any λ), then those free variables in β must be renamed before function application takes place.

Each non-terminal A_j in β is followed by a list of arguments, $\mathbf{x}_j = (x_{j_1}, \ldots, x_{j_{k_j}})$. During parsing, A_j must be rewritten by a λ-function f_j of arity k_j. Like SCFG, a derivation starts with a pair of co-indexed start symbols and ends when all non-terminals have been rewritten. To compute the yield of a derivation, each f_j is applied to its corresponding arguments $\mathbf{x}_j$ to obtain an MR string free of λ-operators with logical variables properly named.

(a) `answer(`x_1`,smallest(`x_2`,(state(`x_1`),area(`x_1`,`x_2`))))`
What is the smallest state by area?

(b) `answer(`x_1`,count(`x_2`,(city(`x_2`),major(`x_2`),loc(`x_2`,`x_3`),next_to(`x_3`,`x_4`),state(`x_3`),`
`equal(`x_4`,stateid(texas)))))`
How many major cities are in states bordering Texas?

Figure 1: Sample logical forms in the GEOQUERY domain and their English glosses.

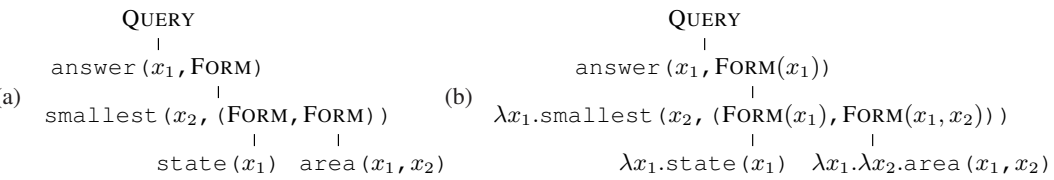

Figure 2: Parse trees of the logical form in Figure 1(a).

As a concrete example, Figure 2(b) shows an MR parse tree that corresponds to the English parse, [*What is the* [*smallest* [*state*] [*by area*]]], based on the λ-SCFG rules in Figure 3. To compute the yield of this MR parse tree, we start from the leaf nodes: apply $\lambda x_1.\texttt{state}(x_1)$ to the argument (x_1), and $\lambda x_1.\lambda x_2.\texttt{area}(x_1,x_2)$ to the arguments (x_1, x_2). This results in two MR strings: $\texttt{state}(x_1)$ and $\texttt{area}(x_1,x_2)$. Substituting these MR strings for the FORM non-terminals in the parent node gives the λ-function $\lambda x_1.\texttt{smallest}(x_2,\texttt{(state}(x_1)\texttt{,area}(x_1,x_2)\texttt{))}$. Applying this λ-function to (x_1) gives the MR string $\texttt{smallest}(x_2,\texttt{(state}(x_1)\texttt{,area}(x_1,x_2)\texttt{))}$. Substituting this MR string for the FORM non-terminal in the grandparent node in turn gives the logical form in Figure 1(a). This is the yield of the MR parse tree, since the root node of the parse tree is reached.

3.1 Lexical Acquisition

Given a set of training sentences paired with their correct logical forms, $\{\langle \mathbf{e}_i, \mathbf{f}_i \rangle\}$, the main learning task is to find a λ-SCFG, G, that covers the training data. Like most existing work on syntax-based SMT (Chiang, 2005; Galley et al., 2006), we construct G using rules extracted from word alignments. We use the $K = 5$ most probable word alignments for the training set given by GIZA++ (Och and Ney, 2003), with variable names ignored to reduce sparsity. Rules are then extracted from each word alignment as follows.

To ground our discussion, we use the word alignment in Figure 4 as an example. To represent the logical form in Figure 4, we use its linearized parse—a list of MRL productions that generate the logical form, in top-down, left-most order (cf. Figure 2(a)). Since the MRL grammar is unambiguous, every logical form has a unique linearized parse. We assume the alignment to be n-to-1, where each word is linked to at most one MRL production.

Rules are extracted in a bottom-up manner, starting with MRL productions at the leaves of the MR parse tree, e.g. FORM $\rightarrow \texttt{state}(x_1)$ in Figure 2(a). Given an MRL production, $A \rightarrow \beta$, a rule $A \rightarrow \langle \alpha, \lambda x_{i_1} \ldots \lambda x_{i_k}.\beta \rangle$ is extracted such that: (1) α is the NL phrase linked to the MRL production; (2) $x_{i_1}, \ldots, x_{i_k}$ are the logical variables that appear in β and outside the current leaf node in the MR parse tree. If $x_{i_1}, \ldots, x_{i_k}$ were not bound by λ, they would become free variables in β, subject to renaming during function application (and therefore, invisible to the rest of the logical form). For example, since x_1 is an argument of the `state` predicate as well as `answer` and `area`, x_1 must be bound (cf. the corresponding tree node in Figure 2(b)). The rule extracted for the `state` predicate is shown in Figure 3.

The case for the internal nodes of the MR parse tree is similar. Given an MRL production, $A \rightarrow \beta$, where β contains non-terminals $A_1, \ldots, A_n$, a rule $A \rightarrow \langle \alpha, \lambda x_{i_1} \ldots \lambda x_{i_k}.\beta' \rangle$ is extracted such that: (1) α is the NL phrase linked to the MRL production, with non-terminals $A_1, \ldots, A_n$ showing the positions of the argument strings; (2) β' is β with each non-terminal A_j replaced with $A_j(x_{j_1}, \ldots, x_{j_{k_j}})$, where $x_{j_1}, \ldots, x_{j_{k_j}}$ are the bound variables in the λ-function used to rewrite A_j; (3) $x_{i_1}, \ldots, x_{i_k}$ are the logical variables that appear in β' and outside the current MR sub-parse. For example, see the rule

FORM → ⟨ *state* , λx_1.state(x_1) ⟩
FORM → ⟨ *by area* , $\lambda x_1.\lambda x_2$.area(x_1, x_2) ⟩
FORM → ⟨ *smallest* FORM[1] FORM[2] , λx_1.smallest$(x_2,$ (FORM[1](x_1), FORM[2](x_1, x_2))) ⟩
QUERY → ⟨ *what is* (1) FORM[1] , answer$(x_1,$ FORM[1](x_1)) ⟩

Figure 3: λ-SCFG rules for parsing the English sentence in Figure 1(a).

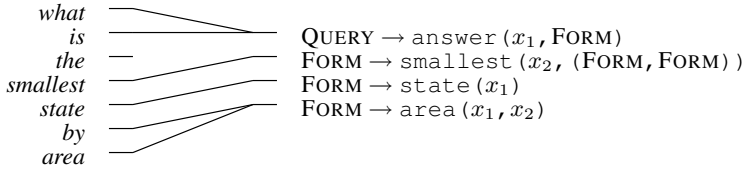

Figure 4: Word alignment for the sentence pair in Figure 1(a).

extracted for the smallest predicate in Figure 3, where x_2 is an argument of smallest, but it does not appear outside the formula smallest(...), so x_2 need not be bound by λ. On the other hand, x_1 appears in β', and it appears outside smallest(...) (as an argument of answer), so x_1 must be bound.

Rule extraction continues in this manner until the root of the MR parse tree is reached. Figure 3 shows all the rules extracted from Figure 4.[1]

3.2 Probabilistic Semantic Parsing Model

Since the learned λ-SCFG can be ambiguous, a probabilistic model is needed for parse disambiguation. We use the maximum-entropy model proposed in Wong and Mooney (2006), which defines a conditional probability distribution over derivations given an observed NL sentence. The output MR is the yield of the most probable derivation according to this model.

Parameter estimation involves maximizing the conditional log-likelihood of the training set. For each rule, r, there is a feature that returns the number of times r is used in a derivation. More features will be introduced in Section 5.

4 Promoting NL/MRL Isomorphism

We have described the λ-WASP algorithm which generates logical forms based on λ-calculus. While reasonably effective, it can be improved in several ways. In this section, we focus on improving lexical acquisition.

To see why the current lexical acquisition algorithm can be problematic, consider the word alignment in Figure 5 (for the sentence pair in Figure 1(b)). No rules can be extracted for the state predicate, because the shortest NL substring that covers the word *states* and the argument string *Texas*, i.e. *states bordering Texas*, contains the word *bordering*, which is linked to an MRL production outside the MR sub-parse rooted at state. Rule extraction is forbidden in this case because it would destroy the link between *bordering* and next_to. In other words, the NL and MR parse trees are not *isomorphic*.

This problem can be ameliorated by transforming the logical form of each training sentence so that the NL and MR parse trees are maximally isomorphic. This is possible because some of the operators used in the logical forms, notably the conjunction operator (,), are both associative (a,(b,c) = (a,b),c = a,b,c) and commutative (a,b = b,a). Hence, conjuncts can be reordered and regrouped without changing the meaning of a conjunction. For example, rule extraction would be possible if the positions of the next_to and state conjuncts were switched. We present a method for regrouping conjuncts to promote isomorphism between NL and MR parse trees.[2] Given a conjunction, it does the following: (See Figure 6 for the pseudocode, and Figure 5 for an illustration.)

Step 1. Identify the MRL productions that correspond to the conjuncts and the meta-predicate that takes the conjunction as an argument (count in Figure 5), and figure them as vertices in an undi-

[1] For details regarding non-isomorphic NL/MR parse trees, removal of bad links from alignments, and extraction of word gaps (e.g. the token (1) in the last rule of Figure 3), see Wong and Mooney (2006).

[2] This method also applies to *any* operators that are associative and commutative, e.g. disjunction. For concreteness, however, we use conjunction as an example.

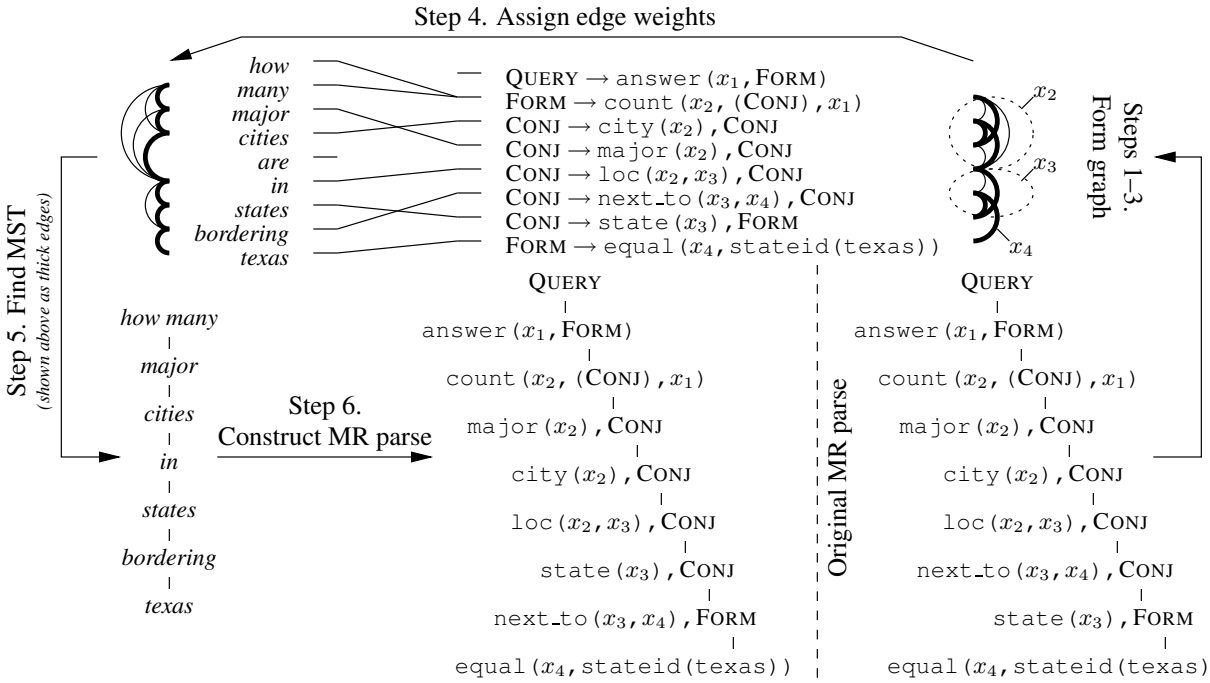

Figure 5: Transforming the logical form in Figure 1(b). The step numbers correspond to those in Figure 6.

Input: A conjunction, $\mathbf{c}$, of n conjuncts; MRL productions, $p_1, \ldots, p_n$, that correspond to each conjunct; an MRL production, p_0, that corresponds to the meta-predicate taking $\mathbf{c}$ as an argument; an NL sentence, $\mathbf{e}$; a word alignment, $\mathbf{a}$.

1 Let $\mathbf{v}(p)$ be the set of logical variables that appear in p. Create an undirected graph, Γ, with vertices $V = \{p_i | i = 0, \ldots, n\}$ and edges $E = \{(p_i, p_j) | i < j, \mathbf{v}(p_i) \cap \mathbf{v}(p_j) \neq \emptyset\}$.
2 Let $\mathbf{e}(p)$ be the set of words in $\mathbf{e}$ to which p is linked according to $\mathbf{a}$. Let $\text{span}(p_i, p_j)$ be the shortest substring of $\mathbf{e}$ that includes $\mathbf{e}(p_i) \cup \mathbf{e}(p_j)$. Subtract $\{(p_i, p_j) | i \neq 0, \text{span}(p_i, p_j) \cap \mathbf{e}(p_0) \neq \emptyset\}$ from E.
3 Add edges (p_0, p_i) to E if p_i is not already connected to p_0.
4 For each edge (p_i, p_j) in E, set edge weight to the minimum word distance between $\mathbf{e}(p_i)$ and $\mathbf{e}(p_j)$.
5 Find a minimum spanning tree, T, for Γ using Kruskal's algorithm.
6 Using p_0 as the root, construct a conjunction $\mathbf{c}'$ based on T, and then replace $\mathbf{c}$ with $\mathbf{c}'$.

Figure 6: Algorithm for regrouping conjuncts to promote isomorphism between NL and MR parse trees.

rected graph, Γ. An edge (p_i, p_j) is in Γ if and only if p_i and p_j contain occurrences of the same logical variables. Each edge in Γ indicates a possible edge in the transformed MR parse tree. Intuitively, two concepts are closely related if they involve the same logical variables, and therefore, should be placed close together in the MR parse tree. By keeping occurrences of a logical variable in close proximity in the MR parse tree, we also avoid unnecessary variable bindings in the extracted rules.

Step 2. Remove edges from Γ whose inclusion in the MR parse tree would prevent the NL and MR parse trees from being isomorphic.

Step 3. Add edges to Γ to make sure that a spanning tree for Γ exists.

Steps 4–6. Assign edge weights based on word distance, find a minimum spanning tree, T, for Γ, then regroup the conjuncts based on T. The choice of T reflects the intuition that words that occur close together in a sentence tend to be semantically related.

This procedure is repeated for all conjunctions that appear in a logical form. Rules are then extracted from the same input alignment used to regroup conjuncts. Of course, the regrouping of conjuncts requires a good alignment to begin with, and that requires a reasonable ordering of conjuncts in the training data, since the alignment model is sensitive to word order. This suggests an iterative algorithm in which a better grouping of conjuncts leads to a better alignment model, which guides further regrouping until convergence. We did not pursue this, as it is not needed in our experiments so far.

(a) answer(x_1,largest(x_2,(state(x_1),major(x_1),river(x_1),traverse(x_1,x_2))))
What is the entity that is a state and also a major river, that traverses something that is the largest?

(b) answer(x_1,smallest(x_2,(highest(x_1,(point(x_1),loc(x_1,x_3),state(x_3))),density(x_1,x_2))))
Among the highest points of all states, which one has the lowest population density?

(c) answer(x_1,equal(x_1,stateid(alaska)))
Alaska?

(d) answer(x_1,largest(x_2,(largest(x_1,(state(x_1),next_to(x_1,x_3),state(x_3))),population(x_1,x_2))))
Among the largest state that borders some other state, which is the one with the largest population?

Figure 7: Typical errors made by the λ-WASP parser, along with their English interpretations, before any language modeling for the target MRL was done.

5 Modeling the Target MRL

In this section, we propose two methods for modeling the target MRL. This is motivated by the fact that many of the errors made by the λ-WASP parser can be detected by inspecting the MR translations alone. Figure 7 shows some typical errors, which can be classified into two broad categories:

1. Type mismatch errors. For example, a state cannot possibly be a river (Figure 7(a)). Also it is awkward to talk about the population density of a state's highest point (Figure 7(b)).

2. Errors that do not involve type mismatch. For example, a query can be overly trivial (Figure 7(c)), or involve aggregate functions on a known singleton (Figure 7(d)).

The first type of errors can be fixed by type checking. Each m-place predicate is associated with a list of m-tuples showing all valid *combinations* of entity types that the m arguments can refer to:

point(_): {(POINT)}
density(_,_):
{(COUNTRY, NUM), (STATE, NUM), (CITY, NUM)}

These m-tuples of entity types are given as domain knowledge. The parser maintains a set of possible entity types for each logical variable introduced in a partial derivation (except those that are no longer visible). If there is a logical variable that cannot refer to any types of entities (i.e. the set of entity types is empty), then the partial derivation is considered invalid. For example, based on the tuples shown above, point(x_1) and density(x_1,_) cannot be both true, because $\{\text{POINT}\} \cap \{\text{COUNTRY}, \text{STATE}, \text{CITY}\} = \emptyset$. The use of type checking is to exploit the fact that people tend not to ask questions that obviously have no valid answers (Grice, 1975). It is also similar to Schuler's (2003) use of model-theoretic interpretations to guide syntactic parsing.

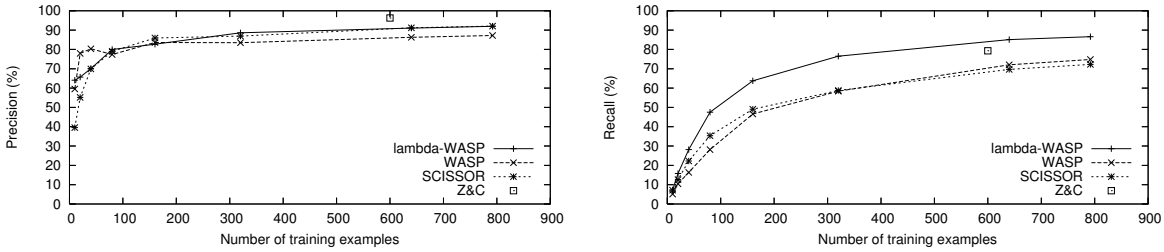
Errors that do not involve type mismatch are handled by adding new features to the maximum-entropy model (Section 3.2). We only consider features that are based on the MR translations, and therefore, these features can be seen as an implicit language model of the target MRL (Papineni et al., 1997). Of the many features that we have tried, one feature set stands out as being the most effective, the *two-level rules* in Collins and Koo (2005), which give the number of times a given rule is used to expand a non-terminal in a given parent rule. We use only the MRL part of the rules. For example, a negative weight for the combination of QUERY $\rightarrow$ answer(x_1,FORM(x_1)) and FORM $\rightarrow \lambda x_1$.equal(x_1,_) would discourage any parse that yields Figure 7(c). The two-level rules features, along with the features described in Section 3.2, are used in the final version of λ-WASP.

6 Experiments

We evaluated the λ-WASP algorithm in the GEOQUERY domain. The larger GEOQUERY corpus consists of 880 English questions gathered from various sources (Wong and Mooney, 2006). The questions were manually translated into Prolog logical forms. The average length of a sentence is 7.57 words.

We performed a single run of 10-fold cross validation, and measured the performance of the learned parsers using *precision* (percentage of translations that were correct), *recall* (percentage of test sentences that were correctly translated), and *F-measure* (harmonic mean of precision and recall). A translation is considered correct if it retrieves the same answer as the correct logical form.

Figure 8 shows the learning curves for the λ-



(a) Precision (b) Recall

(%)	λ-WASP	WASP	SCISSOR	Z&C
Precision	91.95	87.19	92.08	**96.25**
Recall	**86.59**	74.77	72.27	79.29
F-measure	**89.19**	80.50	80.98	86.95

Table 1: Performance of various parsing algorithms on the larger GEOQUERY corpus.

WASP algorithm compared to: (1) the original WASP algorithm which uses a functional query language (FunQL); (2) SCISSOR (Ge and Mooney, 2005), a fully-supervised, combined syntactic-semantic parsing algorithm which also uses FunQL; and (3) Zettlemoyer and Collins (2005) (Z&C), a CCG-based algorithm which uses Prolog logical forms. Table 1 summarizes the results at the end of the learning curves (792 training examples for λ-WASP, WASP and SCISSOR, 600 for Z&C).

A few observations can be made. First, algorithms that use Prolog logical forms as the target MRL generally show better recall than those using FunQL. In particular, λ-WASP has the best recall by far. One reason is that it allows lexical items to be combined in ways not allowed by FunQL or the hand-written templates in Z&C, e.g. [*smallest* [*state*] [*by area*]] in Figure 3. Second, Z&C has the best precision, although their results are based on 280 test examples only, whereas our results are based on 10-fold cross validation. Third, λ-WASP has the best F-measure.

To see the relative importance of each component of the λ-WASP algorithm, we performed two ablation studies. First, we compared the performance of λ-WASP with and without conjunct regrouping (Section 4). Second, we compared the performance of λ-WASP with and without language modeling for the MRL (Section 5). Table 2 shows the results. It is found that conjunct regrouping improves recall ($p < 0.01$ based on the paired t-test), and the use of *two-level rules* in the maximum-entropy model improves precision and recall ($p < 0.05$). Type checking also significantly improves precision and recall.

A major advantage of λ-WASP over SCISSOR and Z&C is that it does not require any prior knowledge of the NL syntax. Figure 9 shows the performance of λ-WASP on the multilingual GEOQUERY data set. The 250-example data set is a subset of the larger GEOQUERY corpus. All English questions in this data set were manually translated into Spanish, Japanese and Turkish, while the corresponding Prolog queries remain unchanged. Figure 9 shows that λ-WASP performed comparably for all NLs. In contrast, SCISSOR cannot be used directly on the non-English data, because syntactic annotations are only available in English. Z&C cannot be used directly either, because it requires NL-specific templates for building CCG grammars.

7 Conclusions

We have presented λ-WASP, a semantic parsing algorithm based on a λ-SCFG that generates logical forms using λ-calculus. A semantic parser is learned given a set of training sentences and their correct logical forms using standard SMT techniques. The result is a robust semantic parser for predicate logic, and it is the best-performing system so far in the GEOQUERY domain.

This work shows that it is possible to use standard SMT methods in tasks where logical forms are involved. For example, it should be straightforward to adapt λ-WASP to the NL generation task—all one needs is a decoder that can handle input logical forms. Other tasks that can potentially benefit from

(%)	Precision	Recall
λ-WASP	**91.95**	**86.59**
w/o conj. regrouping	**90.73**	83.07

(%)	Precision	Recall
λ-WASP	**91.95**	**86.59**
w/o two-level rules	88.46	84.32
and w/o type checking	65.45	63.18

this include question answering and interlingual MT.

In future work, we plan to further generalize the synchronous parsing framework to allow different combinations of grammar formalisms. For example, to handle long-distance dependencies that occur in open-domain text, CCG and TAG would be more appropriate than CFG. Certain applications may require different meaning representations, e.g. frame semantics.

Abstract

Previous studies in data-driven dependency parsing have shown that tree transformations can improve parsing accuracy for specific parsers and data sets. We investigate to what extent this can be generalized across languages/treebanks and parsers, focusing on pseudo-projective parsing, as a way of capturing non-projective dependencies, and transformations used to facilitate parsing of coordinate structures and verb groups. The results indicate that the beneficial effect of pseudo-projective parsing is independent of parsing strategy but sensitive to language or treebank specific properties. By contrast, the construction specific transformations appear to be more sensitive to parsing strategy but have a constant positive effect over several languages.

1 Introduction

Treebank parsers are trained on syntactically annotated sentences and a major part of their success can be attributed to extensive manipulations of the training data as well as the output of the parser, usually in the form of various tree transformations. This can be seen in state-of-the-art constituency-based parsers such as Collins (1999), Charniak (2000), and Petrov et al. (2006), and the effects of different transformations have been studied by Johnson (1998), Klein and Manning (2003), and Bikel (2004). Corresponding manipulations in the form of tree transformations for dependency-based parsers have recently gained more interest (Nivre and Nilsson, 2005; Hall and Novák, 2005; McDonald and Pereira, 2006; Nilsson et al., 2006) but are still less studied, partly because constituency-based parsing has dominated the field for a long time, and partly because dependency structures have less structure to manipulate than constituent structures.

Most of the studies in this tradition focus on a particular parsing model and a particular data set, which means that it is difficult to say whether the effect of a given transformation is dependent on a particular parsing strategy or on properties of a particular language or treebank, or both. The aim of this study is to further investigate some tree transformation techniques previously proposed for data-driven dependency parsing, with the specific aim of trying to generalize results across languages/treebanks and parsers. More precisely, we want to establish, first of all, whether the transformation as such makes specific assumptions about the language, treebank or parser and, secondly, whether the improved parsing accuracy that is due to a given transformation is constant across different languages, treebanks, and parsers.

The three types of syntactic phenomena that will be studied here are non-projectivity, coordination and verb groups, which in different ways pose problems for dependency parsers. We will focus on tree transformations that combine preprocessing with post-processing, and where the parser is treated as a black box, such as the pseudo-projective parsing technique proposed by Nivre and Nilsson (2005) and the tree transformations investigated in Nilsson et al. (2006). To study the influence of lan-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 968–975,
Prague, Czech Republic, June 2007.

guage and treebank specific properties we will use data from Arabic, Czech, Dutch, and Slovene, taken from the CoNLL-X shared task on multilingual dependency parsing (Buchholz and Marsi, 2006). To study the influence of parsing methodology, we will compare two different parsers: MaltParser (Nivre et al., 2004) and MSTParser (McDonald et al., 2005). Note that, while it is possible in principle to distinguish between syntactic properties of a language as such and properties of a particular syntactic annotation of the language in question, it will be impossible to tease these apart in the experiments reported here, since this would require having not only multiple languages but also multiple treebanks for each language. In the following, we will therefore speak about the properties of *treebanks* (rather than *languages*), but it should be understood that these properties in general depend both on properties of the language and of the particular syntactic annotation adopted in the treebank.

The rest of the paper is structured as follows. Section 2 surveys tree transformations used in dependency parsing and discusses dependencies between transformations, on the one hand, and treebanks and parsers, on the other. Section 3 introduces the four treebanks used in this study, and section 4 briefly describes the two parsers. Experimental results are presented in section 5 and conclusions in section 6.

2 Background

2.1 Non-projectivity

The tree transformations that have attracted most interest in the literature on dependency parsing are those concerned with recovering non-projectivity. The definition of non-projectivity can be found in Kahane et al. (1998). Informally, an arc is *projective* if all tokens it covers are descendants of the arc's head token, and a dependency tree is projective if all its arcs are projective.[1]

The full potential of dependency parsing can only be realized if non-projectivity is allowed, which pose a problem for projective dependency parsers. Direct non-projective parsing can be performed with good accuracy, e.g., using the Chu-Liu-Edmonds algorithm, as proposed by McDonald et al. (2005). On the other hand, non-projective parsers tend, among other things, to be slower. In order to maintain the benefits of projective parsing, tree transformations techniques to recover non-projectivity while using a projective parser have been proposed in several studies, some described below.

In discussing the recovery of empty categories in data-driven constituency parsing, Campbell (2004) distinguishes between approaches based on pure post-processing and approaches based on a combination of preprocessing and post-processing. The same division can be made for the recovery of non-projective dependencies in data-driven dependency parsing.

Pure Post-processing

Hall and Novák (2005) propose a corrective modeling approach. The motivation is that the parsers of Collins et al. (1999) and Charniak (2000) adapted to Czech are not able to create the non-projective arcs present in the treebank, which is unsatisfactory. They therefore aim to correct erroneous arcs in the parser's output (specifically all those arcs which should be non-projective) by training a classifier that predicts the most probable head of a token in the neighborhood of the head assigned by the parser.

Another example is the second-order approximate spanning tree parser developed by McDonald and Pereira (2006). It starts by producing the highest scoring projective dependency tree using Eisner's algorithm. In the second phase, tree transformations are performed, replacing lower scoring projective arcs with higher scoring non-projective ones.

Preprocessing with Post-processing

The training data can also be preprocessed to facilitate the recovery of non-projective arcs in the output of a projective parser. The pseudo-projective transformation proposed by Nivre and Nilsson (2005) is such an approach, which is compatible with different parser engines.

First, the training data is *projectivized* by making non-projective arcs projective using a lifting operation. This is combined with an augmentation of the dependency labels of projectivized arcs (and/or surrounding arcs) with information that probably reveals their correct non-projective positions. The out-

[1] If dependency arcs are drawn above the linearly ordered sequence of tokens, preceded by a special root node, then a non-projective dependency tree always has crossing arcs.

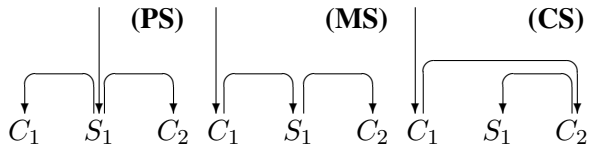

Figure 1: Dependency structure for coordination

put of the parser, trained on the projectivized data, is then *deprojectivized* by a heuristic search using the added information in the dependency labels. The only assumption made about the parser is therefore that it can learn to derive labeled dependency structures with augmented dependency labels.

2.2 Coordination and Verb Groups

The second type of transformation concerns linguistic phenomena that are not impossible for a projective parser to process but which may be difficult to learn, given a certain choice of dependency analysis. This study is concerned with two such phenomena, coordination and verb groups, for which tree transformations have been shown to improve parsing accuracy for MaltParser on Czech (Nilsson et al., 2006). The general conclusion of this study is that coordination and verb groups in the Prague Dependency Treebank (PDT), based on theories of the Prague school (PS), are annotated in a way that is difficult for the parser to learn. By transforming coordination and verb groups in the training data to an annotation similar to that advocated by Mel'čuk (1988) and then performing an inverse transformation on the parser output, parsing accuracy can therefore be improved. This is again an instance of the black-box idea.

Schematically, coordination is annotated in the Prague school as depicted in PS in figure 1, where the conjuncts are dependents of the conjunction. In Mel'čuk style (MS), on the other hand, conjuncts and conjunction(s) form a chain going from left to right. A third way of treating coordination, not discussed by Nilsson et al. (2006), is used by the parser of Collins (1999), which internally represents coordination as a direct relation between the conjuncts. This is illustrated in CS in figure 1, where the conjunction depends on one of the conjuncts, in this case on the rightmost one.

Nilsson et al. (2006) also show that the annotation of verb groups is not well-suited for parsing PDT using MaltParser, and that transforming the dependency structure for verb groups has a positive impact on parsing accuracy. In PDT, auxiliary verbs are dependents of the main verb, whereas it according to Mel'čuk is the (finite) auxiliary verb that is the head of the main verb. Again, the parsing experiments in this study show that verb groups are more difficult to parse in PS than in MS.

2.3 Transformations, Parsers, and Treebanks

Pseudo-projective parsing and transformations for coordination and verb groups are instances of the same general methodology:

1. Apply a tree transformation to the training data.
2. Train a parser on the transformed data.
3. Parse new sentences.
4. Apply an inverse transformation to the output of the parser.

In this scheme, the parser is treated as a black box. All that is assumed is that it is a data-driven parser designed for (projective) labeled dependency structures. In this sense, the tree transformations are independent of parsing methodology. Whether the beneficial effect of a transformation, if any, is also independent of parsing methodology is another question, which will be addressed in the experimental part of this paper.

The pseudo-projective transformation is independent not only of parsing methodology but also of treebank (and language) specific properties, as long as the target representation is a (potentially non-projective) labeled dependency structure. By contrast, the coordination and verb group transformations presuppose not only that the language in question contains these constructions but also that the treebank adopts a PS annotation. In this sense, they are more limited in their applicability than pseudo-projective parsing. Again, it is a different question whether the transformations have a positive effect for all treebanks (languages) to which they can be applied.

3 Treebanks

The experiments are mostly conducted using treebank data from the CoNLL shared task 2006. This

	Slovene SDT	Arabic PADT	Dutch Alpino	Czech PDT
# T	29	54	195	1249
# S	1.5	1.5	13.3	72.7
%-NPS	22.2	11.2	36.4	23.2
%-NPA	1.8	0.4	5.4	1.9
%-C	9.3	8.5	4.0	8.5
%-A	8.8	-	-	1.3

Table 1: Overview of the data sets (ordered by size), where # S * 1000 = number of sentences, # T * 1000 = number of tokens, %-NPS = percentage of non-projective sentences, %-NPA = percentage of non-projective arcs, %-C = percentage of conjuncts, %-A = percentage of auxiliary verbs.

subsection summarizes some of the important characteristics of these data sets, with an overview in table 1. Any details concerning the conversion from the original formats of the various treebanks to the CoNLL format, a pure dependency based format, are found in documentation referred to in Buchholz and Marsi (2006).

PDT (Hajič et al., 2001) is the largest manually annotated treebank, and as already mentioned, it adopts PS for coordination and verb groups. As the last four rows reveal, PDT contains a quite high proportion of non-projectivity, since almost every fourth dependency graph contains at least one non-projective arc. The table also shows that coordination is more common than verb groups in PDT. Only 1.3% of the tokens in the training data are identified as auxiliary verbs, whereas 8.5% of the tokens are identified as conjuncts.

Both Slovene Dependency Treebank (Džeroski et al., 2006) (SDT) and Prague Arabic Dependency Treebank (Hajič et al., 2004) (PADT) annotate coordination and verb groups as in PDT, since they too are influenced by the theories of the Prague school. The proportions of non-projectivity and conjuncts in SDT are in fact quite similar to the proportions in PDT. The big difference is the proportion of auxiliary verbs, with many more auxiliary verbs in SDT than in PDT. It is therefore plausible that the transformations for verb groups will have a larger impact on parser accuracy in SDT.

Arabic is not a Slavic languages such as Czech and Slovene, and the annotation in PADT is therefore more dissimilar to PDT than SDT is. One such example is that Arabic does not have auxiliary verbs. Table 1 thus does not give figures verb groups. The amount of coordination is on the other hand comparable to both PDT and SDT. The table also reveals that the amount of non-projective arcs is about 25% of that in PDT and SDT, although the amount of non-projective sentences is still as large as 50% of that in PDT and SDT.

Alpino (van der Beek et al., 2002) in the CoNLL format, the second largest treebank in this study, is not as closely tied to the theories of the Prague school as the others, but still treats coordination in a way similar to PS. The table shows that coordination is less frequent in the CoNLL version of Alpino than in the three other treebanks. The other characteristic of Alpino is the high share of non-projectivity, where more than every third sentence is non-projective. Finally, the lack of information about the share of auxiliary verbs is not due to the non-existence of such verbs in Dutch but to the fact that Alpino adopts an MS annotation of verb groups (i.e., treating main verbs as dependents of auxiliary verbs), which means that the verb group transformation of Nilsson et al. (2006) is not applicable.

4 Parsers

The parsers used in the experiments are MaltParser (Nivre et al., 2004) and MSTParser (McDonald et al., 2005). These parsers are based on very different parsing strategies, which makes them suitable in order to test the parser independence of different transformations. MaltParser adopts a greedy, deterministic parsing strategy, deriving a labeled dependency structure in a single left-to-right pass over the input and uses support vector machines to predict the next parsing action. MSTParser instead extracts a maximum spanning tree from a dense weighted graph containing all possible dependency arcs between tokens (with Eisner's algorithm for projective dependency structures or the Chu-Liu-Edmonds algorithm for non-projective structures), using a global discriminative model and online learning to assign weights to individual arcs.[2]

[2]The experiments in this paper are based on the first-order factorization described in McDonald et al. (2005)

5 Experiments

The experiments reported in section 5.1–5.2 below are based on the training sets from the CoNLL-X shared task, except where noted. The results reported are obtained by a ten-fold cross-validation (with a pseudo-randomized split) for all treebanks except PDT, where 80% of the data was used for training and 20% for development testing (again with a pseudo-randomized split). In section 5.3, we give results for the final evaluation on the CoNLL-X test sets using all three transformations together with MaltParser.

Parsing accuracy is primarily measured by the unlabeled attachment score (AS_U), i.e., the proportion of tokens that are assigned the correct head, as computed by the official CoNLL-X evaluation script with default settings (thus excluding all punctuation tokens). In section 5.3 we also include the *labeled* attachment score (AS_L) (where a token must have both the correct head and the correct dependency label to be counted as correct), which was the official evaluation metric in the CoNLL-X shared task.

5.1 Comparing Treebanks

We start by examining the effect of transformations on data from different treebanks (languages), using a single parser: MaltParser.

Non-projectivity

The question in focus here is whether the effect of the pseudo-projective transformation for MaltParser varies with the treebank. Table 2 presents the unlabeled attachment score results (AS_U), comparing the pseudo-projective parsing technique (P-Proj) with two baselines, obtained by training the strictly projective parser on the original (non-projective) training data (N-Proj) and on projectivized training data with no augmentation of dependency labels (Proj).

The first thing to note is that pseudo-projective parsing gives a significant improvement for PDT, as previously reported by Nivre and Nilsson (2005), but also for Alpino, where the improvement is even larger, presumably because of the higher proportion of non-projective dependencies in the Dutch treebank. By contrast, there is no significant improvement for either SDT or PADT, and even a small drop in the accuracy figures for SDT. Finally, in contrast to the results reported by Nivre and Nilsson (2005), simply projectivizing the training data (without using an inverse transformation) is not beneficial at all, except possibly for Alpino.

	N-Proj	**Proj**	**P-Proj**
SDT	**77.27**	76.63**	77.11
PADT	76.96	**77.07***	**77.07***
Alpino	82.75	83.28**	**87.08****
PDT	83.41	83.32**	**84.42****

Table 2: AS_U for pseudo-projective parsing with MaltParser. McNemar's test: $^{*} = p < .05$ and $^{**} = p < 0.01$ compared to **N-Proj**.

	1	**2**	**3**	**>3**
SDT	88.4	9.1	1.7	0.84
PADT	66.5	14.4	5.2	13.9
Alpino	84.6	13.8	1.5	0.07
PDT	93.8	5.6	0.5	0.1

Table 3: The number of lifts for non-projective arcs.

But why does not pseudo-projective parsing improve accuracy for SDT and PADT? One possible factor is the complexity of the non-projective constructions, which can be measured by counting the number of lifts that are required to make non-projective arcs projective. The more deeply nested a non-projective arc is, the more difficult it is to recover because of parsing errors as well as search errors in the inverse transformation. The figures in table 3 shed some interesting light on this factor.

For example, whereas 93.8% of all arcs in PDT require only one lift before they become projective (88.4% and 84.6% for SDT and Alpino, respectively), the corresponding figure for PADT is as low as 66.5%. PADT also has a high proportion of very deeply nested non-projective arcs (>3) in comparison to the other treebanks, making the inverse transformation for PADT more problematic than for the other treebanks. The absence of a positive effect for PADT is therefore understandable given the deeply nested non-projective constructions in PADT.

However, one question that still remains is why SDT and PDT, which are so similar in terms of both nesting depth and amount of non-projectivity, be-

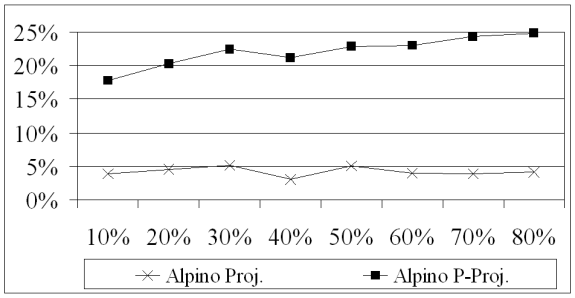

Figure 2: Learning curves for Alpino measured as error reduction for AS_U.

	None	Coord	VG
SDT	77.27	79.33**	77.92**
PADT	76.96	79.05**	-
Alpino	82.75	83.38**	-
PDT	83.41	85.51**	83.58**

Table 4: AS_U for coordination and verb group transformations with MaltParser (None = N-Proj). McNemar's test: ** $= p < .01$ compared to **None**.

have differently with respect to pseudo-projective parsing. Another factor that may be important here is the amount of training data available. As shown in table 1, PDT is more than 40 times larger than SDT. To investigate the influence of training set size, a learning curve experiment has been performed. Alpino is a suitable data set for this due to its relatively large amount of both data and non-projectivity.

Figure 2 shows the learning curve for pseudo-projective parsing (P-Proj), compared to using only projectivized training data (Proj), measured as error reduction in relation to the original non-projective training data (N-Proj). The experiment was performed by incrementally adding cross-validation folds 1–8 to the training set, using folds 9–0 as static test data.

One can note that the error reduction for Proj is unaffected by the amount of data. While the error reduction varies slightly, it turns out that the error reduction is virtually the same for 10% of the training data as for 80%. That is, there is no correlation if information concerning the lifts are not added to the labels. However, with a pseudo-projective transformation, which actively tries to recover non-projectivity, the learning curve clearly indicates that the amount of data matters. Alpino, with 36% non-projective sentences, starts at about 17% and has a climbing curve up to almost 25%.

Although this experiment shows that there is a correlation between the amount of data and the accuracy for pseudo-projective parsing, it does probably not tell the whole story. If it did, one would expect that the error reduction for the pseudo-projective transformation would be much closer to Proj when the amount of data is low (to the left in the figure) than they apparently are. Of course, the difference is likely to diminish with even less data, but it should be noted that 10% of Alpino has about half the size of PADT, for which the positive impact of pseudo-projective parsing is absent. The absence of increased accuracy for SDT can partially be explained by the higher share of non-projective arcs in Alpino (3 times more).

Coordination and Verb Groups

The corresponding parsing results using MaltParser with transformations for coordination and verb groups are shown in table 4. For SDT, PADT and PDT, the annotation of coordination has been transformed from PS to MS, as described in Nilsson et al. (2006). For Alpino, the transformation is from PS to CS (cf. section 2.2), which was found to give slightly better performance in preliminary experiments. The baseline with no transformation (None) is the same as N-Proj in table 2.

As the figures indicate, transforming coordination is beneficial not only for PDT, as reported by Nilsson et al. (2006), but also for SDT, PADT, and Alpino. It is interesting to note that SDT, PADT and PDT, with comparable amounts of conjuncts, have comparable increases in accuracy (about 2 percentage points each), despite the large differences in training set size. It is therefore not surprising that Alpino, with a much smaller amount of conjuncts, has a lower increase in accuracy. Taken together, these results indicate that the frequency of the construction is more important than the size of the training set for this type of transformation.

The same generalization over treebanks holds for verb groups too. The last column in table 4 shows that the expected increase in accuracy for PDT is ac-

Algorithm	N-Proj	Proj	P-Proj
Eisner	81.79	83.23	**86.45**
CLE	86.39		

Table 5: Pseudo-projective parsing results (AS_U) for Alpino with MSTParser.

companied by a even higher increase for SDT. This can probably be attributed to the higher frequency of auxiliary verbs in SDT.

5.2 Comparing Parsers

The main question in this section is to what extent the positive effect of different tree transformations is dependent on parsing strategy, since all previous experiments have been performed with a single parser (MaltParser). For comparison we have performed two experiments with MSTParser, version 0.1, which is based on a very different parsing methdology (cf. section 4). Due to some technical difficulties (notably the very high memory consumption when using MSTParser for labeled dependency parsing), we have not been able to replicate the experiments from the preceding section exactly. The results presented below must therefore be regarded as a preliminary exploration of the dependencies between tree transformations and parsing strategy.

Table 5 presents AS_U results for MSTParser in combination with pseudo-projective parsing applied to the Alpino treebank of Dutch.[3] The first row contains the result for Eisner's algorithm using no transformation (N-Proj), projectivized training data (Proj), and pseudo-projective parsing (P-Proj). The figures show a pattern very similar to that for MaltParser, with a boost in accuracy for Proj compared to N-Proj, and with a significantly higher accuracy for P-Proj over Proj. It is also worth noting that the error reduction between N-Proj and P-Proj is actually higher for MSTParser here than for MaltParser in table 2.

The second row contains the result for the Chu-Liu-Edmonds algorithm (CLE), which constructs non-projective structures directly and therefore does not require the pseudo-projective transformation. A comparison between Eisner's algorithm with pseudo-projective transformation and CLE reveals that pseudo-projective parsing is at least as accurate as non-projective parsing for AS_U. (The small difference is not statistically significant.)

[3]The figures are not completely comparable to the previously presented Dutch results for MaltParser, since MaltParser's feature model has access to all the information in the CoNLL data format, whereas MSTParser in this experiment only could handle word forms and part-of-speech tags.

Trans.	None	Coord	VG
AS_U	84.5	83.5	84.5

Table 6: Coordination and verb group transformations for PDT with the CLE algorithm.

		Dev	Eval	Niv	McD
SDT	AS_U	80.40	82.01	78.72	83.17
	AS_L	71.06	72.44	70.30	73.44
PADT	AS_U	78.97	78.56	77.52	79.34
	AS_L	67.63	67.58	66.71	66.91

	AS_L	84.02	79.73	78.59	79.19
PDT	AS_U	85.72	85.98	84.80	87.30
	AS_L	78.56	78.80	78.42	80.18

Table 7: Evaluation on CoNLL-X test data; MaltParser with all transformations (**Dev** = development, **Eval** = CoNLL test set, **Niv** = Nivre et al. (2006), **McD** = McDonald et al. (2006))

By contrast, no positive effect could be detected for the coordination and verb group transformations togther with MSTParser. The figures in table 6 are not based on CoNLL data, but instead on the evaluation test set of the original PDT 1.0, which enables a direct comparison to McDonald et. al. (2005) (the **None** column). We see that there is even a negative effect for the coordination transformation. These results clearly indicate that the effect of these transformations is at least partly dependent on parsing strategy, in contrast to what was found for the pseudo-projective parsing technique.

5.3 Combining Transformations

In order to assess the combined effect of all three transformations in relation to the state of the art, we performed a final evaluation using MaltParser on the dedicated test sets from the CoNLL-X shared task. Table 7 gives the results for both development (cross-validation for SDT, PADT, and Alpino;

development set for PDT) and final test, compared to the two top performing systems in the shared task, MSTParser with approximate second-order non-projective parsing (McDonald et al., 2006) and MaltParser with pseudo-projective parsing (but no coordination or verb group transformations) (Nivre et al., 2006). Looking at the labeled attachment score (AS_L), the official scoring metric of the CoNLL-X shared task, we see that the combined effect of the three transformations boosts the performance of MaltParser for all treebanks and in two cases out of four outperforms MSTParser (which was the top scoring system for all four treebanks).

6 Conclusion

In this paper, we have examined the generality of tree transformations for data-driven dependency parsing. The results indicate that the pseudo-projective parsing technique has a positive effect on parsing accuracy that is independent of parsing methodology but sensitive to the amount of training data as well as to the complexity of non-projective constructions. By contrast, the construction-specific transformations targeting coordination and verb groups appear to have a more language-independent effect (for languages to which they are applicable) but do not help for all parsers. More research is needed in order to know exactly what the dependencies are between parsing strategy and tree transformations. Regardless of this, however, it is safe to conclude that pre-processing and post-processing is important not only in constituency-based parsing, as previously shown in a number of studies, but also for inductive dependency parsing.

Abstract

This paper explores methods for generating subjectivity analysis resources in a new language by leveraging on the tools and resources available in English. Given a bridge between English and the selected target language (e.g., a bilingual dictionary or a parallel corpus), the methods can be used to rapidly create tools for subjectivity analysis in the new language.

1 Introduction

There is growing interest in the automatic extraction of opinions, emotions, and sentiments in text (*subjectivity*), to provide tools and support for various natural language processing applications. Most of the research to date has focused on English, which is mainly explained by the availability of resources for subjectivity analysis, such as lexicons and manually labeled corpora.

In this paper, we investigate methods to automatically generate resources for subjectivity analysis for a new target language by leveraging on the resources and tools available for English, which in many cases took years of work to complete. Specifically, through experiments with cross-lingual projection of subjectivity, we seek answers to the following questions.

First, can we derive a subjectivity lexicon for a new language using an existing English subjectivity lexicon and a bilingual dictionary? Second, can we derive subjectivity-annotated corpora in a new language using existing subjectivity analysis tools for English and a parallel corpus? Finally, third, can we build tools for subjectivity analysis for a new target language by relying on these automatically generated resources?

We focus our experiments on Romanian, selected as a representative of the large number of languages that have only limited text processing resources developed to date. Note that, although we work with Romanian, the methods described are applicable to any other language, as in these experiments we (purposely) do not use any language-specific knowledge of the target language. Given a bridge between English and the selected target language (e.g., a bilingual dictionary or a parallel corpus), the methods can be applied to other languages as well.

After providing motivations, we present two approaches to developing sentence-level subjectivity classifiers for a new target language. The first uses a subjectivity lexicon translated from an English one. The second uses an English subjectivity classifier and a parallel corpus to create target-language training data for developing a statistical classifier.

2 Motivation

Automatic subjectivity analysis methods have been used in a wide variety of text processing applications, such as tracking sentiment timelines in online forums and news (Lloyd et al., 2005; Balog et al., 2006), review classification (Turney, 2002; Pang et al., 2002), mining opinions from product reviews (Hu and Liu, 2004), automatic expressive text-to-speech synthesis (Alm et al., 2005), text semantic analysis (Wiebe and Mihalcea, 2006; Esuli and Sebastiani, 2006), and question answering (Yu and Hatzivassiloglou, 2003).

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 976–983,
Prague, Czech Republic, June 2007.

While much recent work in subjectivity analysis focuses on *sentiment* (a type of subjectivity, namely positive and negative emotions, evaluations, and judgments), we opt to focus on recognizing subjectivity in general, for two reasons.

First, even when sentiment is the desired focus, researchers in sentiment analysis have shown that a two-stage approach is often beneficial, in which subjective instances are distinguished from objective ones, and then the subjective instances are further classified according to polarity (Yu and Hatzivassiloglou, 2003; Pang and Lee, 2004; Wilson et al., 2005; Kim and Hovy, 2006). In fact, the problem of distinguishing subjective versus objective instances has often proved to be more difficult than subsequent polarity classification, so improvements in subjectivity classification promise to positively impact sentiment classification. This is reported in studies of manual annotation of phrases (Takamura et al., 2006), recognizing contextual polarity of expressions (Wilson et al., 2005), and sentiment tagging of words and word senses (Andreevskaia and Bergler, 2006; Esuli and Sebastiani, 2006).

Second, an NLP application may seek a wide range of types of subjectivity attributed to a person, such as their motivations, thoughts, and speculations, in addition to their positive and negative sentiments. For instance, the opinion tracking system Lydia (Lloyd et al., 2005) gives separate ratings for subjectivity and sentiment. These can be detected with subjectivity analysis but not by a method focused only on sentiment.

There is world-wide interest in text analysis applications. While work on subjectivity analysis in other languages is growing (e.g., Japanese data are used in (Takamura et al., 2006; Kanayama and Nasukawa, 2006), Chinese data are used in (Hu et al., 2005), and German data are used in (Kim and Hovy, 2006)), much of the work in subjectivity analysis has been applied to English data. Creating corpora and lexical resources for a new language is very time consuming. In general, we would like to leverage resources already developed for one language to more rapidly create subjectivity analysis tools for a new one. This motivates our exploration and use of cross-lingual lexicon translations and annotation projections.

Most if not all work on subjectivity analysis has been carried out in a monolingual framework. We are not aware of multi-lingual work in subjectivity analysis such as that proposed here, in which subjectivity analysis resources developed for one language are used to support developing resources in another.

3 A Lexicon-Based Approach

Many subjectivity and sentiment analysis tools rely on manually or semi-automatically constructed lexicons (Yu and Hatzivassiloglou, 2003; Riloff and Wiebe, 2003; Kim and Hovy, 2006). Given the success of such techniques, the first approach we take to generating a target-language subjectivity classifier is to create a subjectivity lexicon by translating an existing source language lexicon, and then build a classifier that relies on the resulting lexicon.

Below, we describe the translation process and discuss the results of an annotation study to assess the quality of the translated lexicon. We then describe and evaluate a lexicon-based target-language classifier.

3.1 Translating a Subjectivity Lexicon

The subjectivity lexicon we use is from OpinionFinder (Wiebe and Riloff, 2005), an English subjectivity analysis system which, among other things, classifies sentences as subjective or objective. The lexicon was compiled from manually developed resources augmented with entries learned from corpora. It contains 6,856 unique entries, out of which 990 are multi-word expressions. The entries in the lexicon have been labeled for part of speech, and for reliability – those that appear most often in subjective contexts are *strong* clues of subjectivity, while those that appear less often, but still more often than expected by chance, are labeled *weak*.

To perform the translation, we use two bilingual dictionaries. The first is an authoritative English-Romanian dictionary, consisting of 41,500 entries,[1] which we use as the main translation resource for the lexicon translation. The second dictionary, drawn from the Universal Dictionary download site (UDP, 2007) consists of 4,500 entries written largely by Web volunteer contributors, and thus is not error free. We use this dictionary only for those entries that do not appear in the main dictionary.

[1]Unique English entries, each with multiple Romanian translations.

There were several challenges encountered in the translation process. First, although the English subjectivity lexicon contains inflected words, we must use the lemmatized form in order to be able to translate the entries using the bilingual dictionary. However, words may lose their subjective meaning once lemmatized. For instance, the inflected form of *memories* becomes *memory*. Once translated into Romanian (as *memorie*), its main meaning is objective, referring to the power of retaining information as in *Iron supplements may improve a woman's memory*.

Second, neither the lexicon nor the bilingual dictionary provides information on the sense of the individual entries, and therefore the translation has to rely on the most probable sense in the target language. Fortunately, the bilingual dictionary lists the translations in reverse order of their usage frequencies. Nonetheless, the ambiguity of the words and the translations still seems to represent an important source of error. Moreover, the lexicon sometimes includes identical entries expressed through different parts of speech, e.g., *grudge* has two separate entries, for its noun and verb roles, respectively. On the other hand, the bilingual dictionary does not make this distinction, and therefore we have again to rely on the "most frequent" heuristic captured by the translation order in the bilingual dictionary.

Finally, the lexicon includes a significant number (990) of multi-word expressions that pose translation difficulties, sometimes because their meaning is idiomatic, and sometimes because the multi-word expression is not listed in the bilingual dictionary and the translation of the entire phrase is difficult to reconstruct from the translations of the individual words. To address this problem, when a translation is not found in the dictionary, we create one using a word-by-word approach. These translations are then validated by enforcing that they occur at least three times on the Web, using counts collected from the AltaVista search engine. The multi-word expressions that are not validated in this process are discarded, reducing the number of expressions from an initial set of 990 to a final set of 264.

The final subjectivity lexicon in Romanian contains 4,983 entries. Table 1 shows examples of entries in the Romanian lexicon, together with their corresponding original English form. The table also shows the reliability of the expression (*weak* or *strong*) and the part of speech – attributes that are provided in the English subjectivity lexicon.

Romanian	English	attributes
înfrumuseţa	beautifying	strong, verb
notabil	notable	weak, adj
plin de regret	full of regrets	strong, adj
sclav	slaves	weak, noun

Table 1: Examples of entries in the Romanian subjectivity lexicon

Manual Evaluation.
We want to assess the quality of the translated lexicon, and compare it to the quality of the original English lexicon. The English subjectivity lexicon was evaluated in (Wiebe and Riloff, 2005) against a corpus of English-language news articles manually annotated for subjectivity (the *MPQA* corpus (Wiebe et al., 2005)). According to this evaluation, 85% of the instances of the clues marked as *strong* and 71.5% of the clues marked as *weak* are in subjective sentences in the MPQA corpus.

Since there is no comparable Romanian corpus, an alternate way to judge the subjectivity of a Romanian lexicon entry is needed.

Two native speakers of Romanian annotated the subjectivity of 150 randomly selected entries. Each annotator independently read approximately 100 examples of each drawn from the Web, including a large number from news sources. The subjectivity of a word was consequently judged in the contexts where it most frequently appears, accounting for its most frequent meanings on the Web.

The tagset used for the annotations consists of *S(ubjective)*, *O(bjective)*, and *B(oth)*. A *W(rong)* label is also used to indicate a wrong translation. Table 2 shows the contingency table for the two annotators' judgments on this data.

	S	O	B	W	Total
S	53	6	9	0	68
O	1	27	1	0	29
B	5	3	18	0	26
W	0	0	0	27	27
Total	59	36	28	27	150

Table 2: Agreement on 150 entries in the Romanian lexicon

Without counting the wrong translations, the agreement is measured at 0.80, with a Kappa κ =

0.70, which indicates consistent agreement. After the disagreements were reconciled through discussions, the final set of 123 correctly translated entries does include 49.6% (61) subjective entries, but fully 23.6% (29) were found in the study to have primarily objective uses (the other 26.8% are mixed).

Thus, this study suggests that the Romanian subjectivity clues derived through translation are less reliable than the original set of English clues. In several cases, the subjectivity is lost in the translation, mainly due to word ambiguity in either the source or target language, or both. For instance, the word *fragile* correctly translates into Romanian as *fragil*, yet this word is frequently used to refer to breakable objects, and it loses its subjective meaning of *delicate*. Other words, such as *one-sided*, completely lose subjectivity once translated, as it becomes in Romanian *cu o singura latură*, meaning *with only one side* (as of objects).

Interestingly, the reliability of clues in the English lexicon seems to help preserve subjectivity. Out of the 77 entries marked as *strong*, 11 were judged to be objective in Romanian (14.3%), compared to 14 objective Romanian entries obtained from the 36 *weak* English clues (39.0%).

3.2 Rule-based Subjectivity Classifier Using a Subjectivity Lexicon

Starting with the Romanian lexicon, we developed a lexical classifier similar to the one introduced by (Riloff and Wiebe, 2003). At the core of this method is a high-precision subjectivity and objectivity classifier that can label large amounts of raw text using only a subjectivity lexicon. Their method is further improved with a bootstrapping process that learns extraction patterns. In our experiments, however, we apply only the rule-based classification step, since the extraction step cannot be implemented without tools for syntactic parsing and information extraction not available in Romanian.

The classifier relies on three main heuristics to label subjective and objective sentences: (1) if two or more strong subjective expressions occur in the same sentence, the sentence is labeled *Subjective*; (2) if no strong subjective expressions occur in a sentence, and at most two weak subjective expressions occur in the previous, current, and next sentence combined, then the sentence is labeled *Objective*; (3) otherwise, if none of the previous rules apply, the sentence is labeled *Unknown*.

The quality of the classifier was evaluated on a Romanian gold-standard corpus annotated for subjectivity. Two native Romanian speakers (Ro_1 and Ro_2) manually annotated the subjectivity of the sentences of five randomly selected documents (504 sentences) from the Romanian side of an English-Romanian parallel corpus, according to the annotation scheme in (Wiebe et al., 2005). Agreement between annotators was measured, and then their differences were adjudicated. The baseline on this data set is 54.16%, which can be obtained by assigning a default *Subjective* label to all sentences. (More information about the corpus and annotations are given in Section 4 below, where agreement between English and Romanian aligned sentences is also assessed.)

As mentioned earlier, due to the lexicon projection process that is performed via a bilingual dictionary, the entries in our Romanian subjectivity lexicon are in a lemmatized form. Consequently, we also lemmatize the gold-standard corpus, to allow for the identification of matches with the lexicon. For this purpose, we use the Romanian lemmatizer developed by Ion and Tufiş (Ion, 2007), which has an estimated accuracy of 98%.[2]

Table 3 shows the results of the rule-based classifier. We show the precision, recall, and F-measure independently measured for the subjective, objective, and all sentences. We also evaluated a variation of the rule-based classifier that labels a sentence as objective if there are at most three weak expressions in the previous, current, and next sentence combined, which raises the recall of the objective classifier. Our attempts to increase the recall of the subjective classifier all resulted in significant loss in precision, and thus we kept the original heuristic.

In its original English implementation, this system was proposed as being high-precision but low coverage. Evaluated on the MPQA corpus, it has subjective precision of 90.4, subjective recall of 34.2, objective precision of 82.4, and objective recall of 30.7; overall, precision is 86.7 and recall is 32.6 (Wiebe and Riloff, 2005). We see a similar behavior on Romanian for subjective sentences. The subjective precision is good, albeit at the cost of low

[2] Dan Tufiş, personal communication.

Measure	Subjective	Objective	All
subj = at least two strong; obj = at most two weak			
Precision	80.00	56.50	62.59
Recall	20.51	48.91	33.53
F-measure	32.64	52.52	43.66
subj = at least two strong; obj = at most three weak			
Precision	80.00	56.85	61.94
Recall	20.51	61.03	39.08
F-measure	32.64	58.86	47.93

Table 3: Evaluation of the rule-based classifier

recall, and thus the classifier could be used to harvest subjective sentences from unlabeled Romanian data (e.g., for a subsequent bootstrapping process). The system is not very effective for objective classification, however. Recall that the objective classifier relies on the weak subjectivity clues, for which the transfer of subjectivity in the translation process was particularly low.

4 A Corpus-Based Approach

Given the low number of subjective entries found in the automatically generated lexicon and the subsequent low recall of the lexical classifier, we decided to also explore a second, corpus-based approach. This approach builds a subjectivity-annotated corpus for the target language through projection, and then trains a statistical classifier on the resulting corpus (numerous statistical classifiers have been trained for subjectivity or sentiment classification, e.g., (Pang et al., 2002; Yu and Hatzivassiloglou, 2003)). The hypothesis is that we can eliminate some of the ambiguities (and consequent loss of subjectivity) observed during the lexicon translation by accounting for the context of the ambiguous words, which is possible in a corpus-based approach. Additionally, we also hope to improve the recall of the classifier, by addressing those cases not covered by the lexicon-based approach.

In the experiments reported in this section, we use a parallel corpus consisting of 107 documents from the SemCor corpus (Miller et al., 1993) and their manual translations into Romanian.[3] The corpus consists of roughly 11,000 sentences, with approximately 250,000 tokens on each side. It is a balanced corpus covering a number of topics in sports, politics, fashion, education, and others.

[3]The translation was carried out by a Romanian native speaker, student in a department of "Foreign Languages and Translations" in Romania.

Below, we begin with a manual annotation study to assess the quality of annotation and preservation of subjectivity in translation. We then describe the automatic construction of a target-language training set, and evaluate a classifier trained on that data.

Annotation Study.
We start by performing an agreement study meant to determine the extent to which subjectivity is preserved by the cross-lingual projections. In the study, three annotators – one native English speaker (*En*) and two native Romanian speakers (Ro_1 and Ro_2) – first trained on 3 randomly selected documents (331 sentences). They then independently annotated the subjectivity of the sentences of two randomly selected documents from the parallel corpus, accounting for 173 aligned sentence pairs. The annotators had access exclusively to the version of the sentences in their language, to avoid any bias that could be introduced by seeing the translation in the other language.

Note that the Romanian annotations (after all differences between the Romanian annotators were adjudicated) of all 331 + 173 sentences make up the gold standard corpus used in the experiments reported in Sections 3.2 and 4.1.

Before presenting the results of the annotation study, we give some examples. The following are English subjective sentences and their Romanian translations (the subjective elements are shown in bold).

> [en] **The desire to** give Broglio as many starts as possible.
> [ro] **Dorinţa de** a-i da lui Broglio cât mai multe starturi posibile.

> [en] **Suppose** he did lie beside Lenin, **would it be permanent ?**
> [ro] **Să presupunem** că ar fi aşezat alături de Lenin, **oare va fi pentru totdeauna?**

The following are examples of objective parallel sentences.

> [en]The Pirates have a 9-6 record this year and the Redbirds are 7-9.
> [ro] Piraţii au un palmares de 9 la 6 anul acesta si Păsările Roşii au 7 la 9.

> [en] One of the obstacles to the easy control of a 2-year old child is a lack of verbal communication.
> [ro] Unul dintre obstacolele în controlarea unui copil de 2 ani este lipsa comunicării verbale.

The annotators were trained using the MPQA annotation guidelines (Wiebe et al., 2005). The tagset consists of *S(ubjective)*, *O(bjective)* and *U(ncertain)*. For the *U* tags, a class was also given; *OU* means, for instance, that the annotator is uncertain but she is leaning toward *O*. Table 4 shows the pairwise agreement figures and the Kappa (κ) calculated for the three annotators. The table also shows the agreement when the borderline uncertain cases are removed.

	all sentences		Uncertain removed		
pair	agree	κ	agree	κ	(%) removed
Ro_1 & Ro_2	0.83	0.67	0.89	0.77	23
En & Ro_1	0.77	0.54	0.86	0.73	26
En & Ro_2	0.78	0.55	0.91	0.82	20

Table 4: Agreement on the data set of 173 sentences. Annotations performed by three annotators: one native English speaker (*En*) and two native Romanian speakers (Ro_1 and Ro_2)

When all the sentences are included, the agreement between the two Romanian annotators is measured at 0.83 (κ = 0.67). If we remove the borderline cases where at least one annotator's tag is *Uncertain*, the agreement rises to 0.89 with κ = 0.77. These figures are somewhat lower than the agreement observed during previous subjectivity annotation studies conducted on English (Wiebe et al., 2005) (the annotators were more extensively trained in those studies), but they nonetheless indicate consistent agreement.

Interestingly, when the agreement is conducted cross-lingually between an English and a Romanian annotator, the agreement figures, although somewhat lower, are comparable. In fact, once the *Uncertain* tags are removed, the monolingual and cross-lingual agreement and κ values become almost equal, which suggests that in most cases the sentence-level subjectivity is preserved.

The disagreements were reconciled first between the labels assigned by the two Romanian annotators, followed by a reconciliation between the resulting Romanian "gold-standard" labels and the labels assigned by the English annotator. In most cases, the disagreement across the two languages was found to be due to a difference of opinion about the sentence subjectivity, similar to the differences encountered in monolingual annotations. However, there are cases where the differences are due to the subjectivity being lost in the translation. Sometimes, this is due to several possible interpretations for the translated sentence. For instance, the following sentence:

> [en] They **honored** the battling Billikens last night.
> [ro] Ei i-au celebrat pe Billikens seara trecută.

is marked as *Subjective* in English (in context, the English annotator interpreted *honored* as referring to praises of the Billikens). However, the Romanian translation of *honored* is *celebrat* which, while correct as a translation, has the more frequent interpretation of *having a party.* The two Romanian annotators chose this interpretation, which correspondingly lead them to mark the sentence as *Objective*.

In other cases, in particular when the subjectivity is due to figures of speech such as irony, the translation sometimes misses the ironic aspects. For instance, the translation of *egghead* was not perceived as ironic by the Romanian annotators, and consequently the following sentence labeled *Subjective* in English is annotated as *Objective* in Romanian.

> [en] I have lived for many years in a Connecticut commuting town with a high percentage of [...] business executives of **egghead** tastes.
> [ro] Am trăit mulţi ani într-un oraş din apropiere de Connecticut ce avea o mare proporţie de [...] oameni de afaceri cu gusturi intelectuale.

4.1 Translating a Subjectivity-Annotated Corpus and Creating a Machine Learning Subjectivity Classifier

To further validate the corpus-based projection of subjectivity, we developed a subjectivity classifier trained on Romanian subjectivity-annotated corpora obtained via cross-lingual projections.

Ideally, one would generate an annotated Romanian corpus by translating English documents manually annotated for subjectivity such as the MPQA corpus. Unfortunately, the manual translation of this corpus would be prohibitively expensive, both timewise and financially. The other alternative – automatic machine translation – has not yet reached a level that would enable the generation of a high-quality translated corpus. We therefore decided to use a different approach where we automatically annotate the English side of an existing English-Romanian corpus, and subsequently project the annotations onto the Romanian side of the parallel cor-

	Precision	Recall	F-measure
high-precision	86.7	32.6	47.4
high-coverage	79.4	70.6	74.7

Table 5: Precision, recall, and F-measure for the two OpinionFinder classifiers, as measured on the MPQA corpus.

pus across the sentence-level alignments available in the corpus.

For the automatic subjectivity annotations, we generated two sets of the English-side annotations, one using the high-precision classifier and one using the high-coverage classifier available in the OpinionFinder tool. The high-precision classifier in OpinionFinder uses the clues of the subjectivity lexicon to harvest subjective and objective sentences from a large amount of unannotated text; this data is then used to automatically identify a set of extraction patterns, which are then used iteratively to identify a larger set of subjective and objective sentences.

In addition, in OpinionFinder, the high-precision classifier is used to produce an English labeled data set for training, which is used to generate its Naive Bayes high-coverage subjectivity classifier. Table 5 shows the performance of the two classifiers on the MPQA corpus as reported in (Wiebe and Riloff, 2005). Note that 55% of the sentences in the MPQA corpus are subjective – which represents the baseline for this data set.

The two OpinionFinder classifiers are used to label the training corpus. After removing the 504 test sentences, we are left with 10,628 sentences that are automatically annotated for subjectivity. Table 6 shows the number of subjective and objective sentences obtained with each classifier.

Classifier	Subjective	Objective	All
high-precision	1,629	2,334	3,963
high-coverage	5,050	5,578	10,628

Table 6: Subjective and objective training sentences automatically annotated with OpinionFinder.

Next, the OpinionFinder annotations are projected onto the Romanian training sentences, which are then used to develop a probabilistic classifier for the automatic labeling of subjectivity in Romanian sentences.

Similar to, e.g., (Pang et al., 2002), we use a Naive Bayes algorithm trained on word features co-occurring with the subjective and the objective classifications. We assume word independence, and we use a 0.3 cut-off for feature selection. While recent work has also considered more complex syntactic features, we are not able to generate such features for Romanian as they require tools currently not available for this language.

We create two classifiers, one trained on each data set. The quality of the classifiers is evaluated on the 504-sentence Romanian gold-standard corpus described above. Recall that the baseline on this data set is 54.16%, the percentage of sentences in the corpus that are subjective. Table 7 shows the results.

	Subjective	Objective	All
projection source: OF high-precision classifier			
Precision	65.02	69.62	64.48
Recall	82.41	47.61	64.48
F-measure	72.68	56.54	64.68
projection source: OF high-coverage classifier			
Precision	66.66	70.17	67.85
Recall	81.31	52.17	67.85
F-measure	72.68	56.54	67.85

Table 7: Evaluation of the machine learning classifier using training data obtained via projections from data automatically labeled by OpinionFinder (OF).

Our best classifier has an F-measure of 67.85, and is obtained by training on projections from the high-coverage OpinionFinder annotations. Although smaller than the 74.70 F-measure obtained by the English high-coverage classifier (see Table 5), the result appears remarkable given that no language-specific Romanian information was used.

The overall results obtained with the machine learning approach are considerably higher than those obtained from the rule-based classifier (except for the precision of the subjective sentences). This is most likely due to the lexicon translation process, which as mentioned in the agreement study in Section 3.1, leads to ambiguity and loss of subjectivity. Instead, the corpus-based translations seem to better account for the ambiguity of the words, and the subjectivity is generally preserved in the sentence translations.

5 Conclusions

In this paper, we described two approaches to generating resources for subjectivity annotations for a new

language, by leveraging on resources and tools available for English. The first approach builds a target language subjectivity lexicon by translating an existing English lexicon using a bilingual dictionary. The second generates a subjectivity-annotated corpus in a target language by projecting annotations from an automatically annotated English corpus.

These resources were validated in two ways. First, we carried out annotation studies measuring the extent to which subjectivity is preserved across languages in each of the two resources. These studies show that only a relatively small fraction of the entries in the lexicon preserve their subjectivity in the translation, mainly due to the ambiguity in both the source and the target languages. This is consistent with observations made in previous work that subjectivity is a property associated not with words, but with word *meanings* (Wiebe and Mihalcea, 2006). In contrast, the sentence-level subjectivity was found to be more reliably preserved across languages, with cross-lingual inter-annotator agreements comparable to the monolingual ones.

Second, we validated the two automatically generated subjectivity resources by using them to build a tool for subjectivity analysis in the target language. Specifically, we developed two classifiers: a rule-based classifier that relies on the subjectivity lexicon described in Section 3.1, and a machine learning classifier trained on the subjectivity-annotated corpus described in Section 4.1. While the highest precision for the subjective classification is obtained with the rule-based classifier, the overall best result of 67.85 F-measure is due to the machine learning approach. This result is consistent with the annotation studies, showing that the corpus projections preserve subjectivity more reliably than the lexicon translations.

Finally, neither one of the classifiers relies on language-specific information, but rather on knowledge obtained through projections from English. A similar method can therefore be used to derive tools for subjectivity analysis in other languages.

Abstract

Text is not unadulterated fact. A text can make you laugh or cry but can it also make you short sell your stocks in company A and buy up options in company B? Research in the domain of finance strongly suggests that it can. Studies have shown that both the informational and affective aspects of news text affect the markets in profound ways, impacting on volumes of trades, stock prices, volatility and even future firm earnings. This paper aims to explore a computable metric of positive or negative polarity in financial news text which is consistent with human judgments and can be used in a quantitative analysis of news sentiment impact on financial markets. Results from a preliminary evaluation are presented and discussed.

1 Introduction

Research in sentiment analysis has emerged to address the research questions: what is affect in text? what features of text serve to convey it? how can these features be detected and measured automatically. Sentence and phrase level sentiment analysis involves a systematic examination of texts, such as blogs, reviews and news reports, for positive, negative or neutral emotions (Wilson et al., 2005; Grefenstette et al., 2004). The term "sentiment analysis" is used rather differently in financial economics where it refers to the derivation of market confidence indicators from proxies such as stock prices and trading volumes. There is a tradition going back to the Nobel Sveriges–Riksbank Laureates Herbert Simon (1978 Prize) and Daniel Kahneman (2002 Prize), that shows that investors and traders in such markets can behave irrationally and that this bounded rationality is inspired by what the traders and investors hear from others about the conditions that may or may not prevail in the markets. Robert Engle (2003 Prize) has given a mathematical description of the asymmetric and affective impact of news on prices: positive news is typically related to large changes in prices but only for a short time; conversely the effect of negative news on prices and volumes of trading is longer lasting. The emergent domain of sociology of finance examines financial markets as social constructs and how communications, such as e-mails and news reports, may be loaded with sentiment which could distort market trading (MacKenzie, 2003).

It would appear that news affects the markets in profound ways, impacting on volumes of trade, stock returns, volatility of prices and even future firm earnings. In the domain of news impact analysis in finance, in recent years the focus has expanded from informational to affective content of text in an effort to explain the relationship between text and the markets. All text, be it news, blogs, accounting reports or poetry, has a non-factual dimension conveying opinion, invoking emotion, providing a nuanced perspective of the factual content of the text. With the increase of computational power and lexical and corpus resources it seems computationally feasible to detect some of the affective content of text automatically. The motivation for the work reported here is to identify a metric for sentiment po-

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 984–991,
Prague, Czech Republic, June 2007.

larity which reliably replicates human evaluations and which is readily derivable from free text. This research is being carried out in the context of a study of the impact of news and its attendant biases on financial markets, formalizing earlier multi-lingual, corpus-based empirical work that analysed change in sentiment and volume of news in large financial news corpora (Ahmad et al., 2006). A systematic analysis of the impact of news bias or polarity on market variables requires a numeric value for sentiment intensity, as well as a binary tag for sentiment polarity, to identify trends in the sentiment indicator as well as turning points. In this approach, the contribution to an overall sentiment polarity and intensity metric of individual lexical items which are "affective" by definition is determined by their connectivity and position within a representation of the text as a whole based on the principles of lexical cohesion. The contribution of each element is therefore not purely additive but rather is mitigated by its relevance and position relative to other elements.

Section 2 sets out related work in the sentiment analysis domain both in computational linguistics and in finance where these techniques have been applied with some success. Section 3 outlines the cohesion-based algorithm for sentiment polarity detection, the resources used and the benefits of using the graph-based text representation approach. This approach was evaluated relative to a small corpus of gold standard sentiment judgments. The derivation of the gold standard and details of the evaluation are outlined in section 4. The results are presented and discussed in section 5 and section 6 concludes with a look at future challenges for this research.

2 Related Work

2.1 Cognitive Theories of Emotion

In order to understand how emotion can be realised in text, we must first have a notion of what emotion is and how people experience it. Current cognitive theories of what constitutes emotion are divided between two primary approaches: categorical and dimensional. The Darwinian categorical approach posits a finite set of basic emotions which are experienced universally across cultures, (e.g. anger, fear, sadness, surprise (Ekman and Friesen, 1971)). The second approach delineates emotions according to multiple dimensions rather than into discrete categories. The two primary dimensions in this account are a good–bad axis, the dimension of valence or evaluation, and a strong-weak axis, the dimension of activation or intensity (Osgood et al., 1957). The work reported here aims to conflate the evaluation and activation dimensions into one metric with the size of the value indicating strength of activation and its sign, polarity on the evaluation axis.

2.2 Sentiment Analysis

Sentiment analysis in computational linguistics has focused on examining what textual features (lexical, syntactic, punctuation, etc) contribute to affective content of text and how these features can be detected automatically to derive a sentiment metric for a word, sentence or whole text. Wiebe and colleagues have largely focused on identifying subjectivity in texts, i.e. identifying those texts which are affectively neutral and those which are not. This work has been grounded in a strong human evaluative component. The subjectivity identification research has moved from initial work using syntactic class, punctuation and sentence position features for subjectivity classifiers to later work using more lexical features like gradation of adjectives or word frequency (Wiebe et al., 1999; Wiebe et al., 2005). Others, such as Turney (2002), Pang and Vaithyanathan (2002), have examined the positive or negative polarity, rather than presence or absence, of affective content in text. Kim and Hovy (2004), among others, have combined the two tasks, identifying subjective text and detecting its sentiment polarity. The indicators of affective content have been drawn from lexical sources, corpora and the world wide web and combined in a variety of ways, including factor analysis and machine learning techniques, to determine when a text contains affective content and what is the polarity of that content.

2.3 Sentiment and News Impact Analysis

Niederhoffer (1971), academic and hedge fund manager, analysed 20 years of New York Times headlines classified into 19 semantic categories and on a good-bad rating scale to evaluate how the markets reacted to good and bed news: he found that markets do react to news with a tendency to overreact to bad news. Somewhat prophetically, he suggests

that news should be analysed by computers to introduce more objectivity in the analysis. Engle and Ng (1993) proposed the news impact curve as a model for how news impacts on volatility in the market with bad news introducing more volatility than good news. They used the market variable, stock returns, as a proxy for news, an unexpected drop in returns for bad news and an unexpected rise for good news. Indeed, much early work used such market variables or readily quantifiable aspects of news as a proxy for the news itself: e.g. news arrival, type, provenance and volumes (Cutler et al., 1989; Mitchell and Mulherin, 1994). More recent studies have proceeded in a spirit of computer-aided objectivity which entails determining linguistic features to be used to automatically categorise text into positive or negative news. Davis et al (2006) investigate the effects of optimistic or pessimistic language used in financial press releases on future firm performance. They conclude that a) readers form expectations regarding the habitual bias of writers and b) react more strongly to reports which violate these expectations, strongly suggesting that readers, and by extension the markets, form expectations about and react to not only content but also affective aspects of text. Tetlock (2007) also investigates how a pessimism factor, automatically generated from news text through term classification and principal components analysis, may forecast market activity, in particular stock returns. He finds that high negativity in news predicts lower returns up to 4 weeks around story release. The studies establish a relationship between affective bias in text and market activity that market players and regulators may have to address.

3 Approach

3.1 Cohesion-based Text Representation

The approach employed here builds on a cohesion-based text representation algorithm used in a news story comparison application described in (Devitt, 2004). The algorithm builds a graph representation of text from part-of-speech tagged text without disambiguation using WordNet (Fellbaum, 1998) as a real world knowledge source to reduce information loss in the transition from text to text-based structure. The representation is designed within the theoretical framework of lexical cohesion (Halliday and Hasan, 1976). Aspects of the cohesive structure of a text are captured in a graph representation which combines information derived from the text and WordNet semantic content. The graph structure is composed of nodes representing concepts in or derived from the text connected by relations between these concepts in WordNet, such as antonymy or hypernymy, or derived from the text, such as adjacency in the text. In addition, the approach provides the facility to manipulate or control how the WordNet semantic content information is interpreted through the use of topological features of the knowledge base. In order to evaluate the relative contribution of WordNet concepts to the information content of a text as a whole, a node specificity metric was derived based on an empirical analysis of the distribution of topological features of WordNet such as inheritance, hierarchy depth, clustering coefficients and node degree and how these features map onto human judgments of concept specificity or informativity. This metric addresses the issue of the uneven population of most knowledge bases so that the local idiosyncratic characteristics of WordNet can be mitigated by some of its global features.

3.2 Sentiment Polarity Overlay

By exploiting existing lexical resources for sentiment analysis, an explicit affective dimension can be overlaid on this basic text model. Our approach to polarity measurement, like others, relies on a lexicon of tagged positive and negative sentiment terms which are used to quantify positive/negative sentiment. In this first iteration of the work, SentiWN (Esuli and Sebastiani, 2006) was used as it provides a readily interpretable positive and negative polarity value for a set of "affective" terms which conflates Osgood's (1957) evaluative and activation dimensions. Furthermore, it is based on WordNet 2.0 and can therefore be integrated into the existing text representation algorithm, where some nodes in the cohesion graph carry a SentiWN sentiment value and others do not. The contribution of individual polarity nodes to the polarity metric of the text as a whole is then determined with respect to the textual information and WN semantic and topological features encoded in the underlying graph representation of the text. Three polarity metrics were implemented to evaluate the effectiveness of exploiting different

aspects of the cohesion-based graph structure.

Basic Cohesion Metric is based solely on frequency of sentiment-bearing nodes in *or derived from* the source text, i.e. the sum of polarity values for all nodes in the graph.

Relation Type Metric modifies the basic metric with respect to the types of WordNet relations in the text-derived graph. For each node in the graph, its sentiment value is the product of its polarity value and a relation weight for each relation this node enters into in the graph structure. Unlike most lexical chaining algorithms, not all WordNet relations are treated as equal. In this sentiment overlay, the relations which are deemed most relevant are those that potentially denote a relation of the affective dimension, like antonymy, and those which constitute key organising principles of the database, such as hypernymy. Potentially affect-effecting relations have the strongest weighting while more amorphous relations, such as "also see", have the lowest.

Node Specificity Metric modifies the basic metric with respect to a measure of node specificity calculated on the basis of topographical features of WordNet. The intuition behind this measure is that highly specific nodes or concepts may carry more informational and, by extension, affective content than less specific ones. We have noted the difficulty of using a knowledge base whose internal structure is not homogeneous and whose idiosyncrasies are not quantified. The specificity measure aims to factor out population sparseness or density in WordNet by evaluating the contribution of each node relative to its depth in the hierarchy, its connectivity (branchingFactor) and its siblings:

$$Spc = \frac{(depth + \ln(siblings) - ln(branchingFactor))}{NormalizingFactor} \quad (1)$$

The three metrics are further specialised according to the following two boolean flags:

InText: the metric is calculated based on 1) only those nodes representing terms in the source text, or 2) all nodes in the graph representation derived from the text. In this way, the metrics can be calculated using information derived from the graph representation, such as node specificity, without potentially noisy contributions from nodes not in the source text but related to them, via relations such as hypernymy.

Modifiers: the metric is calculated using all open class parts of speech or modifiers alone. On a cursory inspection of SentiWN, it seems that modifiers have more reliable values than nouns or verbs. This option was included to test for possible adverse effects of the lexicon.

In total for each metric there are four outcomes combining **inText** true/false and **modifiers** true/false.

4 Evaluation

The goal of this research is to examine the relationship between financial markets and financial news, in particular the polarity of financial news. The domain of finance provides data and methods for solid quantitative analysis of the impact of sentiment polarity in news. However, in order to engage with this long tradition of analysis of the instruments and related variables of the financial markets, the quantitative measure of polarity must be not only easy to compute, it must be consistent with human judgments of polarity in this domain. This evaluation is a first step on the path to establishing reliability for a sentiment measure of news. Unfortunately, the focus on news, as opposed to other text types, has its difficulties. Much of the work in sentiment analysis in the computational linguistics domain has focused either on short segments, such as sentences (Wilson et al., 2005), or on longer documents with an explicit polarity orientation like movie or product reviews (Turney, 2002). Not all news items may express overt sentiment. Therefore, in order to test our hypothesis, we selected a news topic which was considered a priori to have emotive content.

4.1 Corpus

Markets react strongest to information about firms to which they have an emotional attachment (MacGregor et al., 2000). Furthermore, takeovers and mergers are usually seen as highly emotive contexts. To combine these two emotion-enhancing factors, a corpus of news texts was compiled on the topic of the aggressive takeover bid of a low-cost airline (Ryanair) for the Irish flag-carrier airline (Aer Lingus). Both airlines have a strong (positive and negative) emotional attachment for many in Ireland. Furthermore, both airlines are highly visible within the country and have vocal supporters and detractors in the public arena. The corpus is drawn from the

national media and international news wire sources and spans 4 months in 2006 from the flotation of the flag carrier on the stock exchange in September 2006, through the "surprise" take-over bid announcement by Ryanair, to the withdrawal of the bid by Ryanair in December 2006.[1]

4.2 Gold Standard

A set of 30 texts selected from the corpus was annotated by 3 people on a 7-point scale from *very positive* to *very negative*. Given that a takeover bid has two players, the respondents were asked also to rate the semantic orientation of the texts with respect to the two players, Ryanair and Aer Lingus. Respondents were all native English speakers, 2 female and 1 male. To ensure emotional engagement in the task, they were first asked to rate their personal attitude to the two airlines. The ratings in all three cases were on the extreme ends of the 7 point scale, with very positive attitudes towards the flag carrier and very negative attitudes towards the low-cost airline. Respondent attitudes may impact on their text evaluations but, given the high agreement of attitudes in this study, this impact should at least be consistent across the individuals in the study. A larger study should control explicitly for this variable.

As the respondents gave ratings on a ranked scale, inter-respondent reliability was determined using Krippendorf's alpha, a modification of the Kappa coefficient for ordinal data (Krippendorff, 1980). On the general ranking scale, there was little agreement ($kappa = 0.1685$), corroborating feedback from respondents on the difficulty of providing a general rating for text polarity distinct from a rating with respect to one of the two companies. However, there was an acceptable degree of agreement (Grove et al., 1981) on the Ryanair and Aer Lingus polarity ratings, $kappa = 0.5795$ and $kappa = 0.5589$ respectively. Results report correlations with these ratings which are consistent and, from the financial market perspective, potentially more interesting.[2]

[1] A correlation analysis of human sentiment ratings with Ryanair and Aer Lingus stock prices for the last quarter of 2006 was conducted. The findings suggest that stock prices were correlated with ratings with respect to Aer Lingus, suggesting that, during this takeover period, investors may have been influenced by sentiment expressed in news towards Aer Lingus. However, the timeseries is too short to ensure statistical significance.

[2] Results in this paper are reported with respect to the Ryanair ratings as they had the highest inter-rater agreement.

4.3 Performance Metrics

The performance of the polarity algorithm was evaluated relative to a corpus of human-annotated news texts, focusing on two separate dimensions of polarity:

1. Polarity direction: the task of assigning a binary positive/negative value to a text
2. Polarity intensity: the task of assigning a value to indicate the strength of the negative/positive polarity in a text.

Performance on the former is reported using standard recall and precision metrics. The latter is reported as a correlation with average human ratings.

4.4 Baseline

For the metrics in section 3, the baseline for comparison sums the SentiWN polarity rating for only those lexical items present in the text, not exploiting any aspect of the graph representation of the text. This baseline corresponds to the Basic Cohesion Metric, with $inText = true$ (only lexical items in the text) and $modifiers = false$ (all parts of speech).

5 Results and Discussion

5.1 Binary Polarity Assignment

The baseline results for positive ratings, negative ratings and overall accuracy for the task of assigning a polarity tag are reported in table 1. The results show

Type	Precision	Recall	FScore
Positive	0.381	0.7273	0.5
Negative	0.667	0.3158	0.4286
Overall	0.4667	0.4667	0.4667

Table 1: Baseline results

that the baseline tends towards the positive end of the rating spectrum, with high recall for positive ratings but low precision. Conversely, negative ratings have high precision but low recall. Figures 1 to 3 illustrate the performance for positive, negative and overall ratings of all metric–inText–Modifier combinations, enumerated in table 2, relative to this baseline, the horizontal. Those metrics which surpass this line are deemed to outperform the baseline.

1	Cohesion	**5**	Relation	**9**	NodeSpec
2	CohesionTxt	**6**	RelationTxt	**10**	NodeSpecTxt
3	CohesionMod	**7**	RelationMod	**11**	NodeSpecMod
4	CohesionTxtMod	**8**	RelationTxtMod	**12**	NodeSpecTxtMod

Table 2: Metric types in Figures 1-3

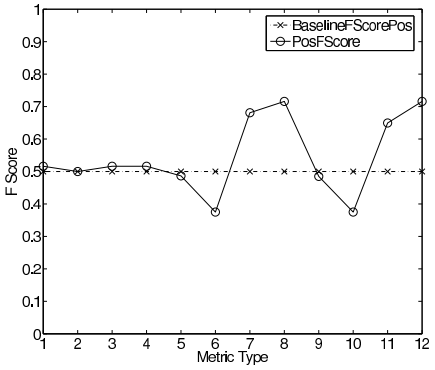

Figure 1: F Score for Positive Ratings

All metrics have a bias towards positive ratings with attendant high positive recall values and improved f-score for positive polarity assignments. The Basic Cohesion Metric marginally outperforms the baseline overall indicating that exploiting the graph structure gives some added benefit. For the Relations and Specificity metrics, system performance greatly improves on the baseline for the $modifiers = true$ options, whereas, when all parts of speech are included ($modifier = false$), performance drops significantly. This sensitivity to inclusion of all word classes could suggest that modifiers are better indicators of text polarity than other word classes or that the metrics used are not appropriate to non-modifier parts of speech. The former hypothesis is not supported by the literature while the latter is not supported by prior successful application of these metrics in a text comparison task. In order to investigate the source of this sensitivity, we intend to examine the distribution of relation types and node specificity values for sentiment-bearing terms to determine how best to tailor these metrics to the sentiment identification task.

A further hypothesis is that the basic polarity values for non-modifiers are less reliable than for adjectives and adverbs. On a cursory inspection of polarity values of nouns and adjectives in SentiWN, it would appear that adjectives are somewhat more reliably labelled than nouns. For example, crime and

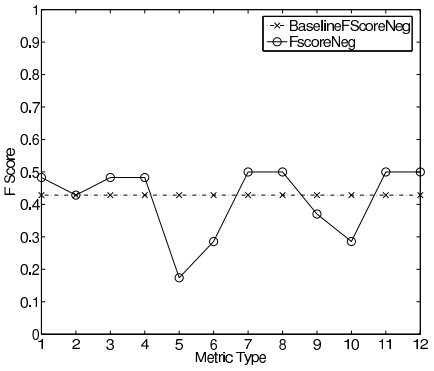

Figure 2: F Score for Negative Ratings

some of its hyponyms are labelled as neutral (e.g. forgery) or even positive (e.g. assault) whereas criminal is labelled as negative. This illustrates a key weakness in a lexical approach such as this: over-reliance on lexical resources. No lexical resource is infallible. It is therefore vital to spread the associated risk by using more than one knowledge source, e.g. multiple sentiment lexica or using corpus data.

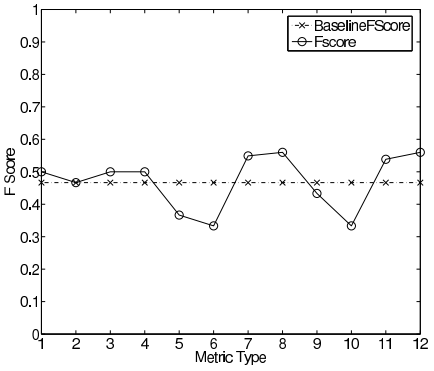

Figure 3: F Score for All Ratings

5.2 Polarity Intensity Values

The results on the polarity intensity task parallel the results on polarity tag assignment. Table 3 sets out the correlation coefficients for the metrics with respect to the average human rating. Again, the best performers are the relation type and node specificity metrics using only modifiers, significant to the 0.05 level. Yet the correlation coefficients overall are not very high. This would suggest that perhaps the relationship between the human ranking scale and the automatic one is not strictly linear. Although the human ratings map approximately onto the automati-

cally derived scale, there does not seem to be a clear one to one mapping. The section that follows discuss this and some of the other issues which this evaluation process has brought to light.

Metric	inText	Modifier	Correlation
Basic Cohesion	No	No	0.47**
	Yes	No	0.42*
	No	Yes	0.47**
	Yes	Yes	0.47**
Relation Type	No	No	-0.1**
	Yes	No	-0.13*
	No	Yes	0.5**
	Yes	Yes	0.38*
Node Specificity	No	No	0.00
	Yes	No	-0.03
	No	Yes	0.48**
	Yes	Yes	0.38*

Table 3: Correlation Coefficients for human ratings.
**. Significant at the 0.01 level. *. Significant at the 0.05 level.

5.3 Issues

The Rating Scale and Thresholding

Overall the algorithm tends towards the positive end of the spectrum in direct contrast to human raters with 55-70% of all ratings being negative. Furthermore, the correlation of human to algorithm ratings is significant but not strongly directional. It would appear that there are more positive lexical items in text, hence the algorithm's positive bias. Yet much of this positivity is not having a strong impact on readers, hence the negative bias observed in these evaluators. This raises questions about the scale of human polarity judgments: are people more sensitive to negativity in text? is there a positive baseline in text that people find unremarkable and ignore? To investigate this issue, we will conduct a comparative corpus analysis of the distribution of positive and negative lexical items in text and their perceived strengths in text. The results of this analysis should help to locate sentiment turning points or thresholds and establish an elastic sentiment scale which allows for baseline but disregarded positivity in text.

The Impact of the Lexicon

The algorithm described here is lexicon-based, fully reliant on available lexical resources. However, we have noted that an over-reliance on lexica has its disadvantages, as any hand-coded or corpus-derived lexicon will have some degree of error or inconsistency. In order to address this issue, it is necessary to spread the risk associated with a single lexical resource by drawing on multiple sources, as in (Kim and Hovy, 2005). The SentiWN lexicon used in this implementation is derived from a seed word set supplemented WordNet relations and as such it has not been psychologically validated. For this reason, it has good coverage but some inconsistency. Whissel's Dictionary of Affect (1989) on the other hand is based entirely on human ratings of terms. It's coverage may be narrower but accuracy might be more reliable. This dictionary also has the advantage of separating out Osgood's (1957) evaluative and activation dimensions as well as an "imaging" rating for each term to allow a multi-dimensional analysis of affective content. The WN Affect lexicon (Valitutti et al., 2004) again provides somewhat different rating types where terms are classified in terms of denoting or evoking different physical or mental affective reactions. Together, these resources could offer not only more accurate base polarity values but also more nuanced metrics that may better correspond to human notions of affect in text.

The Gold Standard

Sentiment rating evaluation is not a straight-forward task. Wiebe et al (2005) note many of the difficulties associated human sentiment ratings of text. As noted above, it can be even more difficult when evaluating news where the text is intended to appear impartial. The attitude of the evaluator can be all important: their attitude to the individuals or organisations in the text, their professional viewpoint as a market player or an ordinary punter, their attitude to uncertainty and risk which can be a key factor in the world of finance. In order to address these issues for the domain of news impact in financial markets, the expertise of market professionals must be elicited to determine what they look for in text and what viewpoint they adopt when reading financial news. In econometric analysis, stock price or trading volume data constitute an alternative gold standard, representing a proxy for human reaction to news. For economic significance, the data must span a time period of several years and compilation of a text and stock

price corpus for a large scale analysis is underway.

6 Conclusions and Future Work

This paper presents a lexical cohesion based metric of sentiment intensity and polarity in text and an evaluation of this metric relative to human judgments of polarity in financial news. We are conducting further research on how best to capture a psychologically plausible measure of affective content of text by exploiting available resources and a broader evaluation of the measure relative to human judgments and existing metrics. This research is expected to contribute to sentiment analysis in finance. Given a reliable metric of sentiment in text, what is the impact of changes in this value on market variables? This involves a sociolinguistic dimension to determine what publications or texts best characterise or are most read and have the greatest influence in this domain and the economic dimension of correlation with economic indicators.

Abstract

We investigate automatic classification of speculative language ('hedging'), in biomedical text using weakly supervised machine learning. Our contributions include a precise description of the task with annotation guidelines, analysis and discussion, a probabilistic weakly supervised learning model, and experimental evaluation of the methods presented. We show that hedge classification is feasible using weakly supervised ML, and point toward avenues for future research.

1 Introduction

The automatic processing of scientific papers using NLP and machine learning (ML) techniques is an increasingly important aspect of technical informatics. In the quest for a deeper machine-driven 'understanding' of the mass of scientific literature, a frequently occuring linguistic phenomenon that must be accounted for is the use of *hedging* to denote propositions of a speculative nature. Consider the following:

1. *Our results prove that XfK89 inhibits Felin-9.*
2. *Our results suggest that XfK89 might inhibit Felin-9.*

The second example contains a hedge, signaled by the use of *suggest* and *might*, which renders the proposition *inhibit(XfK89→Felin-9)* speculative. Such analysis would be useful in various applications; for instance, consider a system designed to identify and extract interactions between genetic entities in the biomedical domain. Case 1 above provides clear textual evidence of such an interaction and justifies extraction of *inhibit(XfK89→Felin-9)*, whereas case 2 provides only weak evidence for such an interaction.

Hedging occurs across the entire spectrum of scientific literature, though it is particularly common in the experimental natural sciences. In this study we consider the problem of learning to automatically classify sentences containing instances of hedging, given only a very limited amount of annotator-labelled 'seed' data. This falls within the *weakly supervised* ML framework, for which a range of techniques have been previously explored. The contributions of our work are as follows:

1. We provide a clear description of the problem of hedge classification and offer an improved and expanded set of annotation guidelines, which as we demonstrate experimentally are sufficient to induce a high level of agreement between independent annotators.
2. We discuss the specificities of hedge classification as a weakly supervised ML task.
3. We derive a probabilistic weakly supervised learning model and use it to motivate our approach.
4. We analyze our learning model experimentally and report promising results for the task on a new publicly-available dataset.[1]

2 Related Work

2.1 Hedge Classification

While there is a certain amount of literature within the linguistics community on the use of hedging in

[1] available from www.cl.cam.ac.uk/∼bwm23/

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 992–999,
Prague, Czech Republic, June 2007.

scientific text, eg. (Hyland, 1994), there is little of direct relevance to the task of classifying speculative language from an NLP/ML perspective.

The most clearly relevant study is Light et al. (2004) where the focus is on introducing the problem, exploring annotation issues and outlining potential applications rather than on the specificities of the ML approach, though they do present some results using a manually crafted substring matching classifier and a supervised SVM on a collection of *Medline* abstracts. We will draw on this work throughout our presentation of the task.

Hedging is sometimes classed under the umbrella concept of *subjectivity*, which covers a variety of linguistic phenomena used to express differing forms of authorial opinion (Wiebe et al., 2004). Riloff et al. (2003) explore bootstrapping techniques to identify subjective nouns and subsequently classify subjective vs. objective sentences in newswire text. Their work bears some relation to ours; however, our domains of interest differ (newswire vs. scientific text) and they do not address the problem of hedge classification directly.

2.2 Weakly Supervised Learning

Recent years have witnessed a significant growth of research into weakly supervised ML techniques for NLP applications. Different approaches are often characterised as either *multi-* or *single-view*, where the former generate multiple redundant (or semi-redundant) 'views' of a data sample and perform mutual bootstrapping. This idea was formalised by Blum and Mitchell (1998) in their presentation of *co-training*. Co-training has also been used for named entity recognition (NER) (Collins and Singer, 1999), coreference resolution (Ng and Cardie, 2003), text categorization (Nigam and Ghani, 2000) and improving gene name data (Wellner, 2005).

Conversely, single-view learning models operate without an explicit partition of the feature space. Perhaps the most well known of such approaches is *expectation maximization* (EM), used by Nigam et al. (2000) for text categorization and by Ng and Cardie (2003) in combination with a meta-level feature selection procedure. *Self-training* is an alternative single-view algorithm in which a labelled pool is incrementally enlarged with unlabelled samples for which the learner is most confident. Early work by Yarowsky (1995) falls within this framework. Banko and Brill (2001) use 'bagging' and agreement to measure confidence on unlabelled samples, and more recently McClosky et al. (2006) use self-training for improving parse reranking.

Other relevant recent work includes (Zhang, 2004), in which random feature projection and a committee of SVM classifiers is used in a hybrid co/self-training strategy for weakly supervised relation classification and (Chen et al., 2006) where a graph based algorithm called *label propagation* is employed to perform weakly supervised relation extraction.

3 The Hedge Classification Task

Given a collection of sentences, $\mathcal{S}$, the task is to label each sentence as either speculative or non-speculative (*spec* or *nspec* henceforth). Specifically, $\mathcal{S}$ is to be partitioned into two disjoint sets, one representing sentences that contain some form of hedging, and the other representing those that do not.

To further elucidate the nature of the task and improve annotation consistency, we have developed a new set of guidelines, building on the work of Light et al. (2004). As noted by Light et al., speculative assertions are to be identified on the basis of judgements about the author's intended meaning, rather than on the presence of certain designated hedge terms.

We begin with the hedge definition given by Light et al. (item 1) and introduce a set of further guidelines to help elucidate various 'grey areas' and tighten the task specification. These were developed after initial annotation by the authors, and through discussion with colleagues. Further examples are given in online Appendix A[2].

The following are considered hedge instances:

1. An assertion relating to a result that does not necessarily follow from work presented, but could be extrapolated from it (Light et al.).
2. Relay of hedge made in previous work.

   Dl and Ser have been proposed to act redundantly in the sensory bristle lineage.
3. Statement of knowledge paucity.

[2] available from www.cl.cam.ac.uk/∼bwm23/

How endocytosis of Dl leads to the activation of N remains to be elucidated.

4. Speculative question.

   A second important question is whether the roX genes have the same, overlapping or complementing functions.

5. Statement of speculative hypothesis.

   To test whether the reported sea urchin sequences represent a true RAG1-like match, we repeated the BLASTP search against all GenBank proteins.

6. Anaphoric hedge reference.

   This hypothesis is supported by our finding that both pupariation rate and survival are affected by EL9.

The following are not considered hedge instances:

1. Indication of experimentally observed non-universal behaviour.

   proteins with single BIR domains can also have functions in cell cycle regulation and cytokinesis.

2. Confident assertion based on external work.

   Two distinct E3 ubiquitin ligases have been shown to regulate Dl signaling in Drosophila melanogaster.

3. Statement of existence of proposed alternatives.

   Different models have been proposed to explain how endocytosis of the ligand, which removes the ligand from the cell surface, results in N receptor activation.

4. Experimentally-supported confirmation of previous speculation.

   Here we show that the hemocytes are the main regulator of adenosine in the Drosophila larva, as was speculated previously for mammals.

5. Negation of previous hedge.

   Although the adgf-a mutation leads to larval or pupal death, we have shown that this is not due to the adenosine or deoxyadenosine simply blocking cellular proliferation or survival, as the experiments in vitro would suggest.

4 Data

We used an archive of 5579 full-text papers from the functional genomics literature relating to Drosophila melanogaster (the fruit fly). The papers were converted to XML and linguistically processed using the RASP toolkit[3]. We annotated six of the papers to form a test set with a total of 380 *spec* sentences and 1157 *nspec* sentences, and randomly selected 300,000 sentences from the remaining papers as training data for the weakly supervised learner. To ensure selection of complete sentences rather than headings, captions etc., unlabelled samples were chosen under the constraints that they must be at least 10 words in length and contain a main verb.

	F_1^{rel}	κ
Original	0.8293	0.9336
Corrected	0.9652	0.9848

Table 1: Agreement Scores

5 Annotation and Agreement

Two separate annotators were commissioned to label the sentences in the test set, firstly one of the authors and secondly a domain expert with no prior input into the guideline development process. The two annotators labelled the data independently using the guidelines outlined in section 3. Relative F_1 (F_1^{rel}) and *Cohen's Kappa* (κ) were then used to quantify the level of agreement. For brevity we refer the reader to (Artstein and Poesio, 2005) and (Hripcsak and Rothschild, 2004) for formulation and discussion of κ and F_1^{rel} respectively.

The two metrics are based on different assumptions about the nature of the annotation task. F_1^{rel} is founded on the premise that the task is to recognise and label *spec* sentences from within a background population, and does not explicitly model agreement on *nspec* instances. It ranges from 0 (no agreement) to 1 (no disagreement). Conversely, κ gives explicit credit for agreement on both *spec* and *nspec* instances. The observed agreement is then corrected for 'chance agreement', yielding a metric that ranges between -1 and 1. Given our definition of hedge classification and assessing the manner in which the annotation was carried out, we suggest that the founding assumption of F_1^{rel} fits the nature of the task better than that of κ.

Following initial agreement calculation, the instances of disagreement were examined. It turned out that the large majority of cases of disagreement were due to negligence on behalf of one or other of the annotators (i.e. cases of clear hedging that were missed), and that the cases of genuine disagreement were actually quite rare. New labelings were then created with the negligent disagreements corrected, resulting in significantly higher agreement scores. Values for the original and negligence-corrected la-

belings are reported in Table 1.

Annotator conferral violates the fundamental assumption of annotator independence, and so the latter agreement scores do not represent the true level of agreement; however, it is reasonable to conclude that the actual agreement is approximately lower bounded by the initial values and upper bounded by the latter values. In fact even the lower bound is well within the range usually accepted as representing 'good' agreement, and thus we are confident in accepting human labeling as a gold-standard for the hedge classification task. For our experiments, we use the labeling of the genetics expert, corrected for negligent instances.

6 Discussion

In this study we use single terms as features, based on the intuition that many hedge cues are single terms (*suggest*, *likely* etc.) and due to the success of 'bag of words' representations in many classification tasks to date. Investigating more complex sample representation strategies is an avenue for future research.

There are a number of factors that make our formulation of hedge classification both interesting and challenging from a weakly supervised learning perspective. Firstly, due to the relative sparsity of hedge cues, most samples contain large numbers of irrelevant features. This is in contrast to much previous work on weakly supervised learning, where for instance in the case of text categorization (Blum and Mitchell, 1998; Nigam et al., 2000) almost all content terms are to some degree relevant, and irrelevant terms can often be filtered out (e.g. stopword removal). In the same vein, for the case of entity/relation extraction and classification (Collins and Singer, 1999; Zhang, 2004; Chen et al., 2006) the context of the entity or entities in consideration provides a highly relevant feature space.

Another interesting factor in our formulation of hedge classification is that the *nspec* class is defined on the basis of the *absence* of hedge cues, rendering it hard to model directly. This characteristic is also problematic in terms of selecting a reliable set of *nspec* seed sentences, as by definition at the beginning of the learning cycle the learner has little knowledge about what a hedge looks like. This problem is addressed in section 10.3.

In this study we develop a learning model based around the concept of iteratively predicting labels for unlabelled training samples, the basic paradigm for both co-training and self-training. However we generalise by framing the task in terms of the acquisition of labelled training data, from which a supervised classifier can subsequently be learned.

7 A Probabilistic Model for Training Data Acquisition

In this section, we derive a simple probabilistic model for acquiring training data for a given learning task, and use it to motivate our approach to weakly supervised hedge classification.

Given:

- sample space $\mathcal{X}$
- set of target concept classes $\mathcal{Y} = \{y_1 \dots y_N\}$
- target function $Y : \mathcal{X} \rightarrow \mathcal{Y}$
- set of seed samples for each class $\mathcal{S}_1 \dots \mathcal{S}_N$ where $\mathcal{S}_i \subset \mathcal{X}$ and $\forall \mathbf{x} \in \mathcal{S}_i[Y(\mathbf{x}) = y_i]$
- set of unlabelled samples $\mathcal{U} = \{\mathbf{x}_1 \dots \mathbf{x}_K\}$

Aim: *Infer a set of training samples $\mathcal{T}_i$ for each concept class y_i such that* $\forall \mathbf{x} \in \mathcal{T}_i[Y(\mathbf{x}) = y_i]$

Now, it follows that $\forall \mathbf{x} \in \mathcal{T}_i[Y(\mathbf{x}) = y_i]$ is satisfied in the case that $\forall \mathbf{x} \in \mathcal{T}_i[P(y_i|x) = 1]$, which leads to a model in which $\mathcal{T}_i$ is initialised to $\mathcal{S}_i$ and then iteratively augmented with the unlabelled sample(s) for which the posterior probability of class membership is maximal. Formally:

At each iteration:

$$\mathcal{T}_i \leftarrow \mathbf{x}_j (\in \mathcal{U}) \quad \text{where } j = \arg\max_j [P(y_i|\mathbf{x}_j)] \tag{1}$$

Expansion with Bayes' Rule yields:

$$\arg\max_j [P(y_i|\mathbf{x}_j)] = \arg\max_j \left[\frac{P(\mathbf{x}_j|y_i) \cdot P(y_i)}{P(\mathbf{x}_j)} \right] \tag{2}$$

An interesting observation is the importance of the sample prior $P(\mathbf{x}_j)$ in the denominator, often ignored for classification purposes because of its invariance to class. We can expand further by

marginalising over the classes in the denominator in expression 2, yielding:

$$\arg\max_j \left[\frac{P(\mathbf{x}_j|y_i) \cdot P(y_i)}{\sum_{n=1}^{N} P(y_n)P(\mathbf{x}_j|y_n)} \right] \quad (3)$$

so we are left with the class priors and class-conditional likelihoods, which can usually be estimated directly from the data, at least under limited dependence assumptions. The class priors can be estimated based on the relative distribution sizes derived from the current training sets:

$$P(y_i) = \frac{|\mathcal{T}_i|}{\sum_k |\mathcal{T}_k|} \quad (4)$$

where $|\mathcal{S}|$ is the number of samples in training set $\mathcal{S}$.

If we assume feature independence, which as we will see for our task is not as gross an approximation as it may at first seem, we can simplify the class-conditional likelihood in the well known manner:

$$P(\mathbf{x}_j|y_i) = \prod_k P(x_{jk}|y_i) \quad (5)$$

and then estimate the likelihood for each feature:

$$P(x_k|y_i) = \frac{\alpha P(y_i) + f(x_k, \mathcal{T}_i)}{\alpha P(y_i) + |\mathcal{T}_i|} \quad (6)$$

where $f(x, \mathcal{S})$ is the number of samples in training set $\mathcal{S}$ in which feature x is present, and α is a universal smoothing constant, scaled by the class prior. This scaling is motivated by the principle that without knowledge of the true distribution of a particular feature it makes sense to include knowledge of the class distribution in the smoothing mechanism. Smoothing is particularly important in the early stages of the learning process when the amount of training data is severely limited resulting in unreliable frequency estimates.

8 Hedge Classification

We will now consider how to apply this learning model to the hedge classification task. As discussed earlier, the speculative/non-speculative distinction hinges on the presence or absence of a few hedge cues within the sentence. Working on this premise, all features are ranked according to their probability of 'hedge cue-ness':

$$P(spec|x_k) = \frac{P(x_k|spec) \cdot P(spec)}{\sum_{n=1}^{N} P(y_n)P(x_k|y_n)} \quad (7)$$

which can be computed directly using (4) and (6). The m most probable features are then selected from each sentence to compute (5) and the rest are ignored. This has the dual benefit of removing irrelevant features and also reducing dependence between features, as the selected features will often be non-local and thus not too tightly correlated.

Note that this idea differs from traditional feature selection in two important ways:

1. Only features indicative of the *spec* class are retained, or to put it another way, *nspec* class membership is inferred from the absence of strong *spec* features.
2. Feature selection in this context is *not* a preprocessing step; i.e. there is no re-estimation after selection. This has the potentially detrimental side effect of skewing the posterior estimates in favour of the *spec* class, but is admissible for the purposes of ranking and classification by posterior thresholding (see next section).

9 Classification

The weakly supervised learner returns a labelled data set for each class, from which a classifier can be trained. We can easily derive a classifier using the estimates from our learning model by:

$$\mathbf{x}_j \rightarrow spec \quad \text{if} \quad P(spec|\mathbf{x}_j) > \sigma \quad (8)$$

where σ is an arbitrary threshold used to control the precision/recall balance. For comparison purposes, we also use Joachims' SVM^{light} (Joachims, 1999).

10 Experimental Evaluation

10.1 Method

To examine the practical efficacy of the learning and classification models we have presented, we use the following experimental method:

1. Generate seed training data: $\mathcal{S}_{spec}$ and $\mathcal{S}_{nspec}$
2. Initialise: $\mathcal{T}_{spec} \leftarrow \mathcal{S}_{spec}$ and $\mathcal{T}_{nspec} \leftarrow \mathcal{S}_{nspec}$
3. Iterate:
   - Order $\mathcal{U}$ by $P(spec|\mathbf{x}_j)$ (expression 3)
   - $\mathcal{T}_{spec} \leftarrow$ most probable batch
   - $\mathcal{T}_{nspec} \leftarrow$ least probable batch
   - Train classifier using $\mathcal{T}_{spec}$ and $\mathcal{T}_{nspec}$

Table 2: Features ranked by $P(spec|x_k)$ for varying α

- Compute *spec* recall/precision BEP (break-even point) on the test data

The batch size for each iteration is set to $0.001 * |\mathcal{U}|$. After each learning iteration, we compute the precision/recall BEP for the *spec* class using both classifiers trained on the current labelled data. We use BEP because it helps to mitigate against misleading results due to discrepancies in classification threshold placement. Disadvantageously, BEP does not measure a classifier's performance across the whole of the recall/precision spectrum (as can be obtained, for instance, from receiver-operating characteristic (ROC) curves), but for our purposes it provides a clear, abstracted overview of a classifier's accuracy given a particular training set.

10.2 Parameter Setting

The training and classification models we have presented require the setting of two parameters: the smoothing parameter α and the number of features per sample m. Analysis of the effect of varying α on feature ranking reveals that when $\alpha = 0$, low frequency terms with spurious class correlation dominate and as α increases, high frequency terms become increasingly dominant, eventually smoothing away genuine low-to-mid frequency correlations. This effect is illustrated in Table 2, and from this analysis we chose $\alpha = 5$ as an appropriate level of smoothing. We use $m = 5$ based on the intuition that five is a rough upper bound on the number of hedge cue features likely to occur in any one sentence.

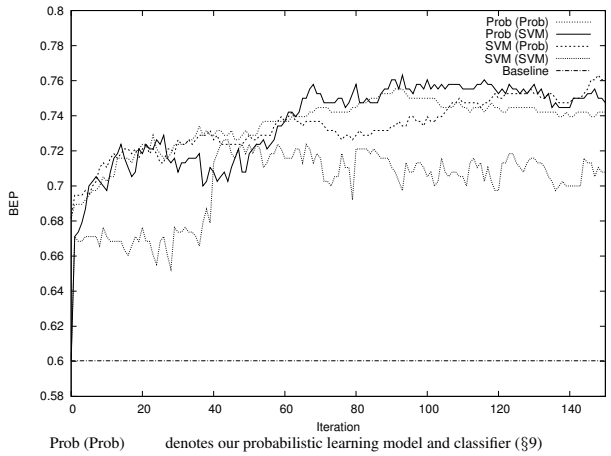
We use the linear kernel for SVM^{light} with the default setting for the regularization parameter C. We construct binary valued, L_2-normalised (unit length) input vectors to represent each sentence, as this resulted in better performance than using frequency-based weights and concords with our presence/absence feature estimates.

10.3 Seed Generation

The learning model we have presented requires a set of seeds for each class. To generate seeds for the *spec* class, we extracted all sentences from $\mathcal{U}$ containing either (or both) of the terms *suggest* or *likely*, as these are very good (though not perfect) hedge cues, yielding 6423 *spec* seeds. Generating seeds for *nspec* is much more difficult, as integrity requires the absence of hedge cues, and this cannot be done automatically. Thus, we used the following procedure to obtain a set of *nspec* seeds:

1. Create initial $\mathcal{S}_{nspec}$ by sampling randomly from $\mathcal{U}$.
2. Manually remove more 'obvious' speculative sentences using pattern matching
3. Iterate:
   - Order $\mathcal{S}_{nspec}$ by $P(spec|\mathbf{x}_j)$ using estimates from $\mathcal{S}_{spec}$ and current $\mathcal{S}_{nspec}$
   - Examine most probable sentences and remove speculative instances

We started with 8830 sentences and after a couple of hours work reduced this down to a (still potentially noisy) *nspec* seed set of 7541 sentences.



Prob (Prob)	denotes our probabilistic learning model and classifier (§9)
Prob (SVM)	denotes probabilistic learning model with SVM classifier
SVM (Prob)	denotes committee-based model (§10.4) with probabilistic classifier
SVM (SVM)	denotes committee-based model with SVM classifier
Baseline	denotes substring matching classifier of (Light et al., 2004)

Figure 1: Learning curves

10.4 Baselines

As a baseline classifier we use the substring matching technique of (Light et al., 2004), which labels a sentence as *spec* if it contains one or more of the following: *suggest*, *potential*, *likely*, *may*, *at least*, *in part*, *possibl*, *further investigation*, *unlikely*, *putative*, *insights*, *point toward*, *promise* and *propose*.

To provide a comparison for our learning model, we implement a more traditional self-training procedure in which at each iteration a committee of five SVMs is trained on randomly generated overlapping subsets of the training data and their cumulative confidence is used to select items for augmenting the labelled training data. For similar work see (Banko and Brill, 2001; Zhang, 2004).

10.5 Results

Figure 1 plots accuracy as a function of the training iteration. After 150 iterations, all of the weakly supervised learning models are significantly more accurate than the baseline according to a binomial sign test ($p < 0.01$), though there is clearly still much room for improvement. The baseline classifier achieves a BEP of 0.60 while both classifiers using our learning model reach approximately 0.76 BEP with little to tell between them. Interestingly, the combination of the SVM committee-based learning model with our classifier (denoted by 'SVM (Prob)'), performs competitively with both of the approaches that use our probabilistic learning model and significantly better than the SVM committee-based learning model with an SVM classifier, 'SVM (SVM)', according to a binomial sign test ($p < 0.01$) after 150 iterations. These results suggest that performance may be enhanced when the learning and classification tasks are carried out by different models. This is an interesting possibility, which we intend to explore further.

An important issue in incremental learning scenarios is identification of the optimum stopping point. Various methods have been investigated to address this problem, such as 'counter-training' (Yangarber, 2003) and committee agreement (Zhang, 2004); how such ideas can be adapted for this task is one of many avenues for future research.

10.6 Error Analysis

Some errors are due to the variety of hedge forms. For example, the learning models were unsuccessful in identifying assertive statements of knowledge paucity, eg: *There is no clear evidence for cytochrome c release during apoptosis in C elegans or Drosophila.* Whether it is possible to learn such examples without additional seed information is an open question. This example also highlights the potential benefit of an enriched sample representation, in this case one which accounts for the negation of the phrase 'clear evidence' which otherwise might suggest a strongly non-speculative assertion.

In many cases hedge classification is challenging even for a human annotator. For instance, distinguishing between a speculative assertion and one relating to a pattern of observed non-universal behaviour is often difficult. The following example was chosen by the learner as a *spec* sentence on the 150th training iteration: *Each component consists of a set of subcomponents that can be localized within a larger distributed neural system.* The sentence does not, in fact, contain a hedge but rather a statement of observed non-universal behaviour. However, an almost identical variant with 'could' instead of 'can' would be a strong speculative candidate. This highlights the similarity between many hedge and non-hedge instances, which makes such cases hard to learn in a weakly supervised manner.

11 Conclusions and Future Work

We have shown that weakly supervised ML is applicable to the problem of hedge classification and that a reasonable level of accuracy can be achieved. The work presented here has application in the wider academic community; in fact a key motivation in this study is to incorporate hedge classification into an interactive system for aiding curators in the construction and population of gene databases. We have presented our initial results on the task using a simple probabilistic model in the hope that this will encourage others to investigate alternative learning models and pursue new techniques for improving accuracy. Our next aim is to explore possibilities of introducing linguistically-motivated knowledge into the sample representation to help the learner identify key hedge-related sentential components, and also to consider hedge classification at the granularity of assertions rather than text sentences.

Abstract

We present a novel approach to automatically annotate images using associated text. We detect and classify all entities (persons and objects) in the text after which we determine the salience (the importance of an entity in a text) and visualness (the extent to which an entity can be perceived visually) of these entities. We combine these measures to compute the probability that an entity is present in the image. The suitability of our approach was successfully tested on 100 image-text pairs of Yahoo! News.

1 Introduction

Our society deals with a growing bulk of unstructured information such as text, images and video, a situation witnessed in many domains (news, biomedical information, intelligence information, business documents, etc.). This growth comes along with the demand for more effective tools to search and summarize this information. Moreover, there is the need to mine information from texts and images when they contribute to decision making by governments, businesses and other institutions. The capability to accurately recognize content in these sources would largely contribute to improved indexing, classification, filtering, mining and interrogation.

Algorithms and techniques for the disclosure of information from the different media have been developed for every medium independently during the last decennium, but only recently the interplay between these different media has become a topic of interest. One of the possible applications is to help analysis in one medium by employing information from another medium. In this paper we study text that is associated with an image, such as for instance image captions, video transcripts or surrounding text in a web page. We develop techniques that extract information from these texts to help with the difficult task of accurate object recognition in images. Although images and associated texts never contain precisely the same information, in many situations the associated text offers valuable information that helps to interpret the image.

The central objective of the CLASS project[1] is to develop advanced learning methods that allow images, video and associated text to be automatically analyzed and structured. In this paper we test the feasibility of automatically annotating images by using textual information in near-parallel image-text pairs, in which most of the content of the image corresponds to content of the text and vice versa. We will focus on entities such as persons and objects. We will hereby take into account the text's discourse structure and semantics, which allow a more fine-grained identification of what content might be present in the image, and will enrich our model with world knowledge that is not present in the text.

We will first discuss the corpus on which we apply and test our techniques in section 2, after which we outline what techniques we have developed: we start with a baseline system to annotate images with person names (section 3) and improve this by computing the importance of the persons in the text (section 4). We will then extend the model to include all

Figure 1: Image-text pair with entity "Hiram Myers" appearing both in the text and in the image.

types of objects (section 5) and improve it by defining and computing the $visualness$ measure (section 6). Finally we will combine these different techniques in one probabilistic model in section 7.

2 The parallel corpus

We have created a parallel corpus consisting of 1700 image-text pairs, retrieved from the Yahoo! News website[2]. Every image has an accompanying text which describes the content of the image. This text will in general discuss one or more persons in the image, possibly one or more other objects, the location and the event for which the picture was taken. An example of an image-text pair is given in fig. 1. Not all persons or objects who are pictured in the images are necessarily described in the texts. The inverse is also true, i.e. content mentioned in the text may not be present in the image.

We have randomly selected 100 text-pairs from the corpus, and one annotator has labeled every image-text pair with the entities (i.e. persons and other objects) that appear both in the image and in the text. For example, the image-text pair shown in fig. 1 is annotated with one entity, "Hiram Myers", since this is the only entity that appears both in the text and in the image. On average these texts contain 15.04 entities, of which 2.58 appear in the image.

To build the appearance model of the text, we have combined different tools. We will evaluate every tool separately on 100 image-text pairs. This way we have a detailed view on the nature of the errors in the final model.

3 Automatically annotating person names

Given a text that is associated with an image, we want to compute a probabilistic *appearance model*, i.e. a collection of entities that are visible in the image. We will start with a model that holds the names of the persons that appear in the image, such as was done by (Satoh et al., 1999; Berg et al., 2004), and extend this model in section 5 to include all other objects.

3.1 Named Entity Recognition

A logical first step to detect person names is Named Entity Recognition (NER). We use the OpenNLP package[3], which detects noun phrase chunks in the sentences that represent persons, locations, organizations and dates. To improve the recognition of person names, we use a dictionary of names, which we have extracted from the Wikipedia[4] website. We have manually evaluated performance of NER on our test corpus and found that performance was satisfying: we obtained a precision of 93.37% and a recall of 97.69%. Precision is the percentage of identified person names by the system that corresponds to correct person names, and recall is the percentage of person names in the text that have been correctly identified by the system.

The texts contain a small number of noun phrase coreferents that are in the form of pronouns, we have resolved these using the LingPipe[5] package.

3.2 Baseline system

We want to annotate an image using the associated text. We try to find the names of persons which are

[2] http://news.yahoo.com/

[3] http://opennlp.sourceforge.net/

[4] http://en.wikipedia.org/

[5] http://www.alias-i.com/lingpipe/

both described in the text *and* visible in the image, and we want to do so by relying *only* on an analysis of the text. In some cases, such as the following example, the text states explicitly whether a person is (not) visible in the image:

> President Bush [...] with Danish Prime Minister Anders Fogh Rasmussen, not pictured, at Camp David [...].

Developing a system that could extract this information is not trivial, and even if we could do so, only a very small percentage of the texts in our corpus contain this kind of information. In the next section we will look into a method that is applicable to a wide range of (descriptive) texts and that does not rely on specific information within the text.

To evaluate the performance of this system, we will compare it with a simple baseline system. The baseline system assumes that all persons in the text are visible in the image, which results in a precision of 71.27% and a recall of 95.56%. The (low) precision can be explained by the fact that the texts often discuss people which are not present in the image.

4 Detection of the salience of a person

Not all persons discussed in a text are equally important. We would like to discover what persons are in the focus of a text and what persons are only mentioned briefly, because we presume that more important persons in the text have a larger probability of appearing in the image than less important persons. Because of the short lengths of the documents in our corpus, an analysis of lexical cohesion between terms in the text will not be sufficient for distinguishing between important and less important entities. We define a measure, *salience*, which is a number between 0 and 1 that represents the importance of an entity in a text. We present here a method for computing this score based on an in depth analysis of the discourse of the text and of the syntactic structure of the individual sentences.

4.1 Discourse segmentation

The discourse segmentation module, which we developed in earlier research, hierarchically and sequentially segments the discourse in different topics and subtopics resulting in a table of contents of a text (Moens, 2006). The table shows the main entities and the related subtopic entities in a tree-like structure that also indicates the segments (by means of character pointers) to which an entity applies. The algorithm detects patterns of thematic progression in texts and can thus recognize the main topic of a sentence (i.e., about whom or what the sentence speaks) and the hierarchical and sequential relationships between individual topics. A mixture model, taking into account different discourse features, is trained with the Expectation Maximization algorithm on an annotated DUC-2003 corpus. We use the resulting discourse segmentation to define the salience of individual entities that are recognized as topics of a sentence. We compute for each noun entity e_r in the discourse its salience ($Sal1$) in the discourse tree, which is proportional with the depth of the entity in the discourse tree -hereby assuming that deeper in this tree more detailed topics of a text are described- and normalize this value to be between zero and one. When an entity occurs in different subtrees, its maximum score is chosen.

4.2 Refinement with sentence parse information

Because not all entities of the text are captured in the discourse tree, we implement an additional refinement of the computation of the salience of an entity which is inspired by (Moens et al., 2006). The segmentation module already determines the main topic of a sentence. Since the syntactic structure is often indicative of the information distribution in a sentence, we can determine the relative importance of the other entities in a sentence by relying on the relationships between entities as signaled by the parse tree. When determining the salience of an entity, we take into account the level of the entity mention in the parse tree ($Sal2$), and the number of children for the entity in this structure ($Sal3$), where the normalized score is respectively inversely proportional with the depth of the parse tree where the entity occurs, and proportional with the number of children.

We combine the three salience values ($Sal1$, $Sal2$ and $Sal3$) by using a linear weighting. We have experimentally determined reasonable coefficients for these three values, which are respectively 0.8, 0.1 and 0.1. Eventually, we could learn these coefficients from a training corpus (e.g., with the

	Precision	Recall	F-measure
NER	71.27%	95.56%	81.65%
NER+DYN	97.66%	92.59%	95.06%

Table 1: Comparison of methods to predict what persons described in the text will appear in the image, using Named Entity Recognition (NER), and the salience measure with dynamic cut-off (DYN).

Expectation Maximization algorithm).

We do not separately evaluate our technology for salience detection as this technology was already extensively evaluated in the past (Moens, 2006).

4.3 Evaluating the improved system

The salience measure defines a ranking of all the persons in a text. We will use this ranking to improve our baseline system. We assume that it is possible to automatically determine the number of faces that are recognized in the image, which gives us an indication of a suitable cut-off value. This approach is reasonable since face detection (determine whether a face is present in the image) is significant easier than face recognition (determine which person is present in the image). In the improved model we assume that persons which are ranked higher than, or equal to, the cut-off value appear in the image. For example, if 4 faces appear in the image, we assume that only the 4 persons of which the names in the text have been assigned the highest salience appear in the image. We see from table 1 that the precision (97.66%) has improved drastically, while the recall remained high (92.59%). This confirms the hypothesis that determining the focus of a text helps in determining the persons that appear in the image.

5 Automatically annotating persons and objects

After having developed a reasonable successful system to detect what persons will appear in the image, we turn to a more difficult case : Detecting persons *and* all other objects that are described in the text.

5.1 Entity detection

We will first detect what words in the text refer to an entity. For this, we perform part-of-speech tagging (i.e., detecting the syntactic word class such as noun, verb, etc.). We take that every noun in the text represents an entity. We have used LTPOS (Mikheev, 1997), which performed the task almost errorless (precision of 98.144% and recall of 97.36% on the nouns in the test corpus). Person names which were segmented using the NER package are also marked as entities.

5.2 Baseline system

We want to detect the objects and the names of persons which are both visible in the image and described in the text. We start with a simple baseline system, in which we assume that every entity in the text appears in the image. As can be expected, this results in a high recall (91.08%), and a very low precision (15.62%). We see that the problem here is far more difficult compared to detecting only person names. This can be explained by the fact that many entities (such as for example *August*, *idea* and *history*) will never (or only indirectly) appear in an image. In the next section we will try to determine what types of entities are more likely to appear in the image.

6 Detection of the visualness of an entity

The assumption that every entity in the text appears in the image is rather crude. We will enrich our model with external world knowledge to find entities which are not likely to appear in an image. We define a measure called *visualness*, which is defined as the extent to which an entity can be perceived visually.

6.1 Entity classification

After we have performed entity detection, we want to classify every entity according to a certain semantic database. We use the WordNet (Fellbaum, 1998) database, which organizes English nouns, verbs, adjectives and adverbs in synsets. A synset is a collection of words that have a close meaning and that represent an underlying concept. An example of such a synset is “person, individual, someone, somebody, mortal, soul”. All these words refer to a hu-

man being. In order to correctly assign a noun in a text to its synset, i.e., to disambiguate the sense of this word, we use an efficient Word Sense Disambiguation (WSD) system that was developed by the authors and which is described in (Deschacht and Moens, 2006). Proper names are labeled by the Named Entity Recognizer, which recognizes persons, locations and organizations. These labels in turn allow us to assign the corresponding WordNet synset.

The combination of the WSD system and the NER package achieved a 75.97% accuracy in classifying the entities. Apart from errors that resulted from erroneous entity detection (32.32%), errors were mainly due to the WSD system (60.56%) and in a smaller amount to the NER package (8.12%).

6.2 WordNet similarity

We determine the visualness for every synset using a method that was inspired by Kamps and Marx (2002). Kamps and Marx use a distance measure defined on the adjectives of the WordNet database together with two seed adjectives to determine the emotive or affective meaning of any given adjective. They compute the relative distance of the adjective to the seed synsets "good" and "bad" and use this distance to define a measure of affective meaning.

We take a similar approach to determine the visualness of a given synset. We first define a similarity measure between synsets in the WordNet database. Then we select a set of seed synsets, i.e. synsets with a predefined visualness, and use the similarity of a given synset to the seed synsets to determine the visualness.

6.3 Distance measure

The WordNet database defines different relations between its synsets. An important relation for nouns is the hypernym/hyponym relation. A noun X is a hypernym of a noun Y if Y is a subtype or instance of X. For example, "bird" is a hypernym of "penguin" (and "penguin" is a hyponym of "bird"). A synset in WordNet can have one or more hypernyms. This relation organizes the synsets in a hierarchical tree (Hayes, 1999).

The similarity measure defined by Lin (1998) uses the hypernym/hyponym relation to compute a semantic similarity between two WordNet synsets S_1 and S_2. First it finds the most specific (lowest in the tree) synset S_p that is a parent of both S_1 and S_2. Then it computes the similarity of S_1 and S_2 as

$$sim(S_1, S_2) = \frac{2logP(S_p)}{logP(S_1) + logP(S_2)}$$

Here the probability $P(S_i)$ is the probability of labeling any word in a text with synset S_i or with one of the descendants of S_i in the WordNet hierarchy. We estimate these probabilities by counting the number of occurrences of a synset in the Semcor corpus (Fellbaum, 1998; Landes et al., 1998), where all noun chunks are labeled with their WordNet synset. The probability $P(S_i)$ is computed as

$$P(S_i) = \frac{C(S_i)}{\sum_{n=1}^{N} C(S_n)} + \sum_{k=1}^{K} P(S_k)$$

where $C(S_i)$ is the number of occurrences of S_i, N is the total number of synsets in WordNet and K is the number of children of S_i. The WordNet::Similarity package (Pedersen et al., 2004) implements this distance measure and was used by the authors.

6.4 Seed synsets

We have manually selected 25 seed synsets in WordNet, where we tried to cover the wide range of topics we were likely to encounter in the test corpus. We have set the visualness of these seed synsets to either 1 (visual) or 0 (not visual). We determine the visualness of all other synsets using these seed synsets. A synset that is close to a visual seed synset gets a high visualness and vice versa. We choose a linear weighting:

$$vis(s) = \sum_i vis(s_i) \frac{sim(s, s_i)}{C(s)}$$

where $vis(s)$ returns a number between 0 and 1 denoting the visualness of a synset s, s_i are the seed synsets, $sim(s, t)$ returns a number between 0 and 1 denoting the similarity between synsets s and t and $C(s)$ is constant given a synset s:

$$C(s) = \sum_i sim(s, s_i)$$

6.5 Evaluation of the visualness computation

To determine the visualness, we first assign the correct WordNet synset to every entity, after which we compute a visualness score for these synsets. Since these scores are floating point numbers, they are hard to evaluate manually. During evaluation, we make the simplifying assumption that all entities with a visualness below a certain threshold are not visual, and all entities above this threshold are visual. We choose this threshold to be 0.5. This results in an accuracy of 79.56%. Errors are mainly caused by erroneous entity detection and classification (63.10%) but also because of an incorrect assignment of the visualness (36.90%) by the method described above.

7 Creating an appearance model using salience and visualness

In the previous section we have created a method to calculate a visualness score for every entity, because we stated that removing the entities which can never be perceived visually will improve the performance of our baseline system. An experiment proves that this is exactly the case. If we assume that only the entities that have a visualness above a 0.5 threshold are visible and will appear in the image, we get a precision of 48.81% and a recall of 87.98%. We see from table 2 that this is already a significant improvement over the baseline system.

In section 4 we have seen that the salience measure helps in determining what persons are visible in the image. We have used the fact that face detection in images is relatively easily and can thus supply a cut-off value for the ranked person names. In the present state-of-the-art, we are not able to exploit a similar fact when detecting all types of entities. We will thus use the salience measure in a different way. We compute the salience of every entity, and we assume that only the entities with a salience score above a threshold of 0.5 will appear in the image. We see that this method drastically improves precision to 66.03%, but also lowers recall until 54.26%.

We now create a last model where we combine both the visualness and the salience measures. We want to calculate the probability of the occurrence of an entity e_{im} in the image, given a text t, $P(e_{im}|t)$. We assume that this probability is proportional with the degree of visualness and salience of e_{im} in t. In our framework, $P(e_{im}|t)$ is computed as the product of the salience of the entity e_{im} and its visualness score, as we assume both scores to be independent.

	Precision	Recall	F-measure
Ent	15.62%	91.08%	26.66%
Ent+Vis	48.81%	87.98%	62.78%
Ent+Sal	66.03%	54.26%	59.56%
Ent+Vis+Sal	70.56%	67.82%	69.39%

Table 2: Comparison of methods to predict the entities that appear in the image, using entity detection (Ent), and the visualness (Vis) and salience (Sal) measures.

Again, for evaluation sake, we choose a threshold of 0.4 to transform this continuous ranking into a binary classification. This results in a precision of 70.56% and a recall of 67.82%. This model is the best of the 4 models for entity annotation which have been evaluated.

8 Related Research

Using text that accompanies the image for annotating images and for training image recognition is not new. The earliest work (only on person names) is by Satoh (1999) and this research can be considered as the closest to our work. The authors make a distinction between proper names, common nouns and other words, and detect entities based on a thesaurus list of persons, social groups and other words, thus exploiting already simple semantics. Also a rudimentary approach to discourse analysis is followed by taking into account the position of words in a text. The results were not satisfactory: 752 words were extracted from video as candidates for being in the accompanying images, but only 94 were correct where 658 were false positives. Mori et al. (2000) learn textual descriptions of images from surrounding texts. These authors filter nouns and adjectives from the surrounding texts when they occur above a certain frequency and obtain a maximum hit rate of top 3 words that is situated between 30% and 40%. Other approaches consider both the textual and image features when building a content model of the image. For instance, some content is selected from the text (such as person names) and from the

image (such as faces) and both contribute in describing the content of a document. This approach was followed by Barnard (2003).

Westerveld (2000) combines image features and words from collateral text into one semantic space. This author uses Latent Semantic Indexing for representing the image/text pair content. Ayache et al. (2005) classify video data into different topical concepts. The results of these approaches are often disappointing. The methods here represent the text as a bag of words possibly augmented with a *tf* (term frequency) x *idf* (inverse document frequency) weight of the words (Amir et al., 2005). In exceptional cases, the hierarchical XML structure of a text document (which was manually annotated) is taken into account (Westerveld et al., 2005). The most interesting work here to mention is the work of Berg et al. (2004) who also process the nearly parallel image-text pairs found in the Yahoo! news corpus. They link faces in the image with names in the text (recognized with named entity recognition), but do not consider other objects. They consider pairs of person names (text) and faces (image) and use clustering with the Expectation Maximization algorithm to find all faces belonging to a certain person. In their model they consider the probability that an entity is pictured given the textual context (i.e., the part-of-speech tags immediately prior and after the name, the location of the name in the text and the distance to particular symbols such as "(R)"), which is learned with a probabilistic classifier in each step of the EM iteration. They obtained an accuracy of 84% on person face recognition.

In the CLASS project we work together with groups specialized in image recognition. In future work we will combine face and object recognition with text analysis techniques. We expect the recognition and disambiguation of faces to improve if many image-text pairs that treat the same person are used. On the other hand our approach is also valuable when there are few image-text pairs that picture a certain person or object. The approach of Berg et al. could be augmented with the typical features that we use, namely salience and visualness. In Deschacht et al. (2007) we have evaluated the ranking of persons and objects by the method we have described here and we have shown that this ranking correlates with the importance of persons and objects in the picture.

None of the above state-of-the-art approaches consider salience and visualness as discriminating factors in the entity recognition, although these aspects could advance the state-of-the-art.

9 Conclusion

Our society in the 21st century produces gigantic amounts of data, which are a mixture of different media. Our repositories contain texts interwoven with images, audio and video and we need automated ways to automatically index these data and to automatically find interrelationships between the various media contents. This is not an easy task. However, if we succeed in recognizing and aligning content in near-parallel image-text pairs, we might be able to use this acquired knowledge in indexing comparable image-text pairs (e.g., in video) by aligning content in these media.

In the experiment described above, we analyze the discourse and semantics of texts of near-parallel image-text pairs in order to compute the probability that an entity mentioned in the text is also present in the accompanying image. First, we have developed an approach for computing the salience of each entity mentioned in the text. Secondly, we have used the WordNet classification in order to detect the visualness of an entity, which is translated into a visualness probability. The combined salience and visualness provide a score that signals the probability that the entity is present in the accompanying image.

We extensively evaluated all the different modules of our system, pinpointing weak points that could be improved and exposing the potential of our work in cross-media exploitation of content.

We were able to detect the persons in the text that are also present in the image with a (evenly weighted) F-measure of more than 95%, and in addition were able to detect the entities that are present in the image with a F-measure of more than 69%. These results have been obtained by relying only on an analysis of the text and were substantially better than the baseline approach. Even if we can not resolve all ambiguity, keeping the most confident hypotheses generated by our textual hypotheses will greatly assist in analyzing images.

In the future we hope to extrinsically evaluate

the proposed technologies, e.g., by testing whether the recognized content in the text, improves image recognition, retrieval of multimedia sources, mining of these sources, and cross-media retrieval. In addition, we will investigate how we can build more refined appearance models that incorporate attributes and actions of entities.

Acknowledgments

The work reported in this paper was supported by the EU-IST project CLASS (Cognitive-Level Annotation using Latent Statistical Structure, IST-027978). We acknowledge the CLASS consortium partners for their valuable comments and we are especially grateful to Yves Gufflet from the INRIA research team (Grenoble, France) for collecting the Yahoo! News dataset.

Abstract

We present a user requirements study for Question Answering on meeting records that assesses the difficulty of users questions in terms of what type of knowledge is required in order to provide the correct answer. We grounded our work on the empirical analysis of elicited user queries. We found that the majority of elicited queries (around 60%) pertain to argumentative processes and outcomes. Our analysis also suggests that standard keyword-based Information Retrieval can only deal successfully with less than 20% of the queries, and that it must be complemented with other types of metadata and inference.

1 Introduction

Meeting records constitute a particularly important and rich source of information. Meetings are a frequent and sustained activity, in which multi-party dialogues take place that are goal-oriented and where participants perform a series of actions, usually aimed at reaching a common goal: they exchange information, raise issues, express opinions, make suggestions, propose solutions, provide arguments (pro or con), negotiate alternatives, and make decisions. As outcomes of the meeting, agreements on future action items are reached, tasks are assigned, conflicts are solved, etc. Meeting outcomes have a direct impact on the efficiency of organization and team performance, and the stored and indexed meeting records serve as reference for further processing (Post et al., 2004). They can also be used in future meetings in order to facilitate the decision-making process by accessing relevant information from previous meetings (Cremers et al., 2005), or in order to make the discussion more focused (Conklin, 2006).

Meetings constitute a substantial and important source of information that improves corporate organization and performance (Corrall, 1998; Romano and Nunamaker, 2001). Novel multimedia techniques have been dedicated to meeting *recording*, *structuring* and content *analysis* according to the metadata schema, and finally, to *accessing* the analyzed content via browsing, querying or filtering (Cremers et al., 2005; Tucker and Whittaker, 2004).

This paper focuses on *debate meetings* (Cugini et al., 1997) because of their particular richness in information concerning the decision-making process. We consider that the meeting content can be organized on three levels: (i) *factual level* (what happens: events, timeline, actions, dynamics); (ii) *thematic level* (what is said: topics discussed and details); (iii) *argumentative level* (which/how common goals are reached).

The information on the first two levels is explicit information that can be usually retrieved directly by searching the meeting records with appropriate IR techniques (i.e., TF-IDF). The third level, on the contrary, contains more abstract and tacit information pertaining to how the explicit information contributes to the rationale of the meeting, and it is not present as such in raw meeting data: whether or not the meeting goal was reached, what issues were debated, what proposals were made, what alternatives were discussed, what arguments were brought, what decisions were made, what task were assigned, etc.

The motivating scenario is the following: A user

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 1008–1015,
Prague, Czech Republic, June 2007.

needs information about a past meeting, either in quality of a participant who wants to recollect a discussion (since the memories of co-participants are often inconsistent, cf. Banerjee et al., 2005), or as a non-participant who missed that meeting. Instead of consulting the entire meeting-related information, which is usually heterogeneous and scaterred (audio-video recordings, notes, minutes, e-mails, handouts, etc.), the user asks natural language questions to a query engine which retrieves relevant information from the meeting records.

In this paper we assess the users' interest in retrieving argumentative information from meetings and what kind of knowledge is required for answering users' queries. Section 2 reviews previous user requirements studies for the meeting domain. Section 3 describes our user requirements study based on the analysis of elicited user queries, presents its main findings, and discusses the implications of these findings for the design of meeting retrieval systems. Section 4 concludes the paper and outlines some directions for future work.

2 Argumentative Information in Meeting Information Retrieval

Depending on the meeting browser type[1], different levels of meeting content become accessible for information retrieval. Audio and video browsers deal with factual and thematic information, while artifact browsers might also touch on deliberative information, as long as it is present, for instance, in the meeting minutes. In contrast, derived-data browsers aim to account for the argumentative information which is not explicitly present in the meeting content, but can be inferred from it. If minutes are likely to contain only the most salient deliberative facts, the derived-data browsers are much more useful, in that they offer access to the full meeting record, and thus to relevant details about the deliberative information sought.

2.1 Importance of Argumentative Structure

As shown by Rosemberg and Silince (1999), tracking argumentative information from meeting discussions is of central importance for building project memories since, in addition to the "strictly factual, technical information", these memories must also store relevant information about decision-making processes. In a business context, the information derived from meetings is useful for future business processes, as it can explain phenomena and past decisions and can support future actions by mining and assessment (Pallotta et al., 2004). The argumentative structure of meeting discussions, possibly visualized in form of argumentation diagrams or maps, can be helpful in meeting browsing. To our knowledge, there are at least three meeting browsers that have adopted argumentative structure: ARCHIVUS (Lisowska et al., 2004b), ViCoDe (Marchand-Maillet and Bruno, 2005), and the Twente-AMI JFerret browser (Rienks and Verbree, 2006).

2.2 Query Elicitation Studies

The users' interest in argumentation dimension of meetings has been highlighted by a series of recent studies that attempted to elicit the potential user questions about meetings (Lisowska et al., 2004a; Benerjee at al., 2005; Cremers et al., 2005).

The study of Lisowska et al. (2004a), part of the IM2 research project[2], was performed in a simulated environment in which users were asked to imagine themselves in a particular role from a series of scenarios. The participants were both IM2 members and non-IM2 members and produced about 300 retrospective queries on recorded meetings. Although this study has been criticized by Post et al. (2004), Cremers et al. (2005), and Banerjee et al. (2005) for being biased, artificial, obtrusive, and not conforming to strong HCI methodologies for survey research, it shed light on potential queries and classified them in two broad categories, that seem to correspond to our argumentative/non-argumentative distinction (Lisowska et al., 2004a: 994):

- “elements related to the interaction among participants: acceptance/rejection, agreement/disagreement; proposal, argumentation (for and against); assertions, statements; decisions; discussions, debates; reactions; questions; solutions”;

[1] (Tucker and Whittaker, 2004) identifies 4 types of meeting browsers: audio browsers, video browsers, artifacts browsers (that exploit meeting minutes or other meeting-related documents), and browsers that work with derived data (such as discourse and temporal structure information).

[2] http://www.im2.ch

- "concepts from the meeting domains: dates, times; documents; meeting index: current, previous, sets; participants; presentations, talks; projects; tasks, responsibilities; topics".

Unfortunately, the study does not provide precise information on the relative proportions of queries for the classification proposed, but simply suggests that overall more queries belong to the second category, while queries requiring understanding of the dialogue structure still comprise a sizeable proportion.

The survey conducted by Banerjee et al. (2005) concerned instead real, non-simulated interviews of busy professionals about actual situations, related either to meetings in which they previously participated, or to meetings they missed. More than half of the information sought by interviewees concerned, in both cases, the argumentative dimension of meetings.

For non-missed meetings, 15 out of the 26 instances (i.e., 57.7%) concerned argumentative aspects: what the decision was regarding a topic (7); what task someone was assigned (4); who made a particular decision (2); what was the participants' reaction to a particular topic (1); what the future plan is (1). The other instances (42.3%) relate to the thematic dimension, i.e., specifics of the discussion on a topic (11).

As for missed meetings, the argumentative instances were equally represented (18/36): decisions on a topic (7); what task was assigned to interviewee (4); whether a particular decision was made (3); what decisions were made (2); reasons for a decision (1); reactions to a topic (1). The thematic questions concern topics discussed, announcements made, and background of participants.

The study also showed that the recovery of information from meeting recordings is significantly faster when discourse annotations are available, such as the distinction between discussion, presentation, and briefing.

Another unobtrusive user requirements study was performed by Cremers et al. (2005) in a "semi-natural setting" related to the design of a meeting browser. The top 5 search interests highlighted by the 60 survey participants were: *decisions made*, participants/speakers, topics, agenda items, and *arguments for decision*. Of these, the ones shown in italics are argumentative. In fact, the authors acknowledge the necessity to include some "functional" categories as innovative search options. Interestingly, from the user interface evaluation presented in their paper, one can indirectly infer how salient the argumentative information is perceived by users: the icons that the authors intended for emotions, i.e., for a emotion-based search facility, were actually interpreted by users as referring to people's opinion: *What is person X's opinion?* – positive, negative, neutral.

3 User Requirements Analysis

The existing query elicitation experiments reported in Section 2 highlighted a series of question types that users typically would like to ask about meetings. It also revealed that the information sought can be classified into two broad categories: argumentative information (about the argumentative process and the outcome of debate meetings), and non-argumentative information (factual, i.e., about the meeting as a physical event, or thematic, i.e., about what has been said in terms of topics).

The study we present in this section is aimed at assessing how difficult it is to answer the questions that users typically ask about a meeting. Our goal is to provide insights into:

- how many queries can be answered using standard IR techniques on meeting artefacts only (e.g., minutes, written agenda, invitations);
- how many queries can be answered with IR on meeting recordings;
- what kind of additional information and inference is needed when IR does not apply or it is insufficient (e.g., information about the participants and the meeting dynamics, external information about the meeting's context such as the relation to a project, semantic interpretation of question terms and references, computation of durations, aggregation of results, etc).

Assessing the level of difficulty of a query based on the two above-mentioned categories might not provide insightful results, because these would be too general, thus less interpretable. Also, the complex queries requiring mixed information would escape observation because assigned to a too general class. We therefore considered it necessary to perform a separate analysis of each query instance, as this provides not only detailed, but also traceable information.

3.1 Data: Collecting User Queries

Our analysis is based on a heterogeneous collection of queries for meeting data. In general, an unbiased queries dataset is difficult to obtain, and the quality of a dataset can vary if the sample is made of too homogenous subjects (e.g., people belonging to the same group as members of the same project). In order to cope with this problem, our strategy was to use three different datasets collected in different settings:

- First, we considered the *IM2 dataset* collected by Lisowska et al. (2004a), the only set of user queries on meetings available to date. It comprises 270 questions (shortly described in Section 2) annotated with a label showing whether or not the query was produced by an IM2-member. These queries are introspective and not related to any particular recorded meeting.
- Second, we cross-validated this dataset with a large corpus of 294 natural language statements about existing meetings records. This dataset, called the *BET observations* (Wellner et al., 2005), was collected by subjects who were asked to watch several meeting recordings and to report what the meeting participants appeared to consider interesting. We use it as a 'validation' set for the IM2 queries: an IM2 query is considered as 'realistic' or 'empirically grounded' if there is a BET observation that represents a possible answer to the query. For instance, the query *Why was the proposal made by X not accepted?* matches the BET observation *Denis eliminated Silence of the Lambs as it was too violent.*
- Finally, we collected a new set of 'real' queries by conducting a survey of user requirements on meeting querying in a natural business setting. The survey involved 3 top managers from a company and produced 35 queries. We called this dataset *Manager Survey Set* (MS-Set).

The queries from the IM2-set (270 queries) and the MS-Set (35 queries) were analyzed by two different teams of two judges. Each team discussed each query, and classified it along the two main dimensions we are interested in:

- *query type*: the type of meeting content to which the query pertains;
- *query difficulty*: the type of information required to provide the answer.

3.2 Query Type Analysis

Each query was assigned exactly one of the following four possible categories (the one perceived as the most salient):

1. *factual*: the query pertains to the factual meeting content;
2. *thematic*: the query pertains to the thematic meeting content;
3. *process*: the query pertains to the argumentative meeting content, more precisely to the argumentative process;
4. *outcome*: the query pertains to the argumentative meeting content, more precisely to the outcome of the argumentative process.

Category	IM2-set (size:270)		MS-Set (size: 35)	
	Team1	Team2	Team1	Team2
Factual	24.8%	45.6%	20.0%	20.0%
Thematic	18.5%		20.0%	11.4%
Process	30.0%	32.6%	22.9%	28.6%
Outcome	26.7%	21.8%	37.1%	40.0%
Process+ Outcome	56.7%	54.4%	60.0%	68.6%

Table 1. Query classification according to the meeting content type.

Results from this classification task for both query sets are reported in Table 1. In both sets, the information most sought was argumentative: about 55% of the IM2-set queries are argumentative (process or outcome). This invalidates the initial estimation of Lisowska et al. (2004a:994) that the non-argumentative queries prevail, and confirms the figures obtained in (Banerjee et al., 2005), according to which 57.7% of the queries are argumentative. In our real managers survey, we obtained even higher percentages for the argumentative queries (60% or 68.6%, depending on the annotation team). The argumentative queries are followed by factual and thematic ones in both query sets, with a slight advantage for factual queries.

The inter-annotator agreement for this first classification is reported in Table 2. The proportion of queries on which annotators agree in classifying them as argumentative is significantly high. We only report here the agreement results for the individual argumentative categories (Process, Outcome) and both (Process & Outcome). There were 213 queries (in IM2-set) and 30 queries (in MS-

set) that were consistently annotated by the two teams on *both* categories. Within this set, a high percentage of queries were argumentative, that is, they were annotated as either Process or Outcome (label AA in the table).

Category	IM2-set (size: 270)		MS-set (size: 35)	
	ratio	kappa	ratio	kappa
Process	84.8%	82.9%	88.6%	87.8%
Outcome	90.7%	89.6%	91.4%	90.9%
Process & Outcome	78.9%	76.2%	85.7%	84.8%
AA	117/213 = **54.9%**		19/30 = **63.3%**	

Table 2. Inter-annotator agreement for query-type classification.

Furthermore, we provided a re-assessment of the proportion of argumentative queries with respect to query origin for the IM2-set (IM2 members vs. non-IM2 members): non-IM2 members issued 30.8% of agreed argumentative queries, a proportion that, while smaller compared to that of IM2 members (69.2%), is still non-negligible. This contrasts with the opinion expressed in (Lisowska et al., 2004a) that argumentative queries are almost exclusively produced by IM2 members.

Among the 90 agreed IM2 queries that were cross-validated with the BET-observation set, 28.9% were argumentative. We also noted that the ratio of BET statements that contain argumentative information is quite high (66.9%).

3.3 Query Difficulty Analysis

In order to assess the difficulty in answering a query, we used the following categories that the annotators could assign to each query, according to the type of information and techniques they judged necessary for answering it:

1. *Role of IR*: states the role of standard[3] Information Retrieval (in combination with Topic Extraction[4]) techniques in answering the query. Possible values:
    a. *Irrelevant* (IR techniques are not applicable). Example: *What decisions have been made?*
    b. *successful* (IR techniques are sufficient). Example: *Was the budget approved?*
    c. *insufficient* (IR techniques are necessary, but not sufficient alone since they require additional inference and information, such as argumentative, cross-meeting, external corporate/project knowledge). Example: *Who rejected the proposal made by X on issue Y?*
2. *Artefacts*: information such as agenda, minutes of previous meetings, e-mails, invitations and other documents related and available before the meeting. Example: *Who was invited to the meeting?*
3. *Recordings*: the meeting recordings (audio, visual, transcription). This is almost always true, except for queries where Artefacts or Metadata are sufficient, such as *What was the agenda?, Who was invited to the meeting?*).
4. *Metadata*: context knowledge kept in static metadata (e.g., speakers, place, time). Example: *Who were the participants at the meeting?*
5. *Dialogue Acts & Adjacency Pairs*: Example: *What was John's response to my comment on the last meeting?*
6. *Argumentation*: metadata (annotations) about the argumentative structure of the meeting content. Example: *Did everybody agree on the decisions, or were there differences of opinion?*
7. *Semantics*: semantic interpretation of terms in the query and reference resolution, including deictics (e.g., for *how long, usually, systematically, criticisms; this, about me, I*). Example: *What decisions got made <u>easily</u>?* The term requiring semantic interpretation is underlined.
8. *Inference*: inference (deriving information that is implicit), calculation, and aggregation (e.g., for 'command' queries asking for lists of things – participants, issues, proposals). Example: *What would be required from me?*

[3] By standard IR we mean techniques based on bag-of-word search and TF-IDF indexing.

[4] Topic extraction techniques are based on topic shift detection (Galley et al., 2003) and keyword extraction (van der Plas et al., 2004).

9. *Multiple meetings*: availability of multiple meeting records. Example: *Who usually attends the project meetings?*
10. *External*: related knowledge, not explicitly present in the meeting records (e.g., information about the corporation or the projects related to the meeting). Example: *Did somebody talk about me or about my work?*

Results of annotation reported on the two query sets are synthesized in Table 3: IR is sufficient for answering 14.4% of the IM2 queries, and 20% of the MS-set queries. In 50% and 25.7% of the cases, respectively, it simply cannot be applied (irrelevant). Finally, IR alone is not enough in 35.6% of the queries from the IM2-set, and in 54.3% of the MS-set; it has to be complemented with other techniques.

IR is:	IM2-set		MS-set	
	all queries	AA	all queries	AA
Sufficient	39/270 = 14.4%	1/117 = 0.8%	7/35 = 20.0%	1/19 = 5.3%
Irrelevant	135/270 = 50.0%	55/117 = 47.0%	9/35 = 25.7%	3/19 = 15.8%
Insufficient	96/270 = 35.6%	61/117 = **52.1%**	19/35 = 54.3%	15/19 = **78.9%**

Table 3. The role of IR (and topic extraction) in answering users' queries.

If we consider agreed argumentative queries (Section 3.2), IR is effective in an extremely low percentage of cases (0.8% for IM2-set and 5.3% for MS-Set). IR is insufficient in most of the cases (52.1% and 78.9%) and inapplicable in the rest of the cases (47% and 15.8%). Only one argumentative query from each set was judged as being answerable with IR alone: *What were the decisions to be made (open questions) regarding the topic t1? When is the NEXT MEETING planned? (e.g. to follow up on action items).*

Table 4 shows the number of queries in each set that require argumentative information in order to be answered, distributed according to the query types. As expected, no argumentation information is necessary for answering factual queries, but some thematic queries do need it, such as *What was decided about topic T?* (24% in the IM2-set and 42.9% in the M.S.-set).

Overall, the majority of queries in both sets require argumentation information in order to be answered (56.3% from IM2 queries, and 65.7% from MS queries).

Category	IM2-set, Annotation 1			MS-set, Annotation 1		
	total	Req. arg.	Ratio	Total	Req. arg.	Ratio
Factual	67	0	0%	7	0	0%
Thematic	50	12	24.0%	7	3	42.9%
Process	81	73	90.1%	8	7	87.5%
Outcome	72	67	93.1%	13	13	100%
All	270	152	**56.3%**	35	23	**65.7%**

Table 4. Queries requiring argumentative information.

We finally looked at what kind of information is needed in those cases where IR is perceived as insufficient or irrelevant. Table 5 lists the most frequent combinations of information types required for the IM2-set and the MS-set.

3.4 Summary of Findings

The analysis of the annotations obtained for the 305 queries (35 from the Manager Survey set, and 270 from the IM2-set) revealed that:

- The information most sought by users from meetings is argumentative (i.e., pertains to the argumentative process and its outcome). It constitutes more than half of the total queries, while factual and thematic information are similar in proportions (Table 1);
- There was no significant difference in this respect between the IM2-set and the MS-set (Table 1);
- The decision as to whether a query is argumentative or not is easy to draw, as suggested by the high inter-annotator agreement shown in Table 2;
- Standard IR and topic extraction techniques are perceived as insufficient in answering most of the queries. Only less than 20% of the whole query set can be answered with IR, and almost no argumentative question (Table 3).
- Argumentative information is needed in answering the majority of the queries (Table 4);
- When IR alone fails, the information types that are needed most are (in addition to recordings): Argumentation, Semantics, Inference, and Metadata (Table 5); see Section 3.3 for their description.

IR alone fails	IM2-set												
Information types	IR insufficient			96 cases		35.6%		IR irrelevant			135 cases		50%
Artefacts									x				
Recordings	x	x	x	x	x	x	x	x	x	x	x		
Meta-data			x		x			x		x		x	x
Dlg acts & Adj. pairs													
Argumentation	x	x	x	x	x	x	x	x	x		x		
Semantics	x	x	x	x	x			x	x	x	x	x	
Inference	x		x	x			x	x	x	x	x	x	
Multiple meetings				x								x	
External													
Cases	15	11	9	8	7	5	4	14	9	8	8	7	5
Ratio (%)	15.6	11.5	9.4	8.3	7.3	5.2	4.2	10.4	6.7	5.9	5.9	5.2	3.7

IR alone fails	MS-set					
Information types	IR insufficient		19 cases	54.3%	IR irrelevant	9 cases 54.3%
Artefacts					x	x

Cases	6	4	2	2	2	2
Ratio (%)	31.6	21	10.5	10.5	22.2	22.2

Table 5. Some of the most frequent combinations of information required for answering the queries in the IM2-Set and in the MS-set when IR alone fails.

3.5 Discussion

Searching relevant information through the recorded meeting dialogues poses important problems when using standard IR indexing techniques (Baeza-Yates and Ribeiro-Nieto, 2000), because users ask different types of queries for which a single retrieval strategy (e.g., keywords-based) is insufficient. This is the case when looking at answers that require some sort of entailment, such as inferring that a proposal has been rejected when a meeting participant says *Are you kidding?*.

Spoken-language information retrieval (Vinciarelli, 2004) and automatic dialogue-act extraction techniques (Stolke et al., 2000; Clark and Popescu-Belis, 2004; Ang et al., 2005) have been applied to meeting recordings and produced good results under the assumption that the user is interested in retrieving either topic-based or dialog act-based information. But this assumption is partially invalidated by our user query elicitation analysis, which showed that such information is only sought in a relatively small fraction of the users' queries. A particular problem for these approaches is that the topic looked for is usually not a query itself (*Was topic T mentioned?)*, but just a parameter in more structured questions (*What was decided about T?*). Moreover, the relevant participants' contributions (dialog acts) need to be retrieved in combination, not in isolation (*The reactions to the proposal made by X*).

4 Conclusion and Future Work

While most of the research community has neglected the importance of argumentative queries in meeting information retrieval, we provided evidence that this type of queries is actually very common. We quantified the proportion of queries involving the argumentative dimension of the meeting content by performing an in-depth analysis of queries collected in two different elicitation surveys. The analysis of the annotations obtained for the 305 queries (270 from the IM2-set, 35 from MS-set) was aimed at providing insights into different matters: what type of information is typically sought by users from meetings; how difficult it is, and what kind of information and techniques are needed in order to answer user queries.

This work represents an initial step towards a better understanding of user queries on the meeting domain. It could provide useful intuitions about

how to perform the automatic classification of answer types and, more importantly, the automatic extraction of argumentative features and their relations with other components of the query (e.g., topic, named entities, events).

In the future, we intend to better ground our first empirical findings by i) running the queries against a real IR system with indexed meeting transcripts and evaluate the quality of the obtained answers; ii) ask judges to manually rank the difficulty of each query, and iii) compare the two rankings. We would also like to see how frequent argumentative queries are in other domains (such as TV talk shows or political debates) in order to generalize our results.

Abstract

Automatic segmentation is important for making multimedia archives comprehensible, and for developing downstream information retrieval and extraction modules. In this study, we explore approaches that can segment multiparty conversational speech by integrating various knowledge sources (e.g., words, audio and video recordings, speaker intention and context). In particular, we evaluate the performance of a Maximum Entropy approach, and examine the effectiveness of multimodal features on the task of dialogue segmentation. We also provide a quantitative account of the effect of using ASR transcription as opposed to human transcripts.

1 Introduction

Recent advances in multimedia technologies have led to huge archives of audio-video recordings of multiparty conversations in a wide range of areas including clinical use, online video sharing services, and meeting capture and analysis. While it is straightforward to replay such recordings, finding information from the often lengthy archives is a more challenging task. Annotating implicit semantics to enhance browsing and searching of recorded conversational speech has therefore posed new challenges to the field of multimedia information retrieval.

One critical problem is how to divide unstructured conversational speech into a number of locally coherent segments. The problem is important for two reasons: First, empirical analysis has shown that annotating transcripts with semantic information (e.g., topics) enables users to browse and find information from multimedia archives more efficiently (Banerjee et al., 2005). Second, because the automatically generated segments make up for the lack of explicit orthographic cues (e.g., story and paragraph breaks) in conversational speech, dialogue segmentation is useful in many spoken language understanding tasks, including anaphora resolution (Grosz and Sidner, 1986), information retrieval (e.g., as input for the TREC Spoken Document Retrieval (SDR) task), and summarization (Zechner and Waibel, 2000).

This study therefore aims to explore whether a Maximum Entropy (MaxEnt) classifier can integrate multiple knowledge sources for segmenting recorded speech. In this paper, we first evaluate the effectiveness of features that have been proposed in previous work, with a focus on features that can be extracted automatically. Second, we examine other knowledge sources that have not been studied systematically in previous work, but which we expect to be good predictors of dialogue segments. In addition, as our ultimate goal is to develop an information retrieval module that can be operated in a fully automatic fashion, we also investigate the impact of automatic speech recognition (ASR) errors on the task of dialogue segmentation.

2 Previous Work

In previous work, the problem of automatic dialogue segmentation is often considered as similar to the problem of topic segmentation. Therefore, research has adopted techniques previously developed

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 1016–1023,
Prague, Czech Republic, June 2007.

to segment topics in text (Kozima, 1993; Hearst, 1997; Reynar, 1998) and in read speech (e.g., broadcast news) (Ponte and Croft, 1997; Allan et al., 1998). For example, lexical cohesion-based algorithms, such as LCSEG (Galley et al., 2003), or its word frequency-based predecessor TextTile (Hearst, 1997) capture topic shifts by modeling the similarity of word repetition in adjacent windows.

However, recent work has shown that LCSEG is less successful in identifying "agenda-based conversation segments" (e.g., *presentation*, *group discussion*) that are typically signalled by differences in group activity (Hsueh and Moore, 2006). This is not surprising since LCSEG considers only lexical cohesion. Previous work has shown that training a segmentation model with features that are extracted from knowledge sources other than words, such as speaker interaction (e.g., overlap rate, pause, and speaker change) (Galley et al., 2003), or participant behaviors, e.g., note taking cues (Banerjee and Rudnicky, 2006), can outperform LCSEG on similar tasks.

In many other fields of research, a variety of features have been identified as indicative of segment boundaries in different types of recorded speech. For example, Brown et al. (1980) have shown that a discourse segment often starts with relatively high pitched sounds and ends with sounds of pitch within a more compressed range. Passonneau and Litman (1993) identified that topic shifts often occur after a pause of relatively long duration. Other prosodic cues (e.g., pitch contour, energy) have been studied for their correlation with story segments in read speech (Tur et al., 2001; Levow, 2004; Christensen et al., 2005) and with theory-based discourse segments in spontaneous speech (e.g., direction-given monologue) (Hirschberg and Nakatani, 1996). In addition, head and hand/forearm movements are used to detect group-action based segments (McCowan et al., 2005; Al-Hames et al., 2005).

However, many other features that we expect to signal segment boundaries have not been studied systematically. For instance, speaker intention (i.e., dialogue act types) and conversational context (e.g., speaker role). In addition, although these features are expected to be complementary to one another, few of the previous studies have looked at the question how to use conditional approaches to model the correlation among features.

3 Methodology

3.1 Meeting Corpus

This study aims to explore approaches that can integrate multimodal information to discover implicit semantics from conversation archives. As our goal is to identify multimodal cues of segmentation in face-to-face conversation, we use the AMI meeting corpus (Carletta et al., 2006), which includes audio-video recordings, to test our approach. In particular, we are using 50 scenario-based meetings from the AMI corpus, in which participants are assigned to different roles and given specific tasks related to designing a remote control. On average, AMI meetings last 26 minutes, with over 4,700 words transpired. This corpus includes annotation for dialogue segmentation and topic labels. In the annotation process, annotators were given the freedom to subdivide a segment into subsegments to indicate when the group was discussing a subtopic. Annotators were also given a set of segment descriptions to be used as labels. Annotators were instructed to add a new label only if they could not find a match in the standard set. The set of segment descriptions can be divided to three categories: activity-based (e.g., presentation, discussion), issue-based (e.g., budget, usability), and functional segments (e.g., chitchat, opening, closing).

3.2 Preprocessing

The first step is to break a recorded meeting into minimal units, which can vary from sentence chunks to blocks of sentences. In this study, we use *spurts*, that is, consecutive speech with no pause longer than 0.5 seconds, as minimal units.

Then, to examine the difference between the set of features that are characteristic of segmentation at both coarse and fine levels of granularity, this study characterizes a dialogue as a sequence of segments that may be further divided into sub-segments. We take the theory-free dialogue segmentation annotations in the corpus and flatten the sub-segment structure and consider only two levels of segmentation: top-level segments and all sub-level segments.[1] We

[1]We take the spurts which the annotators choose as the beginning of a segment as the topic boundaries. On average,

observed that annotators tended to annotate activity-based segments only at the top level, whereas they often included sub-topics when segmenting issue-based segments. For example, a top-level *interface specialist presentation* segment can be divided into *agenda/equipment issues*, *user requirements*, *existing products*, and *look and usability* sub-level segments.

3.3 Intercoder Agreement

To measure intercoder agreement, we employ three different metrics: the kappa coefficient, PK, and WD. Kappa values measure how well a pair of annotators agree on where the segments break. PK is the probability that two spurts drawn randomly from a document are incorrectly identified as belonging to the same segment. WindowDiff (WD) calculates the error rate by moving a sliding window across the transcript counting the number of times the hypothesized and reference segment boundaries are different. While not uncontroversial, the use of these metrics is widespread. Table 1 shows the intercoder agreement of the top-level and sub-level segmentation respectively.

It is unclear whether the kappa values shown here indicate reliable intercoder agreement.[2] But given the low disagreement rate among codings in terms of the PK and WD scores, we will argue for the reliability of the annotation procedure used in this study. Also, to our knowledge the reported degree of agreement is the best in the field of meeting dialogue segmentation.[3]

Intercoder	Kappa	PK	WD
TOP	0.66	0.11	0.17
SUB	0.59	0.23	0.28

Table 1: Intercoder agreement of annotations at the top-level (TOP) and sub-level (SUB) segments.

the annotators marked 8.7 top-level segments and 14.6 sub-segments per meeting.

[2]In computational linguistics, kappa values over 0.67 point to reliable intercoder agreement. But Di Eugenio and Glass (2004) have found that this interpretation does not hold true for all tasks.

[3]For example, Gruenstein et al.(2005) report kappa (PK/WD) of 0.41(0.28/0.34) for determining the top-level and 0.45(0.27/0.35) for the sub-level segments in the ICSI meeting corpus.

3.4 Feature Extraction

As reported in Section 2, there is a wide range of features that are potentially characteristic of segment boundaries, and we expect to find some of them useful for automatic recognition of segment boundaries. The features we explore can be divided into the following five classes:

Conversational Features: We follow Galley et al. (2003) and extracted a set of conversational features, including the amount of overlapping speech, the amount of silence between speaker segments, speaker activity change, the number of cue words, and the predictions of LCSEG (i.e., the lexical cohesion statistics, the estimated posterior probability, the predicted class).

Lexical Features: We compile the list of words that occur more than once in the spurts that have been marked as a top-level or sub-segment boundary in the training set. Each spurt is then represented as a vector space of unigrams from this list.

Prosodic Features: We use the direct modelling approach proposed in Shriberg and Stolcke (2001) and include maximum F0 and energy of the spurt, mean F0 and energy of the spurt, pitch contour (i.e., slope) and energy at multiple points (e.g., the first and last 100 and 200 ms, the first and last quarter, the first and second half) of a spurt. We also include rate of speech, in-spurt silence, preceding and subsequent pauses, and duration. The rate of speech is calculated as both the number of words and the number of syllables spoken per second.

Motion Features: We measure the magnitude of relevant movements in the meeting room using methods that detect movements directly from video recordings in frames of 40 ms. Of special interest are the frontal shots as recorded by the close up cameras, the hand movements as recorded by the overview cameras, and shots of the areas of the room where presentations are made. We then average the magnitude of movements over the frames within a spurt as its feature value.

Contextual Features: These include dialogue act type[4] and speaker role (e.g., project manager, mar-

[4]In the annotations, each dialogue act is classified as one of 15 types, including acts about information exchange (e.g., Inform), acts about possible actions (e.g., Suggest), acts whose primary purpose is to smooth the social functioning (e.g., Be-positive), acts that are commenting on previous discussion (e.g.,

keting expert). As each spurt may consist of multiple dialogue acts, we represent each spurt as a vector of dialogue act types, wherein a component is 1 or 0 depending on whether the type occurs in the spurt.

3.5 Multimodal Integration Using Maximum Entropy Models

Previous work has used MaxEnt models for sentence and topic segmentation and shown that conditional approaches can yield competitive results on these tasks (Christensen et al., 2005; Hsueh and Moore, 2006). In this study, we also use a MaxEnt classifier[5] for dialogue segmentation under the typical supervised learning scheme, that is, to train the classifier to maximize the conditional likelihood over the training data and then to use the trained model to predict whether an unseen spurt in the test set is a segment boundary or not. Because continuous features have to be discretized for MaxEnt, we applied a histogram binning approach, which divides the value range into N intervals that contain an equal number of counts as specified in the histogram, to discretize the data.

4 Experimental Results

4.1 Probabilistic Models

The first question we want to address is whether the different types of characteristic multimodal features can be integrated, using the conditional MaxEnt model, to automatically detect segment boundaries. In this study, we use a set of 50 meetings, which consists of 17,977 spurts. Among these spurts, only 1.7% and 3.3% are top-level and subsegment boundaries. For our experiments we use 10-fold cross validation. The baseline is the result obtained by using LCSEG, an unsupervised approach exploiting only lexical cohesion statistics.

Table 2 shows the results obtained by using the same set of conversational (CONV) features used in previous work (Galley et al., 2003; Hsueh and Moore, 2006), and results obtained by using all the available features (ALL). The evaluation metrics PK and WD are conventional measures of error rates in segmentation (see Section 3.3). In Row 2, we see that using a MaxEnt classifier trained on the conversational features (CONV) alone improves over the LCSEG baseline by 15.3% for top-level segments and 6.8% for sub-level segements. Row 3 shows that combining additional knowledge sources, including lexical features (LX1) and the non-verbal features, prosody (PROS), motion (MOT), and context (CTXT), yields a further improvement (of 8.8% for top-level segmentation and 5.4% for sub-level segmentation) over the model trained on conversational features.

MAXENT(ALL)	0.30	0.33	0.34	0.36

Table 2: Compare the result of MaxEnt models trained with only conversational features (CONV) and with all available features (ALL).

4.2 Feature Effects

The second question we want to address is which knowledge sources (and combinations) are good predictors for segment boundaries. In this round of experiments, we evaluate the performance of different feature combinations. Table 3 further illustrates the impact of each feature class on the error rate metrics (PK/WD). In addition, as the PK and WD score do not reflect the magnitude of over- or underprediction, we also report on the average number of hypothesized segment boundaries (Hyp). The number of reference segments in the annotations is 8.7 at the top-level and 14.6 at the sub-level.

Rows 2-6 in Table 3 show the results of models trained with each individual feature class. We performed a one-way ANOVA to examine the effect of different feature classes. The ANOVA suggests a reliable effect of feature class ($F(5, 54) = 36.1$; $p < .001$). We performed post-hoc tests (Tukey HSD) to test for significant differences. Analysis shows that the model that is trained with lexical features alone (LX1) performs significantly worse than the LCSEG baseline ($p < .001$). This is due to the fact that cue words, such as *okay* and *now*, learned from the training data to signal seg-

Elicit-Assessment), and acts that allow complete segmentation (e.g., Stall).

[5]The parameters of the MaxEnt classifier are optimized using Limited-Memory Variable Metrics.

CONV	3.1	0.34	0.34	2.9	0.37	0.37
PROS	2.3	0.35	0.35	2.5	0.37	0.37
MOT	96.2	0.36	0.40	96.2	0.38	0.41
CTXT	2.6	0.34	0.34	2.2	0.37	0.37
ALL	7.7	0.29	0.33	7.6	0.35	0.38

Table 3: Effects of individual feature classes and their combination on detecting segment boundaries.

ment boundaries, are often used for non-discourse purposes, such as making a semantic contribution to an utterance.[6] Thus, we hypothesize that these ambiguous cue words have led the LX1 model to overpredict. Row 7 further shows that when all available features (including LX1) are used, the combined model (ALL) yields performance that is significantly better than that obtained with individual feature classes ($F(5, 54) = 32.2$; $p < .001$).

	TOP			SUB		
	Hyp	PK	WD	Hyp	PK	WD
ALL	7.7	0.29	0.33	7.6	0.35	0.38
ALL-LX1	3.9	0.35	0.35	3.5	0.37	0.38
ALL-CONV	6.6	0.30	0.34	6.8	0.35	0.37
ALL-PROS	5.6	0.29	0.31	7.4	0.33	0.35
ALL-MOTION	7.5	0.30	0.35	7.3	0.35	0.37
ALL-CTXT	7.2	0.29	0.33	6.7	0.36	0.38

Table 4: Performance change of taking out each individual feature class from the ALL model.

Table 4 illustrates the error rate change (i.e., increased or decreased PK and WD score)[7] that is incurred by leaving out one feature class from the ALL model. Results show that CONV, PROS, MOTION and CTXT can be taken out from the ALL model individually without increasing the error rate significantly.[8] Morevoer, the combined models always perform better than the LX1 model ($p < .01$), cf. Table 3.

This suggests that the non-lexical feature classes are complementary to LX1, and thus it is essential to incorporate some, but not necessarily all, of the non-lexical classes into the model.

	TOP			SUB		
	Hyp	PK	WD	Hyp	PK	WD
LX1	61.2	0.53	0.72	65.1	0.49	0.66
MOT	96.2	0.36	0.40	96.2	0.38	0.41
LX1+CONV	5.3	0.27	0.30	6.9	0.32	0.35
LX1+PROS	6.2	0.30	0.33	7.3	0.36	0.38
LX1+MOT	20.2	0.39	0.49	24.8	0.39	0.47
LX1+CTXT	6.3	0.28	0.31	7.2	0.33	0.35
MOT+PROS	62.0	0.34	0.34	62.1	0.37	0.37
MOT+CTXT	2.7	0.33	0.33	2.3	0.37	0.37

Table 5: Effects of combining complementary features on detecting segment boundaries.

Table 5 further illustrates the performance of different feature combinations on detecting segment boundaries. By subtracting the PK or WD score in Row 1, the LX1 model, from that in Rows 3-6, we can tell how essential each of the non-lexical classes is to be combined with LX1 into one model. Results show that CONV is the most essential, followed by CTXT, PROS and MOT. The advantage of incorporating the non-lexical feature classes is also shown in the noticeably reduced number of overpredictions as compared to that of the LX1 model.

To analyze whether there is a significant interaction between feature classes, we performed another round of ANOVA tests to examine the effect of LX1 and each of the non-lexical feature classes on detecting segment boundaries. This analysis shows that there is a significant interaction effect on detecting both top-level and sub-level segment boundaries ($p < .01$), suggesting that the performance of LX1 is significantly improved when combined with any non-lexical feature class. Also, among the non-lexical feature classes, combining prosodic features significantly improves the performance of the model in which the motion features are combined to detect top-level segment boundaries ($p < .05$).

[6] Hirschberg and Litman (1987) have proposed to discriminate the different uses intonationally.

[7] Note that the increase in error rate indicates performance degradation, and vice versa.

[8] Sign tests were used to test for significant differences between means in each fold of cross validation.

4.3 Degradation Using ASR

The third question we want to address here is whether using the output of ASR will cause significant degradation to the performance of the segmentation approaches. The ASR transcripts used in this experiment are obtained using standard technology including HMM based acoustic modeling and N-gram based language models (Hain et al., 2005). The average word error rates (WER) are 39.1%. We also applied a word alignment algorithm to ensure that the number of words in the ASR transcripts is the same as that in the human-produced transcripts. In this way we can compare the PK and WD metrics obtained on the ASR outputs directly with that on the human transcripts.

In this study, we again use a set of 50 meetings and 10-fold cross validation. We compare the performance of the reference models, which are trained on human transcripts and tested on human transcripts, with that of the ASR models, which are trained on ASR transcripts and tested on ASR transcripts. Table 6 shows that despite the word recognition errors, none of the LCSEG, the MaxEnt models trained with conversational features, and the MaxEnt models trained with all available features perform significantly worse on ASR transcripts than on reference transcripts. One possible explanation for this, which we have observed in our corpus, is that the ASR system is likely to mis-recognize different occurences of words in the same way, and thus the lexical cohesion statistic, which captures the similarity of word repetition between two adjacency windows, is also likely to remain unchanged. In addition, when the models are trained with other features that are not affected by the recognition errors, such as pause and overlap, the negative impacts of recognition errors are further reduced to an insignificant level.

5 Discussion

The results in Section 4 show the benefits of including additional knowledge sources for recognizing segment boundaries. The next question to be addressed is what features in these sources are most useful for recognition. To provide a qualitative account of the segmentation cues, we performed an analysis to determine whether each proposed feature discriminates the class of segment boundaries. Previous work has identified statistical measures (e.g., Log Likelihood ratio) that are useful for determining the statistical association strength (relevance) of the occurrence of an n-gram feature to target class (Hsueh and Moore, 2006). Here we extend that study to calculate the LogLikelihood relevance of all of the features used in the experiments, and use the statistics to rank the features.

Our analysis shows that people do speak and behave differently near segment boundaries. Some of the identified segmentation cues match previous findings. For example, a segment is likely to start with higher pitched sounds (Brown et al., 1980; Ayers, 1994) and a lower rate of speech (Lehiste, 1980). Also, interlocutors pause longer than usual to make sure that everyone is ready to move on to a new discussion (Brown et al., 1980; Passonneau and Litman, 1993) and use some conventional expressions (e.g., *now*, *okay*, *let's*, *um*, *so*).

Our analysis also identified segmentation cues that have not been mentioned in previous research. For example, interlocutors do not move around a lot when a new discussion is brought up; interlocutors mention agenda items (e.g., *presentation*, *meeting*) or content words more often when initiating a new discussion. Also, from the analysis of current dialogue act types and their immediate contexts, we also observe that at segment boundaries interlocutors do the following more often than usual: start speaking before they are ready (*Stall*), give information (*Inform*), elicit an assessment of what has been said so far (*Elicit-assessment*), or act to smooth social functioning and make the group happier (*Be-positive*).

6 Conclusions and Future Work

This study explores the use of features from multiple knowledge sources (i.e., words, prosody, motion, interaction cues, speaker intention and role) for developing an automatic segmentation component in spontaneous, multiparty conversational speech. In particular, we addressed the following questions: (1) Can a MaxEnt classifier integrate the potentially characteristic multimodal features for automatic dialogue segmentation? (2) What are the most discriminative knowledge sources for detecting segment boundaries? (3) Does the use of ASR transcription significantly degrade the performance of a segmentation model?

First of all, our results show that a well performing MaxEnt model can be trained with available knowledge sources. Our results improve on previous work, which uses only conversational features, by 8.8% for top-level segmentation and 5.4% for sub-level segmentation. Analysis of the effectiveness of the various features shows that lexical features (i.e., cue words) are the most essential feature class to be combined into the segmentation model. However, lexical features must be combined with other features, in particular, conversational features (i.e., lexical cohesion, overlap, pause, speaker change), to train well performing models.

In addition, many of the non-lexical feature classes, including those that have been identified as indicative of segment boundaries in previous work (e.g., prosody) and those that we hypothesized as good predictors of segment boundaries (e.g., motion, context), are not beneficial for recognizing boundaries when used in isolation. However, these non-lexical features are useful when combined with lexical features, as the presence of the non-lexical features can balance the tendency of models trained with lexical cues alone to overpredict.

Experiments also show that it is possible to segment conversational speech directly on the ASR outputs. These results encouragingly show that we can segment conversational speech using features extracted from different knowledge sources, and in turn, facilitate the development of a fully automatic segmentation component for multimedia archives.

With the segmentation models developed and discriminative knowledge sources identified, a remaining question is whether it is possible to automatically select the discriminative features for recognition. This is particularly important for prosodic features, because the direct modelling approach we adopted resulted in a large number of features. We expect that by applying feature selection methods we can further improve the performance of automatic segmentation models. In the field of machine learning and pattern analysis, many methods and selection criteria have been proposed. Our next step will be to examine the effectiveness of these methods for the task of automatic segmentation. Also, we will further explore how to choose the best performing ensemble of knowledge sources so as to facilitate automatic selection of knowledge sources to be included.

Abstract

Psychiatric document retrieval attempts to help people to efficiently and effectively locate the consultation documents relevant to their depressive problems. Individuals can understand how to alleviate their symptoms according to recommendations in the relevant documents. This work proposes the use of high-level topic information extracted from consultation documents to improve the precision of retrieval results. The topic information adopted herein includes *negative life events*, *depressive symptoms* and *semantic relations* between symptoms, which are beneficial for better understanding of users' queries. Experimental results show that the proposed approach achieves higher precision than the word-based retrieval models, namely the vector space model (VSM) and Okapi model, adopting word-level information alone.

1 Introduction

Individuals may suffer from negative or stressful life events, such as death of a family member, argument with a spouse and loss of a job. Such events play an important role in triggering depressive symptoms, such as depressed moods, suicide attempts and anxiety. Individuals under these circumstances can consult health professionals using message boards and other services. Health professionals respond with suggestions as soon as possible. However, the response time is generally several days, depending on both the processing time required by health professionals and the number of problems to be processed. Such a long response time is unacceptable, especially for patients suffering from psychiatric emergencies such as suicide attempts. A potential solution considers the problems that have been processed and the corresponding suggestions, called consultation documents, as the psychiatry web resources. These resources generally contain thousands of consultation documents (problem-response pairs), making them a useful information resource for mental health care and prevention. By referring to the relevant documents, individuals can become aware that they are not alone because many people have suffered from the same or similar problems. Additionally, they can understand how to alleviate their symptoms according to recommendations. However, browsing and searching all consultation documents to identify the relevant documents is time consuming and tends to become overwhelming. Individuals need to be able to retrieve the relevant consultation documents efficiently and effectively. Therefore, this work presents a novel mechanism to automatically retrieve the relevant consultation documents with respect to users' problems.

Traditional information retrieval systems represent queries and documents using a bag-of-words approach. Retrieval models, such as the *vector space model (VSM)* (Baeza-Yates and Ribeiro-Neto, 1999) and *Okapi model* (Robertson et al., 1995; Robertson et al., 1996; Okabe et al., 2005), are then adopted to estimate the relevance between queries and documents. The VSM represents each query and document as a vector of words, and adopts the *cosine measure* to estimate their relevance. The Okapi model, which has been used on the Text REtrieval Conference (TREC) collections, developed a family of word-weighting functions

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 1024–1031,
Prague, Czech Republic, June 2007.

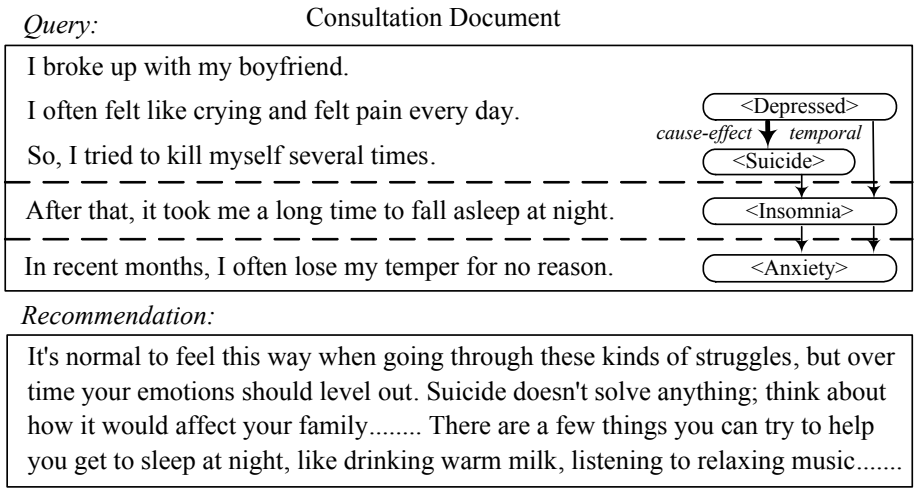

Figure 1. Example of a consultation document. The bold arrowed lines denote cause-effect relations; arrowed lines denote temporal relations; dashed lines denote temporal boundaries, and angle brackets denote depressive symptoms

for relevance estimation. These functions consider word frequencies and document lengths for word weighting. Both the VSM and Okapi models estimate the relevance by matching the words in a query with the words in a document. Additionally, query words can further be expanded by the concept hierarchy within general-purpose ontologies such as WordNet (Fellbaum, 1998), or automatically constructed ontologies (Yeh et al., 2004).

However, such word-based approaches only consider the word-level information in queries and documents, ignoring the high-level topic information that can help improve understanding of users' queries. Consider the example consultation document in Figure 1. A consultation document comprises two parts: the *query* part and *recommendation* part. The query part is a natural language text, containing rich *topic information* related to users' depressive problems. The topic information includes *negative life events*, *depressive symptoms*, and *semantic relations* between symptoms. As indicated in Figure 1, the subject suffered from a love-related event, and several depressive symptoms, such as <Depressed>, <Suicide>, <Insomnia> and <Anxiety>. Moreover, there is a cause-effect relation holding between <Depressed> and <Suicide>, and a temporal relation holding between <Depressed> and <Insomnia>. Different topics may lead to different suggestions decided by experts. Therefore, an ideal retrieval system for consultation documents should consider such topic information so as to improve the retrieval precision.

Natural language processing (NLP) techniques can be used to extract more precise information from natural language texts (Wu et al., 2005a; Wu et al., 2005b; Wu et al., 2006; Yu et al., 2007). This work adopts the methodology presented in (Wu et al. 2005a) to extract depressive symptoms and their relations, and adopts the pattern-based method presented in (Yu et al., 2007) to extract negative life events from both queries and consultation documents. This work also proposes a retrieval model to calculate the similarity between a query and a document by combining the similarities of the extracted topic information.

The rest of this work is organized as follows. Section 2 briefly describes the extraction of topic information. Section 3 presents the retrieval model. Section 4 summarizes the experimental results. Conclusions are finally drawn in Section 5.

2 Framework of Consultation Document Retrieval

Figure 2 shows the framework of consultation document retrieval. The retrieval process begins with receiving a user's query about his depressive problems in natural language. The example query is shown in Figure 1. The topic information is then extracted from the query, as shown in the center of Figure 2. The extracted topic information is repre-

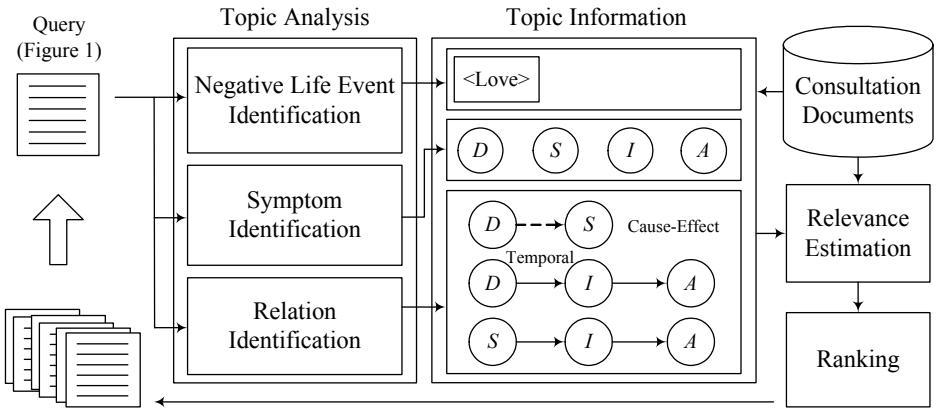

Figure 2. Framework of consultation document retrieval. The rectangle denotes a negative life event related to love relation. Each circle denotes a symptom. *D*: Depressed, *S*: Suicide, *I*: Insomnia, *A*: Anxiety.

sented by the sets of negative life events, depressive symptoms, and semantic relations. Each element in the event set and symptom set denotes an individual event and symptom, respectively, while each element in the relation set denotes a *symptom chain* to retain the order of symptoms. Similarly, the query parts of consultation documents are represented in the same manner. The relevance estimation then calculates the similarity between the input query and the query part of each consultation document by combining the similarities of the sets of events, symptoms, and relations within them. Finally, a list of consultation documents ranked in the descending order of similarities is returned to the user.

In the following, the extraction of topic information is described briefly. The detailed process is described in (Wu et al. 2005a) for symptom and relation identification, and in (Yu et al., 2007) for event identification.

1) **Symptom identification:** A total of 17 symptoms are defined based on the Hamilton Depression Rating Scale (HDRS) (Hamilton, 1960). The identification of symptoms is sentence-based. For each sentence, its structure is first analyzed by a probabilistic context free grammar (PCFG), built from the Sinica Treebank corpus developed by Academia Sinica, Taiwan (http://treebank.sinica.edu.tw), to generate a set of dependencies between word tokens. Each dependency has the format (*modifier*, *head*, $rel_{modifier,head}$). For instance, the dependency (matters, worry about, goal) means that "matters" is the goal to the head of the sentence "worry about". Each sentence can then be associated with a symptom based on the probabilities that dependencies occur in all symptoms, which are obtained from a set of training sentences.

2) **Relation Identification:** The semantic relations of interest include cause-effect and temporal relations. After the symptoms are obtained, the relations holding between symptoms (sentences) are identified by a set of discourse markers. For instance, the discourse markers "because" and "therefore" may signal cause-effect relations, and "before" and "after" may signal temporal relations.

3) **Negative life event identification:** A total of 5 types of events, namely <Family>, <Love>, <School>, <Work> and <Social> are defined based on Pagano et al's (2004) research. The identification of events is a pattern-based approach. A pattern denotes a semantically plausible combination of words, such as <parents, divorce> and <exam, fail>. First, a set of patterns is acquired from psychiatry web corpora by using an evolutionary inference algorithm. The event of each sentence is then identified by using an SVM classifier with the acquired patterns as features.

3 Retrieval Model

The similarity between a query and a document, $Sim(q,d)$, is calculated by combining the similarities of the sets of events, symptoms and relations within them, as shown in (1).

$$Sim(q,d) = \alpha Sim_{Evn}(q,d) + \beta Sim_{Sym}(q,d) + (1-\alpha-\beta) Sim_{Rel}(q,d), \quad (1)$$

where $Sim_{Evn}(q,d)$, $Sim_{Sym}(q,d)$ and $Sim_{Rel}(q,d)$, denote the similarities of the sets of events, symptoms and relations, respectively, between a query and a document, and α and β denote the combination factors.

3.1 Similarity of events and symptoms

The similarities of the sets of events and symptoms are calculated in the same method. The similarity of the event set (or symptom set) is calculated by comparing the events (or symptoms) in a query with those in a document. Additionally, only the events (or symptoms) with the same type are considered. The events (or symptoms) with different types are considered as irrelevant, i.e., no similarity. For instance, the event <Love> is considered as irrelevant to <Work>. The similarity of the event set is calculated by

$$Sim_{Evn}(q,d) = \frac{1}{N(Evn_q \cup Evn_d)} \sum_{e \in q \cap d} Type(e_q, e_d) \cos(e_q, e_d) + const., \quad (2)$$

where Evn_q and Evn_d denote the event set in a query and a document, respectively; e_q and e_d denote the events; $N(Evn_q \cup Evn_d)$ denotes the cardinality of the union of Evn_q and Evn_d as a normalization factor, and $Type(e_q, e_d)$ denotes an identity function to check whether two events have the same type, defined as

$$Type(e_q, e_d) = \begin{cases} 1 & Type(e_q) = Type(e_d) \\ 0 & \text{otherwise} \end{cases}. \quad (3)$$

The $\cos(e_q, e_d)$ denotes the cosine angle between two vectors of words representing e_q and e_d, as shown below.

$$\cos(e_q, e_d) = \frac{\sum_{i=1}^{T} w_{e_q}^i w_{e_d}^i}{\sqrt{\sum_{i=1}^{T} \left(w_{e_q}^i\right)^2} \sqrt{\sum_{i=1}^{T} \left(w_{e_d}^i\right)^2}}, \quad (4)$$

where w denotes a word in a vector, and T denotes the dimensionality of vectors. Accordingly, when two events have the same type, their similarity is given as $\cos(e_q, e_d)$ plus a constant, *const.*. Additionally, $\cos(e_q, e_d)$ and *const.* can be considered as the word-level and topic-level similarities, respectively. The optimal setting of *const.* is determined empirically.

3.2 Similarity of relations

When calculating the similarity of relations, only the relations with the same type are considered. That is, the cause-effect (or temporal) relations in a query are only compared with the cause-effect (or temporal) relations in a document. Therefore, the similarity of relation sets can be calculated as

$$Sim_{Rel}(q,d) = \frac{1}{Z} \sum_{r_q, r_d} Type(r_q, r_d) Sim(r_q, r_d), \quad (5)$$

$$Z = N_C(r_q) N_C(r_d) + N_T(r_q) N_T(r_d), \quad (6)$$

where r_q and r_d denote the relations in a query and a document, respectively; Z denotes the normalization factor for the number of relations; $Type(e_q, e_d)$ denotes an identity function similar to (3), and $N_C(\bullet)$ and $N_T(\bullet)$ denote the numbers of cause-effect and temporal relations.

Both cause-effect and temporal relations are represented by symptom chains. Hence, the similarity of relations is measured by the similarity of symptom chains. The main characteristic of a symptom chain is that it retains the cause-effect or temporal order of the symptoms within it. Therefore, the order of the symptoms must be considered when calculating the similarity of two symptom chains. Accordingly, a *sequence kernel function* (Lodhi et al., 2002; Cancedda et al., 2003) is adopted to calculate the similarity of two symptom chains. A sequence kernel compares two sequences of symbols (e.g., characters, words) based on the subsequences within them, but not individual symbols. Thereby, the order of the symptoms can be incorporated into the comparison process.

The sequence kernel calculates the similarity of two symptom chains by comparing their sub-symptom chains at different lengths. An increasing number of common sub-symptom chains indicates a greater similarity between two symptom chains. For instance, both the two symptom chains $s_1 s_2 s_3 s_4$ and $s_3 s_2 s_1$ contain the same symptoms s_1, s_2 and s_3, but in different orders. To calculate the similarity between these two symptom chains, the sequence kernel first calculates their similarities at length 2 and 3, and then averages the similarities at the two lengths. To calculate the similarity at

length 2, the sequence kernel compares their sub-symptom chains of length 2, i.e., $\{s_1s_2, s_1s_3, s_1s_4, s_2s_3, s_2s_4, s_3s_4\}$ and $\{s_3s_2, s_3s_1, s_2s_1\}$. Similarly, their similarity at length 3 is calculated by comparing their sub-symptom chains of length 3, i.e., $\{s_1s_2s_3,\ s_1s_2s_4,\ s_1s_3s_4,\ s_2s_3s_4\}$ and $\{s_3s_2s_1\}$. Obviously, no similarity exists between $s_1s_2s_3s_4$ and $s_3s_2s_1$, since no sub-symptom chains are matched at both lengths. In this example, the sub-symptom chains of length 1, i.e., individual symptoms, do not have to be compared because they contain no information about the order of symptoms. Additionally, the sub-symptom chains of length 4 do not have to be compared, because the two symptom chains share no sub-symptom chains at this length. Hence, for any two symptom chains, the length of the sub-symptom chains to be compared ranges from two to the minimum length of the two symptom chains. The similarity of two symptom chains can be formally denoted as

$$\begin{aligned} Sim(r_q, r_d) &\equiv Sim(sc_q^{N_1}, sc_d^{N_2}) \\ &= K(sc_q^{N_1}, sc_d^{N_2}) \\ &= \frac{1}{N-1}\sum_{n=2}^{N} K_n(sc_q^{N_1}, sc_d^{N_2}), \end{aligned} \tag{7}$$

where $sc_q^{N_1}$ and $sc_d^{N_2}$ denote the symptom chains corresponding to r_q and r_d, respectively; N_1 and N_2 denote the length of $sc_q^{N_1}$ and $sc_d^{N_2}$, respectively; $K(\bullet, \bullet)$ denotes the sequence kernel for calculating the similarity between two symptom chains; $K_n(\bullet, \bullet)$ denotes the sequence kernel for calculating the similarity between two symptom chains at length n, and N is the minimum length of the two symptom chains, i.e., $N = \min(N_1, N_2)$. The sequence kernel $K_n(sc_i^{N_1}, sc_j^{N_2})$ is defined as

$$\begin{aligned} K_n(sc_i^{N_1}, sc_j^{N_2}) &= \left\langle \frac{\Phi_n(sc_i^{N_1})}{\left\|\Phi_n(sc_i^{N_1})\right\|} \bullet \frac{\Phi_n(sc_j^{N_2})}{\left\|\Phi_n(sc_j^{N_2})\right\|} \right\rangle \\ &= \frac{\sum_{u \in SC^n} \phi_u(sc_i^{N_1})\phi_u(sc_j^{N_2})}{\sqrt{\sum_{u \in SC^n} \phi_u(sc_i^{N_1})\phi_u(sc_j^{N_1})}\sqrt{\sum_{u \in SC^n} \phi_u(sc_i^{N_2})\phi_u(sc_j^{N_2})}}, \end{aligned} \tag{8}$$

where $K_n(sc_i^{N_1}, sc_j^{N_2})$ is the normalized inner product of vectors $\Phi_n(sc_i^{N_1})$ and $\Phi_n(sc_j^{N_2})$; $\Phi_n(\bullet)$ denotes a mapping that transforms a given symptom chain into a vector of the sub-symptom chains of length n; $\phi_u(\bullet)$ denotes an element of the vector, representing the weight of a sub-symptom chain u, and SC^n denotes the set of all possible sub-symptom chains of length n. The weight of a sub-symptom chain, i.e., $\phi_u(\bullet)$, is defined as

$$\phi_u(sc_i^{N_1}) = \begin{cases} 1 & u \text{ is a contiguous sub-symptom chain of } sc_i^{N_1} \\ \lambda^{\theta} & u \text{ is a non-contiguous sub-symptom chain with } \theta \text{ skipped symptoms} \\ 0 & u \text{ does not appear in } sc_i^{N_1}, \end{cases} \tag{9}$$

where $\lambda \in [0,1]$ denotes a *decay factor* that is adopted to penalize the non-contiguous sub-symptom chains occurred in a symptom chain based on the skipped symptoms. For instance, $\phi_{s_1s_2}(s_1s_2s_3) = \phi_{s_2s_3}(s_1s_2s_3) = 1$ since s_1s_2 and s_2s_3 are considered as contiguous in $s_1s_2s_3$, and $\phi_{s_1s_3}(s_1s_2s_3) = \lambda^1$ since s_1s_3 is a non-contiguous sub-symptom chain with one skipped symptom. The decay factor is adopted because a contiguous sub-symptom chain is preferable to a non-contiguous chain when comparing two symptom chains. The setting of the decay factor is domain dependent. If $\lambda = 1$, then no penalty is applied for skipping symptoms, and the cause-effect and temporal relations are transitive. The optimal setting of

Given the two symptom chains, $s_1s_2s_3$ and $s_1s_2s_3s_4$.
Their similarity is calculated as

$$K(s_1s_2s_3, s_1s_2s_3s_4) = \frac{1}{2}\sum_{n=2}^{3} K_n(s_1s_2s_3, s_1s_2s_3s_4).$$

$$\begin{aligned} K_2(s_1s_2s_3, s_1s_2s_3s_4) &= \left\langle \frac{\Phi_2(s_1s_2s_3)}{\left\|\Phi_2(s_1s_2s_3)\right\|} \bullet \frac{\Phi_2(s_1s_2s_3s_4)}{\left\|\Phi_2(s_1s_2s_3s_4)\right\|} \right\rangle \\ &= \frac{2+\lambda^2}{\sqrt{(3+2\lambda^2+\lambda^4)(2+\lambda^2)}} = 0.71(\lambda = 1) \end{aligned}$$

Similarly, $K_3(s_1s_2s_3, s_1s_2s_3s_4) = 0.5$.

	$\phi_{s_1s_2}$	$\phi_{s_1s_3}$	$\phi_{s_1s_4}$	$\phi_{s_2s_3}$	$\phi_{s_2s_4}$	$\phi_{s_3s_4}$	...	$\phi_{s_{16}s_{17}}$	
$\Phi_2(s_1s_2s_3) = ($	1	λ	0	1	0	0	...	0	$)$
$\Phi_2(s_1s_2s_3s_4) = ($	1	λ	λ^2	1	λ	1	...	0	$)$

$\Phi_2(s_1s_2s_3) \bullet \Phi_2(s_1s_2s_3s_4) = 2+\lambda^2$
$\Phi_2(s_1s_2s_3) \bullet \Phi_2(s_1s_2s_3) - 2+\lambda^2$
$\Phi_2(s_1s_2s_3s_4) \bullet \Phi_2(s_1s_2s_3s_4) = 3+2\lambda^2+\lambda^4$

4 Experimental Results

4.1 Experiment setup

1) **Corpus:** The consultation documents were collected from the mental health website of the John Tung Foundation (http://www.jtf.org.tw) and the PsychPark (http://www.psychpark.org), a virtual psychiatric clinic, maintained by a group of volunteer professionals of Taiwan Association of Mental Health Informatics (Bai et al. 2001). Both of the web sites provide various kinds of free psychiatric services and update the consultation documents periodically. For privacy consideration, all personal information has been removed. A total of 3,650 consultation documents were collected for evaluating the retrieval model, of which 20 documents were randomly selected as the test query set, 100 documents were randomly selected as the tuning set to obtain the optimal parameter settings of involved retrieval models, and the remaining 3,530 documents were the reference set to be retrieved. Table 1 shows the average number of events, symptoms and relations in the test query set.

2) **Baselines:** The proposed method, denoted as Topic, was compared to two word-based retrieval models: the VSM and Okapi BM25 models. The VSM was implemented in terms of the standard TF-IDF weight. The Okapi BM25 model is defined as

$$\sum_{t \in Q} w^{(1)} \frac{(k_1+1)tf}{K+tf} \frac{(k_3+1)qtf}{k_3+qtf} + k_2 |Q| \frac{avdl-dl}{avdl+dl}, \quad (10)$$

where t denotes a word in a query Q; qtf and tf denote the word frequencies occurring in a query and a document, respectively, and $w^{(1)}$ denotes the Robertson-Sparck Jones weight of t (without relevance feedback), defined as

$$w^{(1)} = \log \frac{N-n+0.5}{n+0.5}, \quad (11)$$

where N denotes the total number of documents, and n denotes the number of documents containing t. In (10), K is defined as

$$K = k_1((1-b)+b \cdot dl/avdl), \quad (12)$$

where dl and $avdl$ denote the length and average length of a document, respectively. The default values of k_1, k_2, k_3 and b are describe in (Robertson et al., 1996), where k_1 ranges from 1.0 to 2.0; k_2 is set to 0; k_3 is set to 8, and b ranges from 0.6 to 0.75. Additionally, BM25 can be considered as BM15 and BM11 when b is set to 1 and 0, respectively.

3) **Evaluation metric:** To evaluate the retrieval models, a multi-level relevance criterion was adopted. The relevance criterion was divided into four levels, as described below.
   - Level 0: No topics are matched between a query and a document.
   - Level 1: At least one topic is partially matched between a query and a document.
   - Level 2: All of the three topics are partially matched between a query and a document.
   - Level 3: All of the three topics are partially matched, and at least one topic is exactly matched between a query and a document.

   To deal with the multi-level relevance, the *discounted cumulative gain (DCG)* (Jarvelin and Kekalainen, 2000) was adopted as the evaluation metric, defined as

$$DCG[i] = \begin{cases} G[1], & \text{if } i = 1 \\ DCG[i-1] + G[i]/\log_c i, & \text{otherwise} \end{cases} \quad (13)$$

where i denotes the i-th document in the retrieved list; $G[i]$ denotes the gain value, i.e., relevance levels, of the i-th document, and c denotes the parameter to penalize a retrieved document in a lower rank. That is, the DCG simultaneously considers the relevance levels, and the ranks in the retrieved list to measure the retrieval precision. For instance, let <3,2,3,0,0> denotes the retrieved list of five documents with their relevance levels. If no penalization is used, then the DCG values for

Relevance Level	Avg. Number
Level 1	18.50
Level 2	9.15
Level 3	2.20

Table 2. Average number of relevant documents for the test query set.

Retrieval Model	Avg. Time (seconds)
Topic	17.13
VSM	0.68
BM25	0.48

Table 4. Average query processing time of different retrieval models.

	DCG(5)	DCG(10)	DCG(20)	DCG(50)	DCG(100)
Topic	4.7516*	6.9298	7.6040*	8.3606*	9.3974*
BM25	4.4624	6.7023	7.1156	7.8129	8.6597
BM11	3.8877	4.9328	5.9589	6.9703	7.7057
VSM	2.3454	3.3195	4.4609	5.8179	6.6945
BM15	2.1362	2.6120	3.4487	4.5452	5.7020

Table 3. DCG values of different retrieval models. * Topic vs BM25 significantly different (p<0.05)

the retrieved list are <3,5,8,8,8>, and thus DCG[5]=8. Conversely, if c=2, then the documents retrieved at ranks lower than two are penalized. Hence, the DCG values for the retrieved list are <3,5,6.89,6.89,6.89>, and DCG[5]=6.89.

The relevance judgment was performed by three experienced physicians. First, the *pooling* method (Voorhees, 2000) was adopted to generate the candidate relevant documents for each test query by taking the top 50 ranked documents retrieved by each of the involved retrieval models, namely the VSM, BM25 and Topic. Two physicians then judged each candidate document based on the multilevel relevance criterion. Finally, the documents with disagreements between the two physicians were judged by the third physician. Table 2 shows the average number of relevant documents for the test query set.

4) **Optimal parameter setting:** The parameter settings of BM25 and Topic were evaluated using the tuning set. The optimal setting of BM25 were k_1 =1 and b=0.6. The other two parameters were set to the default values, i.e., $k_2 = 0$ and $k_3 = 8$. For the Topic model, the parameters required to be evaluated include the combination factors, α and β, described in (1); the constant *const.* described in (2), and the decay factor, λ, described in (9). The optimal settings were $\alpha = 0.3$; $\beta = 0.5$; *const.*=0.6 and $\lambda = 0.8$.

4.2 Retrieval results

The results are divided into two groups: the *precision* and *efficiency*. The retrieval precision was measured by DCG values. Additionally, a paired, two-tailed *t-test* was used to determine whether the performance difference was statistically significant. The retrieval efficiency was measure by the query processing time, i.e., the time for processing all the queries in the test query set.

Table 3 shows the comparative results of retrieval precision. The two variants of BM25, namely BM11 and BM15, are also considered in comparison. For the word-based retrieval models, both BM25 and BM11 outperformed the VSM, and BM15 performed worst. The Topic model achieved higher DCG values than both the BM-series models and VSM. The reasons are three-fold. First, a negative life event and a symptom can each be expressed by different words with the same or similar meaning. Therefore, the word-based models often failed to retrieve the relevant documents when different words were used in the input query. Second, a word may relate to different events and symptoms. For instance, the term "worry about" is

a good indicator for both the symptoms <Anxiety> and <Hypochondriasis>. This may result in ambiguity for the word-based models. Third, the word-based models cannot capture semantic relations between symptoms. The Topic model incorporates not only the word-level information, but also more useful topic information about depressive problems, thus improving the retrieval results.

The query processing time was measured using a personal computer with Windows XP operating system, a 2.4GHz Pentium IV processor and 512MB RAM. Table 4 shows the results. The topic model required more processing time than both VSM and BM25, since identification of topics involves more detailed analysis, such as semantic parsing of sentences and symptom chain construction. This finding indicates that although the topic information can improve the retrieval precision, incorporating such high-precision features reduces the retrieval efficiency.

5 Conclusion

This work has presented the use of topic information for retrieving psychiatric consultation documents. The topic information can provide more precise information about users' depressive problems, thus improving the retrieval precision. The proposed framework can also be applied to different domains as long as the domain-specific topic information is identified. Future work will focus on more detailed experiments, including the contribution of each topic to retrieval precision, the effect of using different methods to combine topic information, and the evaluation on real users.

Abstract

We present a study aimed at investigating the use of semantic information in a novel NLP application, Electronic Career Guidance (ECG), in German. ECG is formulated as an information retrieval (IR) task, whereby textual descriptions of professions (*documents*) are ranked for their relevance to natural language descriptions of a person's professional interests (*the topic*). We compare the performance of two semantic IR models: (IR-1) utilizing semantic relatedness (SR) measures based on either wordnet or Wikipedia and a set of heuristics, and (IR-2) measuring the similarity between the topic and documents based on Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007). We evaluate the performance of SR measures intrinsically on the tasks of (T-1) computing SR, and (T-2) solving Reader's Digest Word Power (RDWP) questions.

1 Electronic Career Guidance

Career guidance is important both for the person involved and for the state. Not well informed decisions may cause people to drop the training program they are enrolled in, yielding loss of time and financial investments. However, there is a mismatch between what people know about existing professions and the variety of professions, which exist in reality. Some studies report that school leavers typically choose the professions known to them, such as *policeman*, *nurse*, etc. Many other professions, which can possibly match the interests of the person very well, are not chosen, as their titles are unknown and people seeking career advice do not know about their existence, e.g. *electronics installer*, or *chemical laboratory worker*. However, people are very good at describing their professional interests in natural language. That is why they are even asked to write a short essay prior to an appointment with a career guidance expert.

Electronic career guidance is, thus, a supplement to career guidance by human experts, helping young people to decide which profession to choose. The goal is to automatically compute a ranked list of professions according to the user's interests. A current system employed by the German Federal Labour Office (GFLO) in their automatic career guidance front-end[1] is based on vocational trainings, manually annotated using a tagset of 41 keywords. The user must select appropriate keywords according to her interests. In reply, the system consults a knowledge base with professions manually annotated with the keywords by career guidance experts. Thereafter, it outputs a list of the best matching professions to the user. This approach has two significant disadvantages. Firstly, the knowledge base has to be maintained and steadily updated, as the number of professions and keywords associated with them is continuously changing. Secondly, the user has to describe her interests in a very restricted way.

At the same time, GFLO maintains an extensive database with textual descriptions of professions,

[1] http://www.interesse-beruf.de/

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 1032–1039,
Prague, Czech Republic, June 2007.

called BERUFEnet.[2] Therefore, we cast the problem of ECG as an IR task, trying to remove the disadvantages of conventional ECG outlined above by letting the user describe her interests in a short natural language essay, called *a professional profile*.

Example essay translated to English
I would like to work with animals, to treat and look after them, but I cannot stand the sight of blood and take too much pity on them. On the other hand, I like to work on the computer, can program in C, Python and VB and so I could consider software development as an appropriate profession. I cannot imagine working in a kindergarden, as a social worker or as a teacher, as I am not very good at asserting myself.

Textual descriptions of professions are ranked given such an essay by using NLP and IR techniques. As essays and descriptions of professions display a mismatch between the vocabularies of topics and documents and there is lack of contextual information, due to the documents being fairly short as compared to standard IR scenarios, lexical semantic information should be especially beneficial to an IR system. For example, the profile can contain words about some objects or activities related to the profession, but not directly mentioned in the description, e.g. *oven*, *cakes* in the profile and *pastries*, *baker*, or *confectioner* in the document. Therefore, we propose to utilize semantic relatedness as a ranking function instead of conventional IR techniques, as will be substantiated below.

2 System Architecture

Integrating lexical semantic knowledge in ECG requires the existence of knowledge bases encoding domain and lexical knowledge. In this paper, we investigate the utility of two knowledge bases: (i) a German wordnet, GermaNet (Kunze, 2004), and (ii) the German portion of Wikipedia.[3] A large body of research exists on using wordnets in NLP applications and in particular in IR (Moldovan and Mihalcea, 2000). The knowledge in wordnets has been typically utilized by expanding queries with related terms (Vorhees, 1994; Smeaton et al., 1994), concept indexing (Gonzalo et al., 1998), or similarity measures as ranking functions (Smeaton et al., 1994; Müller and Gurevych, 2006). Recently, Wikipedia has been discovered as a promising lexical semantic resource and successfully used in such different NLP tasks as question answering (Ahn et al., 2004), named entity disambiguation (Bunescu and Pasca, 2006), and information retrieval (Katz et al., 2005). Further research (Zesch et al., 2007b) indicates that German wordnet and Wikipedia show different performance depending on the task at hand.

Departing from this, we first compare two semantic relatedness (SR) measures based on the information either in the German wordnet (Lin, 1998) called **LIN**, or in Wikipedia (Gabrilovich and Markovitch, 2007) called Explicit Semantic Analysis, or **ESA**. We evaluate their performance intrinsically on the tasks of (T-1) computing semantic relatedness, and (T-2) solving Reader's Digest Word Power (RDWP) questions and make conclusions about the ability of the measures to model certain aspects of semantic relatedness and their coverage. Furthermore, we follow the approach by Müller and Gurevych (2006), who proposed to utilize the LIN measure and a set of heuristics as an IR model (IR-1).

Additionally, we utilize the ESA measure in a semantic information retrieval model, as this measure is significantly better at vocabulary coverage and at modelling cross part-of-speech relations (Gabrilovich and Markovitch, 2007). We compare the performance of ESA and LIN measures in a task-based IR evaluation and analyze their strengths and limitations. Finally, we apply ESA to directly compute text similarities between topics and documents (IR-2) and compare the performance of two semantic IR models and a baseline Extended Boolean (EB) model (Salton et al., 1983) with query expansion.[4]

To summarize, the *contributions of this paper* are three-fold: (i) we present a novel system, utilizing NLP and IR techniques to perform Electronic Career Guidance, (ii) we study the properties and intrinsically evaluate two SR measures based on GermaNet and Wikipedia for the tasks of computing semantic relatedness and solving Reader's Digest Word Power Game questions, and (iii) we investigate the performance of two semantic IR models in a task based evaluation.

[2] http://infobub.arbeitsagentur.de/berufe/

[3] http://de.wikipedia.org/

[4] We also ran experiments with Okapi BM25 model as implemented in the Terrier framework, but the results were worse than those with the EB model. Therefore, we limit our discussion to the latter.

3 Computing Semantic Relatedness

3.1 SR Measures

GermaNet based measures GermaNet is a German wordnet, which adopted the major properties and database technology from Princeton's WordNet (Fellbaum, 1998). However, GermaNet displays some structural differences and content oriented modifications. Its designers relied mainly on linguistic evidence, such as corpus frequency, rather than psycholinguistic motivations. Also, GermaNet employs artificial, i.e. non-lexicalized concepts, and adjectives are structured hierarchically as opposed to WordNet. Currently, GermaNet includes about 40000 synsets with more than 60000 word senses modelling nouns, verbs and adjectives.

We use the semantic relatedness measure by Lin (1998) (referred to as LIN), as it consistently is among the best performing wordnet based measures (Gurevych and Niederlich, 2005; Budanitsky and Hirst, 2006). Lin defined semantic similarity using a formula derived from information theory. This measure is sometimes called a universal semantic similarity measure as it is supposed to be application, domain, and resource independent. *Lin* is computed as:

$$sim_{c_1,c_2} = \frac{2 \times \log p(LCS(c_1, c_2))}{\log p(c_1) + \log p(c_2)}$$

where c_1 and c_2 are concepts (word senses) corresponding to w_1 and w_2, $\log p(c)$ is the information content, and $LCS(c_1, c_2)$ is the lowest common subsumer of the two concepts. The probability p is computed as the relative frequency of words (representing that concept) in the taz[5] corpus.

Wikipedia based measures Wikipedia is a free online encyclopedia that is constructed in a collaborative effort of voluntary contributors and still grows exponentially. During this process, Wikipedia has probably become the largest collection of freely available knowledge. Wikipedia shares many of its properties with other well known lexical semantic resources (like dictionaries, thesauri, semantic wordnets or conventional encyclopedias) (Zesch et al., 2007a). As Wikipedia also models relatedness between concepts, it is better suited for computing semantic relatedness than GermaNet (Zesch et al., 2007b).

In very recent work, Gabrilovich and Markovitch (2007) introduce a SR measure called *Explicit Semantic Analysis* (ESA). The ESA measure represents the meaning of a term as a high-dimensional concept vector. The concept vector is derived from Wikipedia articles, as each article focuses on a certain topic, and can thus be viewed as expressing a concept. The dimension of the concept vector is the number of Wikipedia articles. Each element of the vector is associated with a certain Wikipedia article (or concept). If the term can be found in this article, the term's tfidf score (Salton and McGill, 1983) in this article is assigned to the vector element. Otherwise, 0 is assigned. As a result, a term's concept vector represents the importance of the term for each concept. Semantic relatedness of two terms can then be easily computed as the cosine of their corresponding concept vectors. If we want to measure the semantic relatedness of texts instead of terms, we can also use ESA concept vectors. A text is represented as the average concept vector of its terms' concept vectors. Then, the relatedness of two texts is computed as the cosine of their average concept vectors.

As ESA uses all textual information in Wikipedia, the measure shows excellent coverage. Therefore, we select it as the second measure for integration into our IR system.

3.2 Datasets

Semantic relatedness datasets for German employed in our study are presented in Table 1. Gurevych (2005) conducted experiments with two datasets: i) a German translation of the English dataset by Rubenstein and Goodenough (1965) (**Gur65**), and ii) a larger dataset containing 350 word pairs (**Gur350**). Zesch and Gurevych (2006) created a third dataset from domain-specific corpora using a semi-automatic process (**ZG222**). Gur65 is rather small and contains only noun-noun pairs connected by either synonymy or hypernymy. Gur350 contains nouns, verbs and adjectives that are connected by classical and non-classical relations (Morris and Hirst, 2004). However, word pairs for this dataset are biased towards strong classical relations, as they were manually selected from a corpus.

[5] http://www.taz.de

Dataset	Year	Language	# Pairs	POS	Scores	# Subjects	Correlation r Inter	Intra
Gur65	2005	German	65	N	discrete {0,1,2,3,4}	24	.810	-
Gur350	2006	German	350	N, V, A	discrete {0,1,2,3,4}	8	.690	-
ZG222	2006	German	222	N, V, A	discrete {0,1,2,3,4}	21	.490	.647

Table 1: Comparison of datasets used for evaluating semantic relatedness in German.

ZG222 does not have this bias.

Following the work by Jarmasz and Szpakowicz (2003) and Turney (2006), we created a second dataset containing multiple choice questions. We collected 1072 multiple-choice word analogy questions from the German **Reader's Digest Word Power Game** (RDWP) from January 2001 to December 2005 (Wallace and Wallace, 2005). We discarded 44 questions that had more than one correct answer, and 20 questions that used a phrase instead of a single term as query. The resulting 1008 questions form our evaluation dataset. An example question is given below:

Muffin (**muffin**)
a) Kleingebäck (small cake)
b) Spenglerwerkzeug (plumbing tool)
c) Miesepeter (killjoy)
d) Wildschaf (moufflon)

The task is to find the correct choice - 'a)' in this case.

This dataset is significantly larger than any of the previous datasets employed in this type of evaluation. Also, it is not restricted to synonym questions, as in the work by Jarmasz and Szpakowicz (2003), but also includes hypernymy/hyponymy, and few non-classical relations.

3.3 Analysis of Results

Table 2 gives the results of evaluation on the task of correlating the results of an SR measure with human judgments using Pearson correlation. The GermaNet based LIN measure outperforms ESA on the Gur65 dataset. On the other datasets, ESA is better than LIN. This is clearly due to the fact, that Gur65 contains only noun-noun word pairs connected by classical semantic relations, while the other datasets also contain cross part-of-speech pairs connected by non-classical relations. The Wikipedia based ESA measure can better capture such relations. Additionally, Table 3 shows that ESA also covers almost all word pairs in each dataset, while GermaNet is much lower for Gur350 and ZG222. ESA performs even better on the Reader's Digest task (see Table 4). It shows high coverage and near human performance regarding the relative number of correctly solved questions.[6] Given the high performance and coverage of the Wikipedia based ESA measure, we expect it to yield better IR results than LIN.

	Gur65	Gur350	ZG222
# covered word pairs	53	116	55
Upper bound	0.80	0.64	0.44
GermaNet Lin	0.73	0.50	0.08
Wikipedia ESA	0.56	0.52	0.32

Table 2: Pearson correlation r of human judgments with SR measures on word pairs covered by GermaNet and Wikipedia.

Dataset	# Pairs	Covered Pairs Lin	ESA
Gur65	65	60	65
Gur350	350	208	333
ZG222	222	88	205

Table 3: Number of covered word pairs based on Lin or ESA measure on different datasets.

4 Information Retrieval

4.1 IR Models

Preprocessing For creating the search index for IR models, we apply first tokenization and then remove stop words. We use a general German stop

[6] Values for human performance are for one subject. Thus, they only indicate the approximate difficulty of the task. We plan to use this dataset with a much larger group of subjects.

	#Answered	#Correct	Ratio
Human	1008	874	0.87
GermaNet Lin	298	153	0.51
Wikipedia ESA	789	572	0.72

Table 4: Evaluation results on multiple-choice word analogy questions.

word list extended with highly frequent domain specific terms. Before adding the remaining words to the index, they are lemmatized. We finally split compounds into their constituents, and add both, constituents and compounds, to the index.

EB model Lucene[7] is an open source text search library based on an EB model. After matching the preprocessed queries against the index, the document collection is divided into a set of relevant and irrelevant documents. The set of relevant documents is, then, ranked according to the formula given in the following equation:

$$r_{EB}(d,q) = \sum_{i=1}^{n_q} tf(t_q,d) \cdot idf(t_q) \cdot lengthNorm(d)$$

where n_q is the number of terms in the query, $tf(t_q,d)$ is the term frequency factor for term t_q in document d, $idf(t_q)$ is the inverse document frequency of the term, and $lengthNorm(d)$ is a normalization value of document d, given the number of terms within the document. We added a simple query expansion algorithm using (i) synonyms, and (ii) hyponyms, extracted from GermaNet.

IR based on SR For the (IR-1) model, we utilize two SR measures and a set of heuristics: (i) the Lin measure based on GermaNet (LIN), and (ii) the ESA measure based on Wikipedia (ESA-Word). This algorithm was applied to the German IR benchmark with positive results by Müller and Gurevych (2006). The algorithm computes a SR score for each query and document term pair. Scores above a predefined threshold are summed up and weighted by different factors, which boost or lower the scores for documents, depending on how many query terms are contained exactly or contribute a high enough SR score. In order to integrate the strengths of traditional IR models, the inverse document frequency *idf* is considered, which measures the general importance of a term for predicting the content of a document. The final formula of the model is as follows:

$$r_{SR}(d,q) = \frac{\sum_{i=1}^{n_d} \sum_{j=1}^{n_q} idf(t_{q,j}) \cdot s(t_{d,i}, t_{q,j})}{(1+n_{nsm}) \cdot (1+n_{nr})}$$

where n_d is the number of tokens in the document, n_q the number of tokens in the query, $t_{d,i}$ the i-th document token, $t_{q,j}$ the j-th query token, $s(t_{d,i}, t_{q,j})$ the SR score for the respective document and query term, n_{nsm} the number of query terms not exactly contained in the document, n_{nr} the number of query tokens, which do not contribute a SR score above the threshold.

For the (IR-2) model, we apply the ESA method for directly comparing the query with documents, as described in Section 3.1.

4.2 Data

The corpus employed in our experiments was built based on a real-life IR scenario in the domain of ECG, as described in Section 1. The **document collection** is extracted from BERUFEnet,[8] a database created by the GFLO. It contains textual descriptions of about 1,800 vocational trainings, and 4,000 descriptions of professions. We restrict the collection to a subset of BERUFEnet documents, consisting of 529 descriptions of vocational trainings, due to the process necessary to obtain relevance judgments, as described below. The documents contain not only details of professions, but also a lot of information concerning the training and administrative issues. We only use those portions of the descriptions, which characterize the profession itself.

We collected real natural language **topics** by asking 30 human subjects to write an essay about their professional interests. The topics contain 130 words, on average. Making **relevance judgments** for ECG requires domain expertise. Therefore, we applied an automatic method, which uses the knowledge base employed by the GFLO, described in Section 1. To obtain relevance judgments, we first annotate each essay with relevant keywords from the tagset of 41 and retrieve a ranked list of professions, which were assigned one or more keywords by domain experts. To map the ranked list to a set of relevant and irrelevant professions, we use a threshold of 3, as suggested by career guidance experts. This setting yields on average 93 relevant documents per topic. The quality of the automatically created gold standard depends on the quality of the applied knowledge base. As the knowledge base was created by

[7] http://lucene.apache.org

[8] http://berufenet.arbeitsamt.de/

domain experts and is at the core of the electronic career guidance system of the GFLO, we assume that the quality is adequate to ensure a reliable evaluation.

4.3 Analysis of Results

In Table 5, we summarize the results of the experiments applying different IR models on the BERUFEnet data. We build queries from natural language essays by (QT-1) extracting nouns, verbs, and adjectives, (QT-2) using only nouns, and (QT-3) manually assigning suitable keywords from the tagset with 41 keywords to each topic. We report the results with two different thresholds (.85 and .98) for the Lin model, and with three different thresholds (.11, .13 and .24) for the ESA-Word models. The evaluation metrics used are *mean average precision* (MAP), *precision after ten documents* (P10), *the number of relevant returned documents* (#RRD). We compute the absolute value of *Spearman's rank correlation coefficient* (SRCC) by comparing the relevance ranking of our system with the relevance ranking of the knowledge base employed by the GFLO.

Using query expansion for the EB model decreases the retrieval performance for most configurations. The SR based models outperform the EB model in all configurations and evaluation metrics, except for P10 on the keyword based queries. The Lin model is always outperformed by at least one of the ESA models, except for (QT-3). (IR-2) performs best on longer queries using nouns, verbs, adjectives or just nouns.

Comparing the number of relevant retrieved documents, we observe that the IR models based on SR are able to return more relevant documents than the EB model. This supports the claim that semantic knowledge is especially helpful for the vocabulary mismatch problem, which cannot be addressed by conventional IR models. E.g., only SR-based models can find the job *information technician* for a profile which contains the sentence *My interests and skills are in the field of languages and IT*. The job could only be judged as relevant, as the semantic relation between *IT* in the profile and *information technology* in the professional description could be found.

In our analysis of the BERUFEnet results obtained on (QT-1), we noticed that many errors were due to the topics expressed in free natural language essays. Some subjects deviated from the given task to describe their professional interests and described facts that are rather irrelevant to the task of ECG, e.g. *It is important to speak different languages in the growing European Union*. If all content words are extracted to build a query, a lot of noise is introduced.

Therefore, we conducted further experiments with (QT-2) and (QT-3): building the query using only nouns, and using manually assigned keywords based on the tagset of 41 keywords. For example, the following query is built for the professional profile given in Section 1.

```
Keywords assigned:
care for/nurse/educate/teach; use/program computer;
office; outside:  outside facilities/natural
environment; animals/plants
```

IR results obtained on (QT-2) and (QT-3) show that the performance is better for nouns, and significantly better for the queries built of keywords. This suggests that in order to achieve high IR performance for the task of Electronic Career Guidance, it is necessary to preprocess the topics by performing information extraction to remove the noise from free text essays. As a result of the preprocessing, natural language essays should be mapped to a set of keywords relevant for describing a person's interests. Our results suggest that the word-based semantic relatedness IR model (IR-1) performs significantly better in this setting.

5 Conclusions

We presented a system for Electronic Career Guidance utilizing NLP and IR techniques. Given a natural language professional profile, relevant professions are computed based on the information about semantic relatedness. We intrinsically evaluated and analyzed the properties of two semantic relatedness measures utilizing the lexical semantic information in a German wordnet and Wikipedia on the tasks of estimating semantic relatedness scores and answering multiple-choice questions. Furthermore, we applied these measures to an IR task, whereby they were used either in combination with a set of heuristics or the Wikipedia based measure was used to directly compute semantic relatedness of topics and

Model	(QT-1) Nouns, Verbs, Adj.				(QT-2) Nouns				(QT-3) Keywords

documents. We experimented with three different query types, which were built from the topics by: (QT-1) extracting nouns, verbs, adjectives, (QT-2) extracting only nouns, or (QT-3) manually assigning several keywords to each topic from a tagset of 41 keywords.

In an intrinsic evaluation of LIN and ESA measures on the task of computing semantic relatedness, we found that ESA captures the information about semantic relatedness and non-classical semantic relations considerably better than LIN, which operates on an *is-a* hierarchy and, thus, better captures the information about semantic similarity. On the task of solving RDWP questions, the ESA measure significantly outperformed the LIN measure in terms of correctness. On both tasks, the coverage of ESA is much better. Despite this, the performance of LIN and ESA as part of an IR model is only slightly different. ESA performs better for all lengths of queries, but the differences are not as significant as in the intrinsic evaluation. This indicates that the information provided by both measures, based on different knowledge bases, might be complementary for the IR task.

When ESA is applied to directly compute semantic relatedness between topics and documents, it outperforms IR-1 and the baseline EB model by a large margin for QT-1 and QT-2 queries. For QT-3, i.e., the shortest type of query, it performs worse than IR-1 utilizing ESA and a set of heuristics. Also, the performance of the baseline EB model is very strong in this experimental setting. This result indicates that IR-2 utilizing conventional information retrieval techniques and semantic information from Wikipedia is better suited for longer queries providing enough context. For shorter queries, *soft* matching techniques utilizing semantic relatedness tend to be beneficial.

It should be born in mind, that the construction of QT-3 queries involved a manual step of assigning the keywords to a given essay. In this experimental setting, all models show the best performance. This indicates that professional profiles contain a lot of noise, so that more sophisticated NLP analysis of topics is required. This will be improved in our future work, whereby the system will incorporate an information extraction component for automatically mapping the professional profile to a set of keywords. We will also integrate a component for analyzing the sentiment structure of the profiles. We believe that the findings from our work on applying IR techniques to the task of Electronic Career Guidance generalize to similar application domains, where topics and documents display similar properties (with respect to their length, free-text structure and mismatch of vocabularies) and domain and lexical knowledge is required to achieve high levels of performance.

Abstract

We present a general framework for automatically extracting social networks and biographical facts from conversational speech. Our approach relies on fusing the output produced by multiple information extraction modules, including entity recognition and detection, relation detection, and event detection modules. We describe the specific features and algorithmic refinements effective for conversational speech. These cumulatively increase the performance of social network extraction from 0.06 to 0.30 for the development set, and from 0.06 to 0.28 for the test set, as measured by f-measure on the ties within a network. The same framework can be applied to other genres of text — we have built an automatic biography generation system for general domain text using the same approach.

1 Introduction

A social network represents social relationships between individuals or organizations. It consists of *nodes* and *ties*. *Nodes* are individual actors within the networks, generally a person or an organization. *Ties* are the relationships between the nodes. Social network analysis has become a key technique in many disciplines, including modern sociology and information science.

In this paper, we present our system for automatically extracting social networks and biographical facts from conversational speech transcripts by integrating the output of different IE modules. The IE modules are the building blocks; the fusing module depicts the ways of assembling these building blocks. The final output depends on which fundamental IE modules are used and how their results are integrated.

The contributions of this work are two fold. We propose a general framework for extracting social networks and biographies from text that applies to conversational speech as well as other genres, including general newswire stories. Secondly, we present specific methods that proved effective for us for improving the performance of IE systems on conversational speech transcripts. These improvements include feature engineering and algorithmic revisions that led to a nearly five-fold performance increase for both development and test sets.

In the next section, we present our framework for extracting social networks and other biographical facts from text. In Section 3, we discuss the refinements we made to our IE modules in order to reliably extract information from conversational speech transcripts. In Section 4, we describe the experiments, evaluation metrics, and the results of social network and biography extraction. In Section 5, we show the results of applying the framework to other genres of text. Finally, we discuss related work and conclude with lessons learned and future work.

2 The General Framework

For extraction of social networks and biographical facts, our approach relies on three standard IE modules — entity detection and recognition, relation detection, and event detection — and a fusion module that integrates the output from the three IE systems.

2.1 Entity, Relation, and Event Detection

We use the term *entity* to refer to a person, an organization, or other real world entities, as adopted

Proceedings of the 45th Annual Meeting of the Association of Computational Linguistics, pages 1040–1047,
Prague, Czech Republic, June 2007.

in the Automatic Content Extraction (ACE) Workshops (ACE, 2005). A *mention* is a reference to a real world entity. It can be *named* (e.g. "John Lennon"), *nominal* (e.g. "mother"), or *pronominal* (e.g. "she").

Entity detection is generally accomplished in two steps: first, a mention detection module identifies all the mentions of interest; second, a co-reference module merges mentions that refer to the same entity into a single co-reference chain.

A *relation detection* system identifies (typically) binary relationships between pairs of mentions. For instance, for the sentence "I'm in New York", the following relation exists: *locatedAt (I, New York)*.

An *event detection* system identifies events of interest and the arguments of the event. For example, from the sentence "John married Eva in 1940", the system should identify the marriage event, the people who got married and the time of the event.

The latest ACE evaluations involve all of the above tasks. However, as shown in the next section, our focus is quite different from ACE — we are particularly interested in improving performance for conversational speech and building on top of ACE tasks to produce social networks and biographies.

2.2 Fusion Module

The fusion module merges the output from IE modules to extract social networks and biographical facts. For example, if a relation detection system has identified the relation *motherOf (mother, my)* from the input sentence "my mother is a cook", and if an entity recognition module has generated entities referenced by the mentions {*my, Josh, me, I, I, ...*} and {*mother, she, her, her, Rosa.....*}, then by replacing *my* and *mother* with the named mentions within the same co-reference chains, the fusion module produces the following nodes and ties in a social network: *motherOf (Rosa, Josh)*.

We generate the nodes of social networks by selecting all the PERSON entities produced by the entity recognition system. Typically, we only include entities that contain at least one *named* mention. To identify ties between nodes, we retrieve all relations that indicate social relationships between a pair of nodes in the network.

We extract biographical profiles by selecting the events (extracted by the event extraction module) and corresponding relations (extracted by the relation extraction module) that involve a given individual as an argument. When multiple documents are used, then we employ a cross-document co-reference system.

3 Improving Performance for Conversational Speech Transcripts

Extracting information from conversational speech transcripts is uniquely challenging. In this section, we describe the data collection used in our experiments, and explain specific techniques we used to improve IE performance on this data.

3.1 Conversational Speech Collection

We use a corpus of videotaped, digitized oral interviews with Holocaust survivors in our experiments. This data was collected by the USC Shoah Foundation Institute (formerly known as the Visual History Foundation), and has been used in many research activities under the Multilingual Access to Large Spoken Archives (MALACH) project (Gustman et al., 2002; Oard et al., 2004). The collection contains oral interviews in 32 languages from 52,000 survivors, liberators, rescuers and witnesses of the Holocaust.

This data is very challenging. Besides the usual characteristics of conversational speech, such as speaker turns and speech repairs, the interview transcripts contain a large percentage of ungrammatical, incoherent, or even incomprehensible clauses (a sample interview segment is shown in Figure 1). In addition, each interview covers many people and places over a long time period, which makes it even more difficult to extract social networks and biographical facts.

> *speaker2* in on that ninth of November nineteen hundred thirty eight I was with my parents at home we heard not through the we heard even through the windows the crashing of glass the crashing of and and they are our can't

Figure 1: Sample interview segment.

3.2 The Importance of Co-reference Resolution

Our initial attempts at social network extraction for the above data set resulted in a very poor score

of 0.06 f-measure for finding the relations within a network (as shown in Table 3 as baseline performance).

An error analysis indicated poor co-reference resolution to be the chief culprit for the low performance. For instance, suppose we have two clauses: "his mother's name is Mary" and "his brother Mark went to the army". Further suppose that "his" in the first clause refers to a person named "John" and "his" in the second clause refers to a person named "Tim". If the co-reference system works perfectly, the system should find a social network involving four people: {*John, Tim, Mary, Mark*}, and the ties: *motherOf (Mary, John)*, and *brotherOf (Mark, Tim)*. However, if the co-reference system mistakenly links "John" to "his" in the second clause and links "Tim" to "his" in the first clause, then we will still have a network with four people, but the ties will be: *motherOf (Mary, Tim)*, and *brotherOf (Mark, John)*, which are completely wrong. This example shows that co-reference errors involving mentions that are relation arguments can lead to very bad performance in social network extraction.

Our existing co-reference module is a state-of-the-art system that produces very competitive results compared to other existing systems (Luo et al., 2004). It traverses the document from left to right and uses a mention-synchronous approach to decide whether a mention should be merged with an existing entity or start a new entity.

However, our existing system has shortcomings for this data: the system lacks features for handling conversational speech, and the system often makes mistakes in pronoun resolution. Resolving pronominal references is very important for extracting social networks from conversational speech, as illustrated in the previous example.

3.3 Improving Co-reference for Conversational Speech

We developed a new co-reference resolution system for conversational speech transcripts. Similar to many previous works on co-reference (Ng, 2005), we cast the problem as a classification task and solve it in two steps: (1) train a classifier to determine whether two mentions are co-referent or not, and (2) use a clustering algorithm to partition the mentions into clusters, based on the pairwise predictions.

We added many features to our model specifically designed for conversational speech, and significantly improved the agglomerative clustering used for co-reference, including integrating relations as constraints, and designing better cluster linkage methods and clustering stopping criteria.

3.3.1 Adding Features for Conversational Speech

We added many features to our model specifically designed for conversational speech:

Speaker role identification. In manual transcripts, the speaker turns are given and each speaker is labeled differently (e.g. *"speaker1"*, *"speaker2"*), but the identity of the speaker is not given. An interview typically involves 2 or more speakers and it is useful to identify the roles of each speaker (e.g. interviewer, interviewee, etc.). For instance, "you" spoken by the interviewer is likely to be linked with "I" spoken by the interviewee, but "you" spoken by the third person in the interview is more likely to be referring to the interviewer than to the interviewee.

We developed a program to identify the speaker roles. The program classifies the speakers into three categories: interviewer, interviewee, and others. The algorithm relies on three indicators — number of turns by each speaker, difference in number of words spoken by each speaker, and the ratio of first-person pronouns such as "I", "me", and "we" vs. second-person pronouns such as "you" and "your". This speaker role identification program works very well when we checked the results on the development and test set — the interviewers and survivors in all the documents in the development set were correctly identified.

Speaker turns. Using the results from the speaker role identification program, we enrich certain features with speaker turn information. For example, without this information, the system cannot distinguish "I" spoken by an interviewer from "I" spoken by an interviewee.

Spelling features for speech transcripts. We add additional spelling features so that mentions such as "Cyla C Y L A Lewin" and "Cyla Lewin" are considered as exact matches. Names with spelled-out letters occur frequently in our data collection.

Name Patterns. We add some features that capture frequent syntactic structures that speakers use to express names, such as "her name is Irene", "my cousin Mark", and "interviewer Ellen".

Pronoun features. To improve the perfor-

mance on pronouns, we add features such as the speaker turns of the pronouns, whether the two pronouns agree in person and number, whether there exist other mentions between them, etc.

Other miscellaneous features. We also include other features such as gender, token distance, sentence distance, and mention distance.

We trained a maximum-entropy classifier using these features. For each pair of mentions, the classifier outputs the probability that the two mentions are co-referent.

We also modified existing features to make them more applicable to conversational speech. For instance, we added pronoun-distance features taking into account the presence of other pronominal references in between (if so, the types of the pronouns), other mentions in between, etc.

3.3.2 Improving Agglomerative Clustering

We use an agglomerative clustering approach for partitioning mentions into entities. This is a bottom-up approach which joins the closest pair of clusters (i.e., entities) first. Initially, each mention is placed into its own cluster. If we have N mentions to cluster, we start with N clusters.

The intuition behind choosing the agglomerative method is to merge the most confident pairs first, and use the properties of existing clusters to constrain future clustering. This seems to be especially important for our data collection, since conversational speech tends to have a lot of repetitions or local structures that indicate co-reference. In such cases, it is beneficial to merge these closely related mentions first.

Cluster linkage method. In agglomerative clustering, each cycle merges two clusters into a single cluster, thus reducing the number of clusters by one. We need to decide upon a method of measuring the distance between two clusters.

At each cycle, the two mentions with the highest co-referent probability are linked first. This results in the merging of the two clusters that contain these two mentions.

We improve upon this method by imposing *minimal distance criteria* between clusters. Two clusters C_1 and C_2 can be combined only if the distance between all the mentions from C_1 and all the mentions from C_2 is above the minimal distance threshold. For instance, suppose $C_1 = \{he, father\}$, and $C_2 = \{he, brother\}$, and "he" from C_1 and "he" from C_2 has the highest linkage probability. The standard single linkage method will combine these two clusters, despite the fact that "father" and "brother" are very unlikely to be linked. Imposing minimal distance criteria can solve this problem and prevent the linkage of clusters which contain very dissimilar mentions. In practice, we used multiple minimal distance thresholds, such as minimal distance between two named mentions and minimal distance between two nominal mentions.

We chose not to use complete or average linkage methods. In our data collection, the narrations contain a lot of pronouns and the focus tends to be very local. Whereas the similarity model may be reasonably good at predicting the distance between two pronouns that are close to each other, it is not good at predicting the distance between pronouns that are furthur apart. Therefore, it seems more reasonable to use single linkage method with modifications than complete or average linkage methods.

Using relations to constrain clustering. Another novelty of our co-reference system is the use of relations for constraining co-reference. The idea is that two clusters should not be merged if such merging will introduce contradictory relations. For instance, if we know that person entity A is the mother of person entity B, and person entity C is the sister of B, then A and C should not be linked since the resulting entity will be both the mother and the sister of B.

We construct co-existent relation sets from the training data. For any two pairs of entities, we collect all the types of relations that exist between them. These types of relations are labeled as co-existent. For instance, "motherOf" and "parentOf" can co-exist, but "motherOf" and "sisterOf" cannot. By using these relation constraints, the system refrains from generating contradictory relations in social networks.

Speed improvement. Suppose the number of mentions is N, the time complexity of simple linkage method is $O(N^2)$. With the minimal distance criteria, the complexity is $O(N^3)$. However, N can be dramatically reduced for conversational transcripts by first linking all the first-person pronouns by each speaker.

4 Experiments

In this section, we describe the experimental setup and present sample outputs and evaluation results.

	Train	Dev	Test
Words	198k	73k	255k
Mentions	43k	16k	56k
Relations	7K	3k	8k

Table 2: Experimental Data Sets.

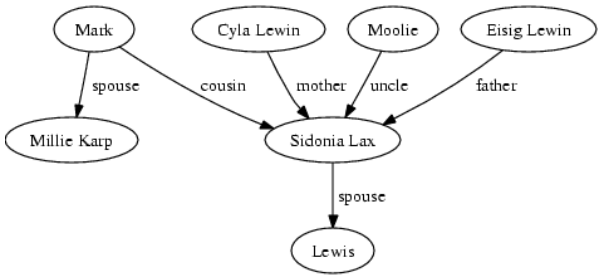

Figure 2: Social network extracted by the system.

4.1 Data Annotation

The data used in our experiments consist of partial or complete English interviews of Holocaust survivors. The input to our system is transcripts of interviews.

We manually annotated manual transcripts with entities, relations, and event categories, specifically designed for this task and the results of careful data analysis. The annotation was performed by a single annotator over a few months. The annotation categories for entities, events, and relations are shown in Table 1. Please note that the event and relation definitions are slightly different than the definitions in ACE.

4.2 Training and Test Sets

We divided the data into training, development, and test data sets. Table 2 shows the size of each data set. The training set includes transcripts of partial interviews. The development set consists of 5 complete interviews, and the test set consists of 15 complete interviews. The reason that the training set contains only partial interviews is due to the high cost of transcription and annotation. Since those partial interviews had already been transcribed for speech recognition purpose, we decided to reuse them in our annotation. In addition, we transcribed and annotated 20 complete interviews (each interview is about 2 hours) for building the development and test sets, in order to give a more accurate assessment of extraction performance.

4.3 Implementation

We developed the initial entity detection, relation detection, and event detection systems using the same techniques as our submission systems to ACE (Florian et al., 2004). Our submission systems use statistical approaches, and have ranked in the top tier in ACE evaluations. We easily built the models for our application by retraining existing systems with our training set.

The entity detection task is accomplished in two steps: mention detection and co-reference resolution. The mention detection is formulated as a labeling problem, and a maximum-entropy classifier is trained to identify all the mentions.

Similarly, relation detection is also cast as a classification problem — for each pair of mentions, the system decides which type of relation exists between them. It uses a maximum-entropy classifier and various lexical, contextual, and syntactic features for such predications.

Event detection is accomplished in two steps: first, identifying the event anchor words using an approach similar to mention detection; then, identifying event arguments using an approach similar to relation detection.

The co-reference resolution system for conversational speech and the fusion module were developed anew.

4.4 The Output

The system aims to extract the following types of information:

- The social network of the survivor.
- Important biographical facts about each person in the social network.
- Track the movements of the survivor and other individuals in the social network.

Figure 2 shows a sample social network extracted by the system (only partial of the network is shown). Figure 3 shows sample biographical facts and movement summaries extracted by the system. In general, we focus more on higher precision than recall.

4.5 Evaluation

In this paper, we focus only on the evaluation of social network extraction. We first describe the metrics for social network evaluation and then present the results of the system.

Entity (12)	Event (8)	Relation (34)		
		Social Rels (12)	Event Args (8)	Bio Facts (14)
AGE	CUSTODY	aidgiverOf	affectedBy	bornAt
COUNTRY	DEATH	auntOf	agentOf	bornOn

ORGANIZATION	VIOLENCE	otherRelativeOf	travelTo	locatedAt
OTHERLOC		parentOf		managerOf
PEOPLE		siblingOf		memberOf
PERSON		spouseOf		near
SALUTATION		uncleOf		partOf
				partOfMany
				resideIn

Table 1: Annotation Categories for Entities, Events, and Relations.

Sidonia Lax:
date of birth: June the eighth nineteen twenty seven

Movements:
Moved To: Auschwitz
Moved To: United States
... ...

Figure 3: Biographical facts and movement summaries extracted by the system.

To compare two social networks, we first need to match the *nodes* and *ties* between the networks. Two nodes (i.e., entities) are matched if they have the same canonical name. Two ties (i.e., edges or relations) are matched if these three criteria are met: they contain the same type of relations, the arguments of the relation are the same, and the order of the arguments are the same if the relation is unsymmetrical.

We define the the following measurements for social network evaluation: the *precision for nodes (or ties)* is the ratio of common nodes (or ties) in the two networks to the total number of nodes (or ties) in the system output, the *recall for nodes (or ties)* is the ratio of common nodes (or ties) in the two networks to the total number of nodes/ties in the reference output, and the *f-measure for nodes (or ties)* is the harmonic mean of precision and recall for nodes (or ties). The *f-measure for ties* indicates the overall performance of social network extraction.

F-mea	Dev		Test	
	Baseline	New	Baseline	New
Nodes	0.59	0.64	0.62	0.66
Ties	0.06	**0.30**	0.06	**0.28**

Table 3: Performance of social network extraction.

Table 3 shows the results of social network extraction. The new co-reference approach improves the performance for f-measure on ties by five-fold on development set and by nearly five-fold for test set.

We also tested the system using automatic transcripts by our speech recognition system. Not surprisingly, the result is much worse: the nodes f-measure is 0.11 for the test set, and the system did not find any relations. A few factors are accountable for this low performance: (1) Speech recognition is very challenging for this data set, since the testimonies contained elderly, emotional, accented speech. Given that the speech recognition system fails to recognize most of the person names, extraction of social networks is difficult. (2) The extraction systems perform worse on automatic transcripts, due to the quality of the automatic transcript, and the discrepancy between the training and test data. (3) Our measurements are very strict, and no partial credit is given to partially correct entities or relations.

We decided not to present the evaluation results of the individual components since the performance of individual components are not at all indicative of the overall performance. For instance, a single pronoun co-reference error might slighlty

change the co-reference score, but can introduce a serious error in the social network, as shown in the example in Section 3.2.

5 Biography Generation from General Domain Text

We have applied the same framework to biography generation from general news articles. This general system also contains three fundamental IE systems and a fusion module, similar to the work presented in the paper. The difference is that the IE systems are trained on general news text using different categories of entities, relations, and events.

A sample biography output extracted from TDT5 English documents is shown in Figure 4. The numbers in brackets indicate the corpus count of the facts.

Saddam Hussein:
Basic Information:
citizenship: Iraq [203]
occupation: president [4412], leader [1792], dictator [664],...
relative: odai [89], qusay [65], uday [65],...

Life Events:
places been to: bagdad [403], iraq [270], palaces [149]...
Organizations associated with: manager of baath party [1000], ...
Custody Events: Saddam was arrested [52],
Communication Events: Saddam said [3587]
... ...

Figure 4: Sample biography output.

6 Related Work

While there has been previous work on extracting social networks from emails and the web (Culotta et al., 2004), we believe this is the first paper to present a full-fledged system for extracting social networks from conversational speech transcripts.

Similarly, most of the work on co-reference resolution has not focused on conversational speech. (Ji et al., 2005) uses semantic relations to refine co-reference decisions, but in a approach different from ours.

7 Conclusions and Future Work

We have described a novel approach for extracting social networks, biographical facts, and movement summaries from transcripts of oral interviews with Holocaust survivors. We have improved the performance of social network extraction five-fold, compared to a baseline system that already uses state-of-the-art technology. In particular, we improved the performance of co-reference resolution for conversational speech, by feature engineering and improving the clustering algorithm.

Although our application data consists of conversational speech transcripts in this paper, the same extraction approach can be applied to general-domain text as well. Extracting general, rich social networks is very important in many applications, since it provides the knowledge of who is connected to whom and how they are connected.

There are many interesting issues involved in biography generation from a large data collection, such as how to resolve contradictions. The counts from the corpus certainly help to filter out false information which would otherwise be difficult to filter. But better technology at detecting and resolving contradictions will definitely be beneficial.

Acknowledgment

We would like to thank Martin Franz and Bhuvana Ramabhadran for their help during this project. This project is funded by NSF under the Information Technology Research (ITR) program, NSF IIS Award No. 0122466. Any opinions, findings and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the NSF.
